Among these, the geoscience and resources agency at Hannover has made an international reputation for itself with its overseas surveys, especially in developing countries (and has also just completed a thorough survey of ground-water resources and their contamination by pollution for the whole of West Germany). The Tübingen veterinary laboratory similarly has a distinguished academic as well as practical reputation. Conspicuous by its absence in West Germany is the string of medical research laboratories that would be found in most other places — a measure of the dominance of the medical faculties but perhaps also a pointer to the need that medical research should be less fragmented.

On the principle that anything the federal government can do the *Länder* can do independently, there is also a spattering of regional research laboratories on the map of West Germany. Veterinary and geological laboratories are common, but Hesse supports the Sigmund Freud institute of psychoanalysis and Lower Saxony plans to set up a microelectronics laboratory once it has chosen between Hannover and Braunschweig. □

What prospects for improvement?

THIS brief survey of science in West Germany is necessarily incomplete. Only a small sample of the important national research laboratories rates is mentioned. Most Max Planck institutes have been overlooked. And much too little has been made of the great wealth of sound biology now flourishing in universities, much of it deliberately fostered by the grant-making agencies such as the Deutsche Forschungsgemeinschaft. It is hoped that these deficiencies can be made good in the months ahead. For what is happening in West Germany, both in laboratories and in the committee rooms that help to shape their work, deserves much closer attention from the rest of the scientific community.

Incomplete though they may be, the preceding pages nevertheless confirm first impressions. Both researchers and those who manage their affairs are unsure of themselves, concerned that the substantial commitment of West Germany to research and development may be yielding less than it might. Comparisons with the United States are constantly preoccupying and rarely confident, which is why the doings of the particle physics laboratory at Hamburg (see page 270) stand out. Here at least is one laboratory not depressed by pointless calculations about the award of Nobel prizes. (For what little worth they have, the figures show that there have been 16 Nobel awards to West German nationals since the Second World War, compared with 124 and 42 awards to American and British nationals respectively.) The important question is how such a state of grace can be brought about elsewhere.

One of the dangers in West German introspection about the quality of research and development is that the distinctive and valuable features of the system will be undermined. Thus for decades other European countries have envied the way West German *Technische Hochschulen* forge such close connections with particular industrial sectors that both partners benefit immensely, as does the West German economy as a whole. Whenever British politicians take up the gloomy question "Why is Britain not more productive?", there is certain to be somebody to remind them that it might be different if British universities chose to follow this West German practice. The report (on page 275) from Aachen shows this practice still flourishes. The snag, for those who look for proof of success in the international award of honours, is that research in the design of machine tools is neither one of the topics mentioned in Nobel's notorious will nor a productive source of references in the primary journals. And while there may be some who complain that the education offered by the hot-houses among engineering schools may be undesirably narrow, or needlessly demanding, the success with which the graduates of these schools are able to make their way in West German industry is surely a proof that the engineering schools and West German industry have found a productive pattern for their relationship.

Elsewhere, however, the university system is in a mess. The reforms of the past quarter of a century have had the benefit of making sure that tenured professors cannot behave as tyrants, and have helped also to give West German universities a sense that their corporate identity extends to all who work in them, but only at the cost of licensing an intolerable and demeaning bureaucracy. Is it any wonder that people seeking a career in research prefer to work elsewhere, at a Max Planck institute perhaps, or even in the United States? The most obvious difficulty is that ridding the system of this blight cannot be accomplished by the universities themselves, only by the twelve governments of West Germany.

Sooner or later, something will have to be done to allow the universities to match their intake of students in all fields to their capacity to teach them properly. The pretence that all universities are educationally and intellectually equal will have to be abandoned. The universities must be rid of the legal harassment by students and would-be students with which they are now plagued, and should be free to decide for themselves the composition of the internal committees that manage their affairs. Nobody pretends that such steps could be taken easily, for they would offend against cherished constitutional principles. But to fail to take them is to perpetuate bumbledom and inefficiency.

There is also a need to change the present balance between the support for basic research by the principal grant-making agencies. The most glaring need is for a closer link between the 6,000-odd researchers who work in the Max Planck institutes and the much greater number of professional scientists who work in universities. Although the Max Planck Society acknowledges the need that new institutes should be sited near universities, although many institutes have members who work on common problems with university colleagues, and although senior members of the institutes are eager (and welcome) teachers at their local universities, the plain truth is that the institutes attract many of the most able younger scientists — and then provide many of them with an environment in which they can securely become less productive. The resentment that has sprung up between the two groups of people is not good for the research enterprise.

There is a need, less obvious but just as urgent, for adjusting the present balance of support for research within the universities. One of the unusual features of the West German system is that the bulk of the cost of university research is met directly by the *Länder* (regional) governments, with the Deutsche Forschungsgemeinschaft playing a relatively minor role. (The official estimate of a ratio of four-to-one is probably an over-estimate, but is not easily verifiable.) At many universities, Heidelberg for example, tenured professors look to the general budget for research support, but more junior colleagues must take their chances with DFG. Could this be why people returning to West German universities after a promising start elsewhere are so often said to slump into inactivity? The doctrine of the unity of research and teaching is wholly admirable but there is a danger that much of the research support now channelled from the regional governments to university researchers finds its way into projects that would not survive the rigours of peer review. This may also explain why the de-deification of the old-style professors has not been matched by a corresponding sense of liberation among junior colleagues. Given the generality of the observation that, compared with their equivalents elsewhere, younger scientists in West Germany are less adventurous — less likely to be disastrously wrong or brilliantly right — a more selective way of offering larger dollops of research support seems necessary. The general anxiety about clinical research argues in the same direction.

The problems peculiar to West Germany appear principally to affect basic research. There are also the familiar problems of what to do with research establishments that have lasted longer than the problems they were intended to solve, arguments about research strategy (how much to spend on solar energy development?) and anxieties about political interference (should a new laboratory go in one place rather than another?). West Germany is not worse afflicted than other places, while the scale of its research enterprise, and the skill of its practitioners, imply immense advantages. So has not the time come for the research community to insist that what it knows to be wrong should be put right? The paradox of West Germany is that the elaborate hierarchy of policy-making bodies that has evolved since the Second World War is somehow incompetent to challenge prevailing ideologies, even those that lead directly to the absurdities now manifest in the university system.

So the hunt goes on for other explanations of why West German science is not the glittering enterprise it should now be. It is like a heavy smoker with a chest infection seeking a psychosomatic explanation for his complaint. Although West German science may to some extent still be made tentative by the awful experience of what is euphemistically called "the period 1933-45", and by the sheer newness of the federal republic, what matters now is that each year increases the distance from that time — and brings a new cohort of productive people to adulthood.

NEWS AND VIEWS

Crust to crust, basalt to basalt

from Peter J. Smith

As the author of Ecclesiastes might have put it, of the making of many geochemical hypotheses for the workings of the Earth's interior there is no end. Or so it seems. Those who don't pay the closest possible attention to the flow of geochemical thinking — and many of those who do, for that matter — can hardly be anything but bewildered at the sheer quantity of it all and the seemingly infinite number of paradoxes and inconsistencies it represents. New sites are continually being investigated, only to provide solutions to some problems whilst revealing fresh anomalies. New methods are continually being introduced, only to fulfil some of their promise but present additional difficulties. New hypotheses are continually being proposed, only to reconcile some data at the expense of mutually exclusive hypotheses that reconcile other data. To the outsider, ever more research must look suspiciously like the source of ever more confusion, offering the reminder that the Earth's interior only looked remarkably simple when next to nothing was known about it. The much-needed global model that succeeds in reconciling the mass of conflicting observational evidence seems as far away as ever.

The new model put forward by Hofmann and White[1] hardly fills that all-embracing role, but, if valid, it should go a long way towards explaining some of the apparent contradictions that have recently come to the fore as a result of the increasing attention being paid to oceanic island basalts (OIB). Not least among the inconsistencies is the fact that, whereas OIB are 'enriched' (that is, with respect to 'primitive', bulk-earth, chondritic material) in incompatible elements such as K, Rb, U and Th and the light rare earth elements (LREE), Nd isotopic data seem to suggest that the source of most OIB is 'depleted' in LREE. For some time now, the differences between OIB and mid-ocean ridge basalts (MORB) have been interpreted as indicating distinct sources in the mantle; and under those circumstances it was possible to hold (not that everyone did) that the OIB were derived from primitive material (such as the lower mantle, if primitive it be) and the MORB came from a relatively depleted source (for example, the asthenosphere, if depleted it be). But the Nd data would seem to rule that out.

So how can LREE-enriched OIB be, or appear to be, derived from an LREE-depleted mantle source? Wasserburg and DePaolo[2] have suggested that perhaps the Nd isotopic data only indicate a non-primitive source for OIB because the initially primitive material gets contaminated with depleted MORB source material in the upper mantle. But that appears to conflict with Pb isotope and other evidence. Menzies and Murthy[3], among others, have proposed that metasomatism enriches the OIB source before melting. But there appears to be no evidence for that, at least from the source material itself. Even earlier, Gast[4] had attempted to account for the enrichment of OIB by supposing that primitive OIB source-material undergoes less melting than MORB source-material. But the degree of melting this requires is probably far lower than most petrologists would countenance.

Hofmann and White cut right through these proposals and objections. They first state that the OIB source cannot be primitive — a conviction based on the "rather conclusive" evidence that (1) no primitive source could give rise to enriched OIB without an unacceptably low degree of melting, and (2) a primitive source is inconsistent with the isotopic data (Rb, Nd, U, Th and so on). Next, they express their faith in Morgan's mantle plume hypothesis[5], because they find "his arguments as persuasive today as they were ten years ago and because . . . no viable alternative model has been proposed that would explain the kinematic and geochemical peculiarities of 'hot-spot' volcanism". They then look round for a possible source of the non-primitive material that forms the mantle plumes, and come up with the bold suggestion that it is ancient, subducted crust.

As might be expected, this is not the first time that the fate of subducted crust has been considered. Ringwood[6], for example, suggested that such crust might sink to the base of the mantle and thus be lost permanently to the convective system. Tatsumato and Knight[7] and, more recently, Anderson[8] have proposed that subducted crust is recycled to form new oceanic crust, including OIB. What Hofmann and White have done, in effect, is to combine components from both these views into the proposal that subducted crust sinks to the bottom of the mantle whence it ultimately rises again in the physical form of mantle plumes.

As new, initially basaltic, oceanic crust moves away from ridges it is subjected to hydrothermal alteration, undergoes low-temperature alteration and accumulates sediments; and as it subducts it experiences metamorphism and partial melting. Even so, its bulk composition is still likely to be more or less basaltic, and its density will almost certainly be higher than that of upper mantle material and probably higher than that of lower mantle material too. It therefore sinks until it reaches a level of density compensation (presumed here to be as deep as the core–mantle boundary), shedding the more refractory part of the lithosphere as it does so. Once at its new site, where it builds up to thicknesses of 100 km or more, it begins to heat up, partly because of radioactive heat production within it and partly through heat transfer from the core. As the temperature rises the layer becomes unstable, and diapirs (plumes) ascend into the upper mantle where the material melts, rises to the surface and forms oceanic islands or continental hotspots as appropriate.

Hofmann and White go to some lengths to demonstrate that such behaviour is thermally and mechanically plausible. But something more than that emerges, for the (admittedly crude and assumption-ridden) calculations also give a hint of the time scale involved. The time taken for the once-crustal layer at the base of the mantle to develop instability seems to be as much as

Peter J. Smith is a Reader in the Department of Earth Sciences, The Open University, Milton Keynes MK7 6AA, UK and editor of Open Earth.

0028-0835/82/210281-02$01.00

one to two billion years, implying that the material now rising as mantle plumes was oceanic crust as long ago as the Proterozoic. In this connection, it is interesting to note that apparent mantle isochrons for recent OIB commonly yield ages of about 1.8 (Pb) and 1.6 (Rb/Sr) billion years. Moreover, Morgan also suggested that plumes may actually initiate seafloor spreading/upper mantle convection by breaking up plates and thus allowing the passive upwelling of mantle material. Putting all this together, it is tempting to envisage an Earth in which periods of plume-triggered mantle convection alternate with intervals of mantle stagnancy during which the stored, subducted crust gradually heats up towards instability.

The first of the geochemical conclusions to be drawn from all this is that, by definition, OIB source-material cannot be primitive. On the other hand, the exact bulk composition of the material is difficult to specify. As the crust subducts it may or may not take sediment with it, it will be metamorphosed to an uncertain extent, and dehydration and partial melting will remove an unknown quantity of incompatible elements. At some point it will then be converted to eclogite and the less dense, depleted part of the lithosphere will separate and return to the MORB reservoir (presumably the asthenosphere). It seems unlikely, however, that these processes will be anything like thorough enough to remove all the incompatible elements — a conclusion for which there is some support from a consideration of what happens to K during subduction and magma production in island arcs. In other words, it would seem that when the subducted crust reaches the lower mantle it is still enriched.

The problem of having to explain how enriched OIB are derived from a depleted source is thus removed; the source is not depleted. What, then, of the Nd isotopic data, which seem to demonstrate otherwise? At this point it is necessary to bear in mind that, according to the Hofmann–White hypothesis, modern OIB are derived from Proterozoic crust — that is, Proterozoic MORB. Studies of mantle-derived basalts have shown that Nd/Sm ratios in large parts of the mantle have become progressively depleted. Thus Proterozoic MORB were less depleted than are modern MORB; and, as a result, modern OIB would be expected to have variable but generally lower $^{143}Nd/^{144}Nd$ ratios than modern MORB — which they do. Moreover, a MORB source would be able to produce OIB with 'normal' degrees of melting — 10 to 30 per cent for tholeiites.

As for the major elements, Hofmann and White point out that the idea of an OIB source of an essentially basaltic composition is "not dear to petrologists", the prevailing view being that basalts are produced by the partial fusion of peridotite. There are indeed problems in envisaging the generation of basalt from eclogite; but they may not be insuperable in this case insofar as the Hofmann–White model does not insist upon a source of pure eclogite. The subducting and sinking crust may not shed quite all of its associated refractory lithosphere. The incorporation of, say, 10–20 per cent of mantle peridotite would be sufficient to overcome the geochemical objections to an eclogite source (such as the fact that most OIB are olivine saturated). Moreover, there is bound to be some interaction between the ascending mantle plumes and the upper mantle peridotite through which they pass. None of this would change significantly the density, incompatible element composition and heat production in the rising plume material but it would easily provide sufficient olivine and pyroxene to bring the major element (and compatible element) composition into line with observation. To this extent, therefore, major element abundances do not impose strong constraints on the new model.

It is a measure of the disarray in which geochemistry finds itself that almost any sentence of substance in any article on the subject can, and is likely to, attract perfectly legitimate objections. Hofmann and White's work is unlikely to be an exception. Indeed, they admit that their model is an extreme one, "a broad target for criticism", a bold idea that may have to be modified if some of the details fail to correspond with future observations. Few people, however, would deny the importance of bringing the question of OIB–MORB differences to the fore. Many, if not most, geochemical models of the mantle have hitherto ignored OIB, largely on the grounds that they are volumetrically small in comparison with MORB. What Hofmann and White have done is show that relative volume may be no measure of scientific significance. □

The gaps in the fossil record

from David E. Schindel

THE fossil record has been both a burden and a blessing to evolutionary biologists — a blessing because the stratigraphical order in which fossils are arrayed provides broad proof of change with time, but a burden in that the gradual morphological transitions between presumed ancestors and descendants, anticipated by most biologists, are missing. Darwin and most of his followers have resolved this dilemma by accepting the blessing and dismissing the burden as an unfortunate but inherent limitation in the fossil record resulting from varying rates of sediment deposition.

In their much cited paper, Eldredge and Gould (ref. 1; see also ref. 2) re-examined the discrepancy between palaeontological patterns and biological processes. They argued that despite the imperfections in the fossil record, the pattern of abrupt appearances of new species might be a faithful rendition of speciation events, if viewed on a geological time scale. They contrasted two models, phyletic gradualism and punctuated equilibria. In the former, new species arise through the steady accumulation of microevolutionary change over significant spans of geological time. The discrepancies between generation-to-generation change and the observed palaeontological pattern would therefore be real, since most species appear abruptly in the fossil record. In the punctuational view, species persist more or less unchanged throughout their duration but infrequently and abruptly give rise to new forms. The long spans of morphological stasis within species would thus be a literal record, not an artefact of an imperfect record. The discrepancy would be more perceived than real, in this view.

Over the past ten years, microstratigraphical studies have appeared which document fine-scale patterns of change. Using the finest scale of sampling possible, investigators have attempted to test the reality of the discrepancy between microevolutionary changes (visible during a human lifetime) and the palaeontological patterns by approaching the time scale on which biological processes operate. These field studies have faced two serious challenges in the past year. First, the scale on which evolutionary patterns are documented is critical, because "one man's punctuated equilibrium may be another's evolutionary gradualism"[3], and "stepwise changes can be made to appear gradual if a coarse enough time scale is selected"[4]. The second and more serious challenge states that the stratigraphical record, as a whole, is so incomplete that fossil patterns are meaningless artefacts of episodic sedimentation[5]. This article provides a response to these challenges by outlining procedures for evaluating the level of time resolution obtained in

0028-0836/82/210282-03$01.00

microstratigraphical studies, and the quality of the patterns they document.

Three criteria are necessary for evaluating temporal resolution in the fossil record. *Temporal scope* is the total time span over which the pattern is documented. *Microstratigraphical acuity* is the time span represented by each individual fossil sample. *Stratigraphical completeness* is the proportion of the total time span (temporal scope) that is represented by strata.

Temporal scope is estimated with the common tools of stratigraphy, ultimately being established by radiometric dating techniques. Acuity and completeness estimates are based on short-term sedimentation rates, which document the rate at which sediments accumulate without gaps. Sedimentation rates based on longer-term observations include periods of non-deposition and erosion, and are therefore lower than short-term rates in similar settings. Brief periods of non-deposition or erosion are undoubtedly common, but are less likely to be described in the literature than are brief periods of active accumulation. The pattern of lower rates of sediment accumulation with longer spans of observation time has been documented in two recent compilations[6,7].

If individual fossil samples are taken from stratigraphical intervals free of evident sedimentological breaks (such as scoured surfaces, hardgrounds, bedding planes, attritional shell and bone beds), then dividing the sample thickness by a short-term sedimentation rate typical for that depositional setting (over, say, 100 yr) gives an estimate of acuity that assumes the interval of strata accumulated without interruptions greater than 100 yr (see refs 6 and 8 for further explanation). Completeness is estimated by first dividing the thickness of the entire strata by the appropriate short-term sedimentation rate, and the time span so derived is then divided by the temporal scope of the entire sequence. This completeness ratio represents the portion of the temporal scope represented by active accumulation of sediment, that is, if the entire sequence accumulated without interruptions greater than the time span of observation for the short-term rate used in the calculation. Sadler[7] provides a detailed and elegant treatment of this procedure.

The table presents data on the stratigraphical thickness and temporal scope of seven published microstratigraphical studies[9-15], along with my estimates for the acuity and completeness inherent in each. Three points emerge from this review of published studies. First, there is a trade-off between scope, acuity and completeness: a study can provide fine sampling resolution, encompass long spans of geological time, or contain a complete record of the time span, but not all three. Second, some microstratigraphical sampling schemes can provide acuity that approaches the time scale of biological processes (decades to centuries), if individual samples are collected with an eye to avoiding sedimentological breaks[6]. (Of course, extra caution is necessary in strata that show signs of bioturbation or resuspension, which act to obscure evidence of breaks.) Third, it is most difficult to evaluate evolutionary patterns in studies with high acuity (minimum of time per sample) and low completeness, unless the investigators document where the breaks occur in the sequence, and attempt to sample between the gaps. In so doing, a procedural trade-off is made by decreasing the scope of the sampled interval, within which acuity and completeness can remain high. This seems to be the case for the study by Williamson[15], and the within-cycle sampling by Schindel[14]. The patterns distilled from these relatively short, complete sequences can be read directly, and can be calibrated in years using short-term sedimentation rates. Without specific knowledge of where the breaks are located it is difficult to judge whether the other documented evolutionary patterns are gap-filled (and therefore may be artefacts of varying sediment input), or if they are relatively gap free, with the unrepresented time concentrated above and below the critical sampled portions of the sequences.

The debate over tempo and mode should proceed beyond the stage of arguing, in terms of generations, how fast is fast, and how slow is slow. It seems possible to estimate the quality of local stratigraphical sequences and the level of sampling acuity achieved in each. The gaps in the stratigraphical record are neither scattered so randomly nor hidden so well as to render the entire fossil record useless. I would therefore replace van Andel's[5] counsel of despair with a call for caution in sampling, and greater awareness among palaeontologists to the progress being made in genetic stratigraphy and facies analysis.

One other point emerges from this treatment of the gaps in the record. Most sedimentological breaks reflect changes in physical environmental conditions (water depth and current regime, sediment influx, carbonate productivity). Certainly, when one considers the large proportion of unrepresented time in the studies reviewed here, it seems very likely that changes in habitat conditions are scattered throughout stratigraphical sections. For this reason alone, one might question the wisdom of extrapolating the generation-to-generation processes witnessed by biologists (primarily during periods of stable conditions) up to geological time spans.

Contrary to a recently expressed[4] and commonly held opinion, the debate between the punctuated and gradual viewpoints is not an argument over rates of change, but an argument over the persistence of rates. Many biologists assume that the generation-to-generation microevolutionary processes they witness are typical short segments of trends that persist through geological time. Using this assumption, morphological stasis can be explained as the result of persistent stabilizing selection, and gradual trends in size or shape would result from sustained directional selection. But the present treatment of the gaps in the fossil record calls into question this assumption of persistent rates, stable environmental conditions and sustained selective regimes. Stasis may result if directional trends are short-lived and frequently reversed. Long-term trends may be processions of morphologically distinct and separate populations, rather

Temporal resolution achieved in seven published microstratigraphical studies, evaluated with three criteria defined in the text

	110 (d)	0.1	0.25	170	73,000	73

Stratigraphical thickness, temporal scope and sample thickness are taken directly from original studies. Microstratigraphical acuity was calculated by doubling each sample thickness to correct for compaction, then dividing by a short-term accumulation rate for uncompacted sediment in that environment estimated from compilation of rates by Schindel[6]; these rates were based arbitrarily on 100 yr periods of observation, and therefore assumed that samples contained gaps no greater than 100 yr. Time represented was estimated by doubling the stratigraphical thickness to compensate for compaction, and dividing by the sedimentation rate appropriate for that environment and the level of sampling acuity, giving the time represented by each entire sequence if it contained gaps no greater than the time span of a sample. Completeness is the percentage of the temporal scope represented by active sediment accumulation at this level of sampling resolution. Note trade-off between scope, acuity and completeness.

(a) Among-cycle study spanning Middle and Upper Pennsylvanian time.

(b) Within-cycle study of a single mudstone interval in the Middle Pennsylvanian. The interval is entirely within a single fossil zone, so temporal scope and completeness cannot be estimated by independent evidence, indicated by (?).

(c) Entire Koobi Fora Formation.

(d) Lower Member, Koobi Fora Formation.

(e) Many samples were collected from bedding planes, and are probably time-averaged attritional assemblages. Estimates presented assume 1cm sample thickness within which breaks are not found.

than gradual modifications within a single standing population.

I do not question the reality of short-term directional changes, but I point out the evidence that abounds in the fossil record for habitat shifts, local extinctions and the general lack of persistence in physical conditions. One might assume that changes in physical habitat conditions occur slowly and imperceptibly, allowing any particular biota to migrate passively within geographical limits of the moving habitat. But this view would be an intuitive notion, not a proven point. The effect of habitat shifts on populations over geological time remains an open question. Microevolutionary processes probably operate within the constraints imposed by higher-order processes, which define the distribution and duration of habitable area available to organisms. The gaps in the record suggest that these processes disengage the short-term fate of individuals from the longer-term fate of populations, species and higher taxa. ☐

The age of galaxies

from M. G. Edmunds

ALTHOUGH it has become apparent in recent years that there are quite a few observational constraints on cosmological models, it remains true that facts in cosmology are rare. Any new information must be greeted with delight, and two recent investigations of time and distance scales in the Universe are particularly welcome.

The observational evidence for the evolution of galaxies over cosmic time dates back to the interpretation of radio source counts. Subsequently the so-called 'luminosity–volume' test was applied with considerable success to suitable samples of quasars, and it was concluded (well reviewed by J.V. Wall in *Phil. Trans. R. Soc.* **A296**, 367; 1980) that very active objects like quasars and radio galaxies were far more numerous in the past. It is not suggested that these sources have now completely disappeared, but rather that many galaxies which are comparatively quiescent at the present time must have been much more active at earlier times. The general indications are that the effective number of certain kinds of sources was greater by a factor of perhaps 1,000 when we look back to redshifts between 1 and 3 (corresponding to about 1/3 to 1/5 of the present age of the Universe, assuming a standard expansion model with fairly low overall density of matter).

It has been realized for several years that back beyond a redshift of 3 there may well be no further increase in source numbers, but the observational problems of carrying out a survey for objects that far away are severe. A significant step backwards (if that is not an impolite way of describing the work!) has been made by P.S. Osmer (*Astrophys. J.* **253**, 28; 1982). He has searched systematically for quasars with redshifts greater than 3.5 (that is, looking back beyond 1/5 of the age of the Universe) in an area of 5 square degrees in the sky by using a special spectrum disperser in front of photographic plates. The disperser, a grating prism, stretches out the images of stars and galaxies into small spectra of just sufficient resolution to allow possible quasars to be identified by their strong emission lines. These faint quasar candidates were then examined at higher resolution with a conventional telescope/spectrograph combination. No quasars were found in the search area between redshifts 3.7 and 4.7 (the limit of the technique). Of course the survey has a faintness limit, but previous work in the redshift interval 2.5–3.5 suggests that at least nine quasars should have been discovered even if the space density of objects were constant beyond redshift 3.5. The fact that none was found implies that the density must decrease significantly. The lack of quasars in this particular area of sky could be attributed to a chance fluctuation in spatial distribution, but if we assume a Poisson distribution on the sky, then for an expected number of nine objects in the area, the variance is nine and the detection of none is a very highly significant result!

The importance of the definite demonstration of a decrease in space density lies in the implication that violent activity in galaxies starts at a time corresponding to around redshift 3.5. Since the activity requires a galaxy we can conclude that galaxies must exist at that time. Furthermore, as activity is thought to begin fairly rapidly after the actual formation of the galaxy as a discrete entity of stars and gas, it can be argued that we are seeing back to the epoch (about 1/5 of the age of the Universe) at which galaxies form.

Despite his careful area-limited search, Osmer must have been disappointed that he did not beat the record for the largest redshift discovered, set at 3.53 about a decade ago. It is perhaps a little ironic that very soon after Osmer's paper was published, a press release appeared from workers in Australia (B. Peterson, A. Savage, D. Jauncy and A. Wright), reporting that optical spectroscopy of the radio source PKS2000 - 330 shows that it is a quasar with redshift 3.78. This in no way vitiates Osmer's result, since it is not at all surprising that there are some quasars beyond redshift 3.5 — but there are not very many of them.

How long ago, in real terms, was this epoch of quasar and, by inference, galaxy formation? The expansion time scale of the Universe has been a controversial issue for many years, the uncertainty arising from the great difficulties of accurately measuring distance in astronomy. The conventional chain of reasoning is a long and indirect one, passing from the parallax measurements of the nearest stars, out to various size and brightness indicators in galaxies of known redshift. The number determined observationally is the Hubble constant, H_0, and the two major determinations of its value are either 50 km s^{-1} Mpc^{-1} or 100 km s^{-1} Mpc^{-1}, depending on whether the Universe is viewed from California or Texas. The pragmatic astronomer might be tempted to take a mean value between the two, and some support for this approach comes from a recent determination of the distance to supernova explosions in distant galaxies by W.D. Arnett (*Astrophys. J.* **254**, 1; 1982). The extreme brightness of supernovae makes them ideal probes of distance and although distance estimates have been attempted before, using kinematic models of their expansion, this is the first time that a dynamical model for type I supernovae has been used. The model is admittedly very simplified, and aims at estimating the intrinsic brightness of the supernova on the basis that the luminous energy is supplied by radioactive decay of ^{56}Ni, freshly synthesized in the explosion. The distance can then be inferred from the supernova's apparent brightness. From a set of supernovae in several clusters of galaxies, a value for H_0 of 70±10 is deduced, which lies nicely between the disputed values. The implied age of the Universe is then about thirteen billion years, again assuming a fairly low mass density. Arnett stresses that his value for H_0 should not yet be taken too literally, since there are many refinements to his simple supernova model that need investigation. Nevertheless, the age of galaxies would then be of the order of ten to eleven billion years, an acceptable time scale compared with present estimates of the ages of some star clusters in the Galaxy,

0028-0836/82/210284-02$01.00

and the age estimates based on comparative abundances of radioactive nuclei. This would at least avoid the problems created by the higher value of H_0 of 100 km s^{-1} Mpc^{-1}, which suggests a Universe age of nine billion years compared with star cluster ages which are estimated to be in excess of ten billion years. The lower value of 50 km s^{-1} Mpc^{-1} cannot be ruled out, although the age of galaxies (following Osmer's result) would have to be at least 14.5 billion years. □

150th anniversary of Gauss's first absolute magnetic measurement

from S.R.C. Malin and D.R. Barraclough

On 26 May 1832, the horizontal component of the Earth's magnetic field at Göttingen was 1.7820 $mg^{1/2} mm^{-1/2} s^{-1}$ (= 17,820 nT). Not particularly remarkable, you might think, except that this was the first ever absolute measurement of the geomagnetic field and its attainment had required much of the armoury of one of the world's greatest mathematicians.

Carl Friedrich Gauss (1777–1855) was a gifted child. His early mathematical feats led his father grudgingly to agree with his teachers that the boy should receive higher education rather than learn a trade, but Gauss was also an exceptional linguist and might equally easily have chosen to study philology. It was the satisfaction he derived in 1796 from demonstrating the construction of a regular 17-sided polygon with ruler and compasses that finally decided him on a career in mathemtics. In his doctoral thesis, he proved the 'fundamental theorem of algebra' (the first of his four independent proofs of this theorem), and most of his work at this time was similarly concerned with pure mathematics. Although this continued to be his main interest, he gradually branched out into many other subjects, including applied mathematics, astronomy, geodesy, optics, telegraphy and geomagnetism.

Soon after 1830, Gauss became interested in the adoption of a universal system of units for all physical quantities, and came to the remarkable conclusion that even magnetic intensity could be measured in terms of mass, length and time. With the practical assistance of Wilhelm Weber, professor of physics in the University of Göttingen, he set about devising an experiment to make this measurement. He explains some of his ideas in a letter to the astronomer Olbers written on 18 February 1832.

"I occupy myself now with the Earth's magnetism, particularly with an *absolute* determination of its intensity. Friend Weber conducts the experiments on my instructions. As, for example, a clear concept of velocity can be given only through statements on time *and* space, so in my opinion, the complete determination of the intensity of the Earth's magnetism requires to specify (1) a weight = p, (2) a length = r, and then the Earth's magnetism can be expressed by $\sqrt{p/r}$."

The experiment came to fruition three months later, after Gauss had slightly revised his dimensional arguments. The apparatus required is very simple — two bar magnets (A and B), one single-filament suspension in which either magnet can be fitted, a ruler, a clock and two weights. The method is also simple, though a number of refinements are required if its full accuracy is to be realized. The first part is the vibration experiment in which magnet A is suspended horizontally, and its period of oscillation either side of magnetic north measured. The period T is related to the magnet's moment of inertia, I, its magnetic moment, M, and the horizontal intensity of the geomagnetic field, H, by

$$T = 2\pi\sqrt{\frac{I}{M\,H}}$$

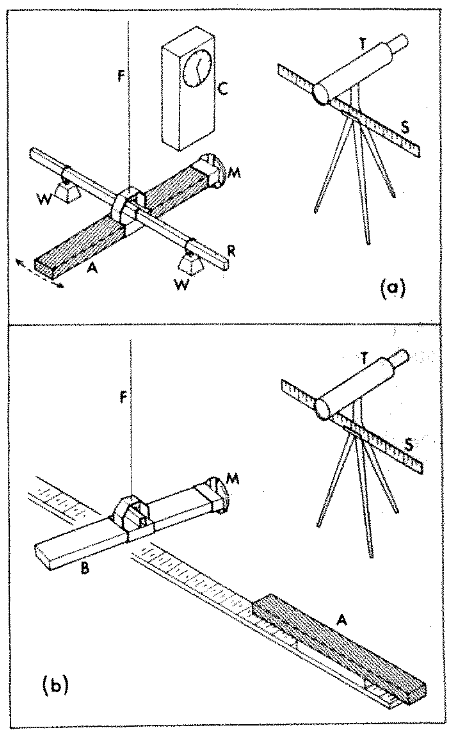
Thus, if I is known, we can infer $M\,H$. Gauss deduced I by adding known increments to it in the form of weights at known distances from the suspension, and noting how this affected T. In calculating I from the several different values of T and ΔI, Gauss used a powerful technique which he had developed himself, the method of least squares. He also took care to adjust T to the value it would attain with vibrations of infinitesimal amplitude, as the equation is strictly valid only for that case.

The second part is the deflection experiment in which the ratio M/H is determined by suspending magnet B and noting its angular deflection from magnetic north when magnet A is placed at a known distance to the east or west. This requires a knowledge of the way in which the magnetic intensity due to a bar magnet falls off with distance. Gauss deduced this from first principles, showing not only that the intensity due to a dipole depends on the inverse cube of the distance, but also that one additional term is both necessary and sufficient to allow for the finite length of the bar magnet. He determined the parameters by measuring the deflection with magnet A at different distances, again solving by the method of least squares.

From a knowledge of $M\,H$ and M/H, both M and H can readily be deduced.

Because of secular change, it is difficult to assess the accuracy of Gauss's original observation but, from internal consistency and backward extrapolation of the trend from later observations, it seems likely that it was within one per cent of the true value. With only minor modifications, Gauss's method continued to be the standard way of measuring H at magnetic observatories and in the field until the 1920s, and it is still in use at some observatories. Nowadays, absolute magnetic intensity measurements are usually made with a proton magnetometer. This gives the answer to an accuracy of about 1 part in 10^6 in a few seconds.

This was not Gauss's only contribution to geomagnetism. He later applied yet another of his inventions, the method of spherical harmonic analysis, to the Earth's magnetic field to show that nearly all of it came from inside the Earth. He was also, with Humboldt, largely responsible for the 'Gottingen Magnetic Union', an international project for the simultaneous observation of the magnetic field on four selected term-days each year at a number of widespread sites. This scheme developed into the worldwide network of magnetic observatories that exists today. □



Gauss's experiment. (a) The vibration experiment. The magnet, A, suspended by a silk thread, F, oscillates in a horizontal plane. Its moment of inertia can be varied by hanging weights, W, from the rod, R. The period of oscillation is obtained by observing the reflection of the scale, S, in mirror M, through the telescope, T, and timing an integral number of swings with the clock, C. (b) The deflection experiment. Magnet B is suspended and is deflected from magnetic north by placing magnet A at a known distance. The deflection is measured by observing the reflection of the scale, S, in mirror M, through the telescope, T.

Cause and treatment of atherosclerosis

from C. T. Dollery

The most common cause of death in developed countries is necrosis of heart muscle (myocardial infarction) resulting from obstruction of the arterial blood supply. The affected artery is usually narrowed by a plaque of atheroma. Two main hypotheses have been proposed for the origin of the atheroma, and although they are not mutually exclusive, as became clear at a recent symposium*, each tends to have its particular supporters.

The first hypothesis holds that plasma lipids diffuse into and are deposited in the arterial wall, and receives support from epidemiological evidence that relates levels of blood lipids in younger people to incidence of atheroma. The second hypothesis is that focal damage to the endothelium leads to deposition of platelets from the blood, release of platelet-derived growth factor and stimulation of smooth muscle migration and hypertrophy. The laminated appearance of many atheromatous deposits, suggesting successive deposition of thrombus, and the presence of platelet antigens in the plaques provide supporting evidence.

In plasma, lipid particles consist of a core of neutral lipid surrounded by protein (the apolipoprotein). A.M. Gotto (Baylor College of Medicine) likened the apolipoprotein to a detergent that solubilizes the lipid and put forward the 'iconoclastic' opinion that the apolipoproteins are more important than the lipids in understanding lipid transport and metabolism.

There are five classes of apolipoprotein (A–E) and many subclasses, and the apolipoproteins E have recently been sequenced. When the arginine residue is replaced at position 112 in apolipoprotein E_3, the molecule is not recognized by the lipoprotein E receptor. Homozygous inheritance of this E_3 deficiency can lead to type 3 hyperlipidaemia.

Lipoprotein receptors on cell membranes regulate entry of lipids into cells, are a target for specific lipoproteins and regulate the plasma lipoprotein concentrations. The best studied lipoprotein receptor is the low-density lipoprotein (LDL) receptor whose absence is responsible for familial hypercholesterolaemia. T.P. Bersot (University of California, San Francisco) showed that this receptor interacts with apolipoproteins B and E (Apo-B is the main apolipoprotein found in LDL whereas E is found in very low-density and high-density lipoproteins). The Apo-B/E receptor has a molecular weight of about 106,000, requires the presence of divalent cations and is inactivated by pronase.

A key difficulty in clinical research is assessing the amount of atheroma in a living human artery. D.H. Blankenhorn (University of Southern California) is using angiograms of the femoral and coronary arteries and computer image processing techniques. The centre line of the vessel is established and variations of wall distance at multiple transverse sections measured. The method has proved successful in postmortem material and is now being used *in vitro* to assess response to lipid-lowering agents. He was hopeful that the method could be applied to intravenous, rather than arterial, injections of radiographic contrast material to permit more frequent measurements. Radiological methods may be replaced by ultrasound in the not so distant future.

Lipid-lowering drugs (clofibrate, cholestyramine, nicotinic acid) have been found to be almost uniformly ineffective in reducing myocardial infarction mortality. In the WHO-sponsored clofibrate trial coordinated by M. Oliver (University of Edinburgh), there had been a reduction in non-fatal myocardial infarcts (none in fatal ones) but the overall mortality had been significantly greater in the treated group. The most effective anti-thrombotic drugs so far used had been the coumarin anticoagulants which had reduced mortality by about 20 per cent compared with placebo. Anticoagulants were almost discarded in the UK in the early 1970s but use has continued in the Netherlands (A.S. Douglas, University of Aberdeen). A recent randomized trial of withdrawal of long-term anticoagulant therapy in that country showed a higher mortality in those who stopped therapy than in those who continued therapy. Trials with anti-platelet drugs (aspirin, dipyridamole, sulphinpyrazone) had shown a smaller effect. The largest trial with aspirin had shown no benefit and the interpretation of one of the sulphinpyrazone trials was hotly contested. Overall these drugs had reduced myocardial infarction mortality by about 10–15 per cent. Four recent positive trials with β-adrenergic blockade, which had shown a reduction of 25–33 per cent in mortality during the first three years after a myocardial infarct, were mentioned only briefly. The speakers would not be drawn into a discussion of why myocardial infarction mortality has declined substantially in the USA but only very slightly in the UK. When asked whether we should all start jogging, restrict saturated fat intake, stop smoking and treat mild hypertension (or await better evidence of efficacy), one of the Americans said that we probably should, and quoted Irvine Page's aphorism "I don't want to be the smartest man in the graveyard".

The last session was concerned with platelet function and the role of prostaglandins in vascular disease. Platelet plugs form very rapidly when small vessels are ruptured and platelet adhesion and aggregation is usually the first step in arterial thrombosis. At least three different mechanisms are responsible for platelet aggregation — contact with collagen, release of ADP and release of the arachidonic acid endoperoxide product thromboxane A_2 (TXA_2). TXA_2, released from platelets and damaged tissues, has received much attention recently but G. Born (King's College, London) reported experiments on bleeding time from punctures made in small mesenteric vessles which support a major role for ADP. The question is important as great efforts are being made to develop inhibitors or antagonists of TXA_2.

PGI_2 (prostacyclin) has attracted great interest because it is formed by the endothelium of blood vessels and is a powerful inhibitor of platelet aggregation. S. Moncada (Wellcome Research Laboratories) suggested that its physiological role is to prevent interactions between platelets and the blood vessel wall. PGI_2 interacts with a receptor on platelets which raises the level of cyclic AMP, makes them less aggregable and inhibits the exposure of fibrinogen receptors on their surface. Moncada was optimistic of the usefulness of PGI_2 in preventing clotting in extracorporeal circulations (cardiopulmonary bypass, charcoal column haemoperfusion, renal dialysis), in platelet consumption coagulopathies (haemolytic uraemic syndrome) and in peripheral vascular disease (gangrene of the lower extremities, Raynauds phenomenon). Others agreed about the value of PGI_2 as a heparin-sparing agent in extracorporeal circulations but contested its value in peripheral vascular disease.

C.T. Dollery (Royal Postgraduate Medical School, London) described a new method for measuring plasma 6-oxo-PGF, the hydrolysis product of PGI_2, which uses gas chromatography-negative ion chemical ionization mass spectrometry and has a sensitivity limit of 500 pg ml^{-1}. The concentrations he measured in venepuncture samples from normal humans were very low, averaging 1.2 pg ml^{-1}, and were almost certainly too low for PGI_2 to have a physiological role in the normal circulation. Large amounts of PGI_2 produced by isolated tissues and perfused organs are caused by the injury involved in their preparation. However, PGI_2 was released in substantial quantities *in vivo* as a result of trauma caused by passing vascular catheters in man or dog and by infusions of hypertonic dextrose into a human forearm vein. He proposed that PGI_2 released from damaged endothelial cells prevented the propagation of the luminal face of a platelet clot in a puncutured vessel and inhibited

C.T. Dollery is Professor at the Royal Postgraduate Medical School, Ducane Road, London W12 0HS.

*The Biological Council symposium on 'Atherosclerosis: Mechanisms and Approaches to Therapy' was held at the Imperial College of Science and Technology, London, on 5–6 April 1982.

0028-0836/82/210286-02$01.00

platelet aggregation in a vessel that had been damaged but not severed. Possible application of this theory to atheroma depended on the frequency and importance of focal damage to arterial endothelium *in vivo*.

The symposium left mixed impressions. Animal and human studies on the pathogenesis of atheroma seem to be making only slow progress. Much of the difficulty arises from the unsatisfactory nature of the animal models and the difficulty of studying a process in man which progresses over decades. In contrast, lipid biochemistry and pharmacology are making important discoveries and eventually this basic knowledge should yield dividends in new forms of therapy. The problem is when, as there appears to be nothing of great promise on the immediate horizon. New methods of measuring plaque regression will make early human studies feasible but very prolonged outcome trials will still be needed. The general gloom about the immediate prospects for development of therapeutic agents can be summed up by two quotes from the discussion "May the risk of controlling risk be greater than the risk itself?" and "You can be sure that a new treatment will do someone harm. You cannot be sure, until you do a large-scale clinical trial, that it will do anyone any good". Your correspondent was excited by the new developments in biochemistry and pharmacology of both the lipoproteins in the blood and the fatty acids in cell membranes and hopes these pessimistic views are wrong. □

The nuclear pore — a biological grommet?

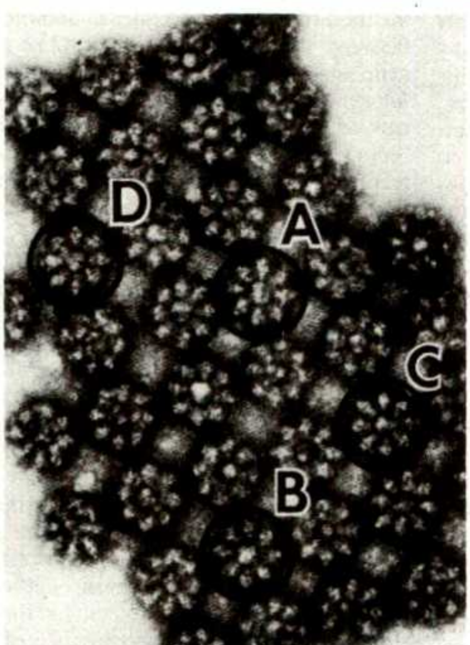
from N. Michael Green

THE double membrane surrounding the nucleus is penetrated by nuclear pore complexes, recognized from the early days of electron microscopy as large structures (1,200 Å in diameter) with a striking eightfold rotational symmetry (reviewed by J.R. Harris in *Electron Microscopy of Proteins* Vol. 1, Academic, New York, 1981). Although they are referred to as pores, the channel is usually filled with a dense plug. The general features of the complex have long been recognized but higher resolution has been prevented by the lability of the structure, which is readily distorted by the processing required for microscopy. New information has now emerged in a paper by Unwin and Milligan (*J. Cell Biol.* **93**, 63; 1982). They used the favoured nuclear envelope of the *Xenopus* oocyte, which contains such a high density of pores that they tend to form tetragonal arrays. The topology of such an array is similar to that of the intercellular gap junction, but whereas the latter shows a regular lattice stabilized by protein interactions, the pores in the nuclear envelope remain distinct and appear to have rotational freedom in the paired lipid bilayers. Nevertheless, the close packing provides mutual support and minimizes distortion caused by drying in the negative stain (either uranyl acetate or gold thioglucose).

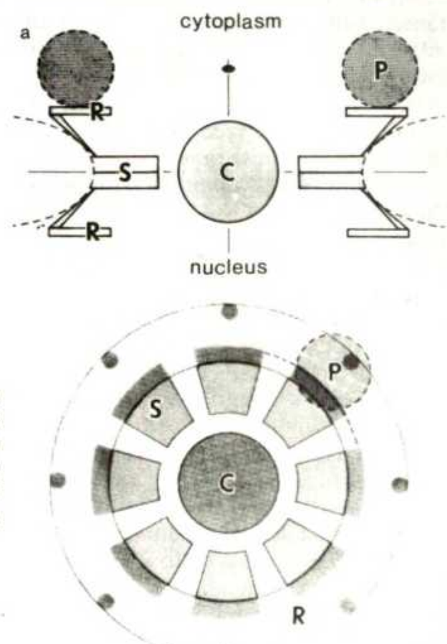
N. Michael Green is in the National Institute for Medical Research, Mill Hill, London NW7 1AA.

The most revealing pictures were obtained by allowing the nuclear envelope to adhere to hydrophilic, polylysine-treated carbon film and then washing either with high salt or with 0.1 per cent Triton X-100. This released both the intact complexes and various substructures, which adhered to the film in the neighbourhood of the original envelope. The following constituents were observed: (1) low-contrast rings with an internal diameter of 800 Å and an external diameter of 1,200 Å; (2) a dense central plug of diameter 370 Å; (3) eight particles of diameter 220 Å, possibly ribosomes, bound to the rings, enhancing their eightfold symmetry, and (4) broad radial spokes which in some way link the plug to the rings. Deciphering the three-dimensional organization of these components was greatly aided by occasional oblique and edgewise views of the complex, from which maximum information was obtained by examining the specimen at various angles on the tilting stage. Individual images, edgewise or *en face*, were analysed by numerical Fourier methods to give an accurate radial density distribution and an approximate distribution perpendicular to the membrane.

Because of the restriction to single images, rather than a regular array, and the problems of specimen preservation, the resolution was limited to 90 Å. Nevertheless, a fascinating picture emerges. The pore structure is basically a three-layered sandwich of a disk between two thin rings. The disk, consisting of a central plug and eight broad spokes, is suspended between the rings by slender extensions of the spokes. Each ring is coplanar with one half of the double membrane. Within the outer circumference of each ring the membranes approach each other, following the



Left: Detached pore complexes released onto the microscope grid from a nuclear envelope immersed in low salt medium containing Triton X-100. A,B,C and D refer to images from which projection maps were obtained.



Right: Diagram of the nuclear pore complex: (A) in central cross-section and (B) in projection down the octad axis. The major constituents are the central plug (C) the spokes (S) and the rings (R). The nuclear membrane and the ribosome (P) are shown as dashed lines.

Reproduced from *J. Cell. Biol.* **93**, 66 & 75 (1982).

0028-0836/82/210287-02$01.00

direction of the connecting strands until they fuse in the mid-line around the periphery of the spokes, at a diameter of 1,000 Å. This interpretation of the structure implies that there are no transmembrane proteins in the usual sense; the proteins of the pore complex merely provide a grommet which stabilizes the hole formed by local fusion of the paired membranes. The eight 'ribosomal' particles were attached only to the cytoplasmic face of the grommet. These particles were readily removable by high salt or EDTA, leaving a structure which at this resolution had eight twofold symmetry axes at right angles to the main eightfold axis.

These findings provoke many further questions about both the structure and function of the pore complex. It has long been known that the nuclear membrane is freely permeable to ions and small metabolites and that even molecules as large as about 90 Å in diameter can pass across with little hindrance. This is consistent with the structure proposed by Unwin and Milligan, but it is less easy to see how ribosomal particles (200 Å in diameter), assembled in the nucleus, manage to pass through the pore. It is possible that this process may be energy dependent and that some movement of plug or spokes is involved. Further structural questions concern the proteins which form the pore structure. Earlier work by Krohne, Franke and Scheer (*Expl Cell Res.* **116**, 85; 1978) has shown only two major components (MW 73,000 to 150,000) in purified pore complexes, together with several minor components. It should be possible to determine the location of at least the major constituents by immunological methods. Beyond this there is the problem of how the assembly of such large structures is controlled. From the dimensions it can be calculated that each of the major constituents (plugs, rings and spoke assembly) must contain several hundred molecules of their constituent protein subunits, giving them 'molecular weights' of 20–40 million. There is no way in which so many identical building blocks will assemble spontaneously into a precise limited structure without some guiding activity by the minor protein constituents or other cellular components.

These provocative developments provide an interesting example of the information which can be extracted from electron micrographs by modern image processing methods, even in the absence of extensive repeating structures. □

A novel gene splice in phage Mu

from Neville Symonds

GENE expression is usually thought of as being controlled through the action of proteins, such as repressors and effectors. Recently, a different mode of control has been reported whereby inactive genes are relocated by some type of recombination process to new sites where transcription takes place. Examples of recombinational control are mating type in yeast (Leupold *Nature* **283**, 811; 1980), phase variation in *Salmonella* (Zieg & Simon *Proc. natn. Acad. Sci. U.S.A.* **77**, 4196; 1980) and host range in phage Mu (Van de Putte *et al. Nature* **286**, 218; 1980). The last example refers to the unexpected finding that two types of Mu phage can be detected which differ with regard to the bacteria they can infect. The difference in host specificity is correlated with the two possible orientations observed in the G region of Mu, an invertible segment of about 3,000 base pairs. With G in one orientation, designated (+), Mu phage can adsorb to one set of hosts, which includes *Escherichia coli* K12; in the other orientation, (–), the phage adsorb to a different set, including certain *Citrobacter* and *Shigella* strains. How does the oscillation in G orientation bring about alterations in host specificity?

In general terms the answer to this question has been known for some time. With G in the (+) orientation, two Mu genes, S and U, which code for tail fibres and enable the phage to adsorb to certain hosts, are expressed; in the (–) orientation two alternative genes, S′ and U′, are expressed, so the host range is altered. The actual genetic mechanism by which this switch is accomplished has, however, only now been elucidated and is described by Giphart-Gassler and co-workers in this issue of *Nature* (p.339).

The intriguing point to the story is that, in a manner somewhat reminiscent of that used to create diversity among immunoglobulins, the variation between the S and S′ genes is brought about by joining a constant DNA sequence, S_c, adjacent to G with either of two different sequences S_v or S_v' located within G. In the (+) orientation, transcription starts at a promoter site outside G, proceeds through S_c and S_v, and then through the adjacent U gene which lies wholly within G. Tail fibres corresponding to S and U are therefore produced. In the (–) orientation the situation is reversed, the reading being in the order $S_c + S_v'$, U′, so that S′ and U′ tail fibres are made but not those corresponding to S and U.

The recombinational control which underlies the three examples mentioned above and is exemplified by the variation in host range of Mu is fundamentally different from control of protein synthesis by positive and negative feedback circuits. Such circuits are able to modulate the activity of genes and, in the extreme case, turn them off completely. Recombinational control, on the other hand, introduces a two-way switch into these circuits, allowing alternative pathways to be introduced into the system. This added flexibility is useful when only one of two possible phenotypes can be tolerated at a particular time. It is well known from experiments involving mixed infection of cells with wild-type phage and host-range phage mutants that progeny particles which receive a mixed complement of tail fibres acquired from different parents have the worst of all worlds, not being able to adsorb properly to any of the usual hosts. If the host range of a phage, such as Mu, is to be extended by providing two distinct sets of tail fibres, then it is clearly advantageous that only one set or the other should be synthesized at any stage — a two-way switch is therefore appropriate.

The precise recombinational mechanism by which the switch between mating types is instituted in yeast, where some type of gene conversion seems to occur, is different from the inversion systems used to bring about phase variation in *Salmonella* or the alternation in host range shown by Mu (and also by phage P where a closely related system operates). All these inversion switches use site-specific recombination systems which act on the short inverted repeats at either end of the relevant inverted region, and which are catalysed by genes immediately adjacent to it. Surprisingly, although the invertible regions in *Salmonella* and Mu are quite distinct, there is some sequence homology between their inverted repeats. The *gin* gene which mediates G inversion and the *hin* gene mediating inversion in *Salmonella* can complement each other (Szekely & Simon *J. Bact.* **148**, 829; 1981). The known recombinational switches of the inversion type therefore all seem to stem from some common origin. Another evolutionary oddity of the G system is that the emergence of two kinds of Mu phage with different host ranges would be expected to lead to an increase in the number of bacterial strains which harbour Mu prophage. However only the original Mu isolate detected in *E. coli* K12 has ever been reported. Whatever the reason for this, the whole of the G region has been preserved in the Mu phage we have, even though within K12 strains part of the region (and the *gin* gene) could easily be deleted and the phage locked in the (+) orientation. Perhaps there is still another twist to come in the G story by which G and *gin* are implicated in some other aspect of the Mu life cycle. □

REVIEW ARTICLE

Active chromatin

Stuart Weisbrod

Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, New York 11724, USA

Active genes are packaged into an altered nucleosome structure forming a chromosomal domain defined by increased sensitivity to nucleases. This structure, reflecting a potential for transcription, contains sites hypersensitive to nuclease digestion adjacent to the coding regions and may also be distinguished by specific non-histone proteins, variant or modified histones or modified DNA. Its formation, by unfolding of a tightly packed chromatin fibre by factors which might affect DNA supercoiling, may be the first step in gene activation.

REGULATION of gene expression is a fundamental mechanism in eukaryotic development and survival. The structure of the chromosome is directly related to this regulation since, for the most part, the DNA in the nucleus is compacted too tightly to be available to the transcriptional apparatus. Therefore the chromatin structure of genes which are transcribed, approximately 10–20% of the total, has to be different from that of the bulk of the DNA. Both the 'housekeeping' genes, those which are expressed in all cell types in the organism, and the genes which distinguish one cell type from another, exist in the active conformation.

Studies on eukaryotic chromosomes have focused mainly on the basic unit of chromatin, the nucleosome, and on how the individual nucleosomes are packed together. The existence, structure, and packaging of nucleosomes have been the subject of a number of reviews[1–3]. Most of the evidence in these studies stems from electron microscopy, where a beaded chromatin fibre is observed, and enzymatic studies which reveal the existence of a repeating unit. The nucleosome consists of 146 to 240 base pairs of DNA wrapped twice around a histone core, made up of two each of the four inner histones H2A, H2B, H3 and H4. A fifth histone, H1, is also associated with the nucleosome but in a manner which is not clear. Extensive endonuclease digestion of chromatin produces a nucleosome core particle containing 146 base pairs of DNA and the histone core (but not H1), indicating that the heterogeneity of nucleosome DNA length is due to variability in the length of DNA linking one nucleosome to the next. The digestion studies also suggest that histone H1 is associated with this 'linker' DNA.

The nucleosome is also involved in the higher orders of structure that fold the DNA into the compact form found in the nucleus. The basic level of organization is the 100 Å 'beads-on-a-string' fibre generated by folding of the internucleosomal linker DNA[4]. This fibre is then coiled into a 300 Å fibre, possibly induced by histone H1 as a crosslinker, to yield a structure with a packing ratio of 25:1, close to that of interphase chromatin[5]. To make a mitotic chromosome from the 300 Å fibre a further two orders of magnitude of compaction are generated by specific nonhistone proteins which form the skeleton or scaffold of the chromosome[6]. Electron microscopy of histone-depleted metaphase chromosomes has demonstrated that the DNA is organized in loops at least 30–40 kilobases in length. Each loop of the chromatin is attached to the scaffold at its base, either by DNA–protein or DNA–RNA interactions[7], and may exist in an expanded or a highly compacted conformation.

A nucleosomal repeat structure does not distinguish between inactive and active genes. Thus the DNA sequence complexity of mononucleosomes is virtually indistinguishable from that of total DNA and they contain sequences corresponding to transcripionally active genes[8]. The nucleosome structure of active genes has also been demonstrated by immuno-electron microscopy[9]. However, there are many ways in which the structure of chromatin from actively transcribed genes could or does differ from that of non-transcribed regions; what is known of these differences will be summarized here.

Nuclease digestion studies

Evidence that chromatin from actively transcribed genes exhibits a structure different from that of non-transcribed regions stems from the use of relatively nonspecific endonucleases as probes in anticipation that they would recognize something special about active genes. Weintraub and Groudine[10] have shown that the globin gene in chick erythrocyte nuclei is preferentially sensitive to digestion by pancreatic DNase I, but not to digestion by micrococcal nuclease. The resistance of the globin gene to micrococcal nuclease suggests that the globin gene is packaged into nucleosome-like particles; its sensitivity to DNase I indicates that these particles are conformationally different from most nucleosomes. The sensitivity of the globin gene to DNase I is tissue specific. Globin chromatin is preferentially digested in red blood cells, but not in the oviduct; conversely, the ovalbumin gene is preferentially sensitive in the chick oviduct but not in red blood cells[11].

The sensitivity to DNase I of actively transcribed genes seems to be a general phenomenon[12–15], but only reflects a potential for a gene to be transcribed rather than transcription itself. For example, the ovalbumin gene remains sensitive in the hormone-withdrawn chick oviduct[16], *Physarum* ribosomal DNA remains sensitive during mitosis when ribosomal RNA transcription is not detectable[12] and the mouse globin gene exhibits the same sensitivity in induced (transcribed) as well as uninduced (non-transcribed) Friend erythroleukaemia cells[17]. The boundaries of the sensitive regions of chromatin are very precise, since in a hamster cell line transformed by adenovirus, only those adenovirus sequences that are transcribed are sensitive to DNase I while adjacent non-transcribed sequences are not sensitive[13].

Using DNase II, an enzyme which cuts primarily between nucleosomes, Gottesfeld and Butler[18] have shown that after chromatin is digested, nontranscribed nucleosomes can be selectively precipitated with 2 mM Mg^{2+}. The DNA in the active, non-precipitated nucleosomes is enriched for sequences coding for messenger RNA. Surprisingly, the active nucleosomes sedimented at 14S compared with 11S for bulk nucleosomes. When treated with RNase, the 14S structure converts to 11S, suggesting that the difference in S values can be attributed to the presence of nascent RNA chains. Other evidence[19] confirms that this technique, as well as similar fractionation techniques using micrococcal nuclease[20], will only separate actively transcribing genes and genes which are

0028–0836/82/210289—07$01.00

transcribed at different rates might be represented in different proportions in the active fraction. Since these procedures do not result in the complete digestion of active sequences, they are potentially useful for investigating the properties of active nucleosomes, but unfortunately they have proven difficult to reproduce.

Endonucleases have also been used to investigate higher order organization of active chromatin. A very light digestion of *Drosophila* nuclei by DNase I or micrococcal nuclease revealed preferential cleavage sites in a number of heat shock loci[20]. These hypersensitive sites were originally suggested to act as boundaries of a supranucleosomal structure, but subsequent analyses (see below) have placed them within the active domain. The overall sensitivity of specific genes and adjacent noncoding regions has been measured by monitoring the disappearance of specific restriction bands after a mild DNase I digestion of nuclei[22-24]. In one case[23], a 25 to 50 kilobase region adjacent to the highly DNase I-sensitive globin coding region in erythrocytes was characterized, distinguished by a level of DNase I sensitivity intermediate between that of an expressed and a totally inactive gene. It was postulated that this domain might be equivalent to a lampbrush loop, and the DNase I sensitivity an indication that it is in a relaxed rather than a condensed configuration.

Proteins associated with active chromatin

Once the nuclease digestion experiments had demonstrated that the conformation of active nucleosomes is different from that of bulk nucleosomes, it was logical to seek the structural basis of this difference. From monitoring the proteins released by DNase I digestion and the characteristics of the various enriched fractions the suggestion arose that the active structure is due to altered or modified histones and/or the presence of nonhistone chromatin proteins in the nucleosome.

The nonhistone protein fraction most often detected associated with active nucleosomes is that of the high mobility group (HMG). The characteristics of this group have recently been extensively reviewed[25]. HMGs are highly conserved proteins with low molecular weight (<30,000), have an unusual amino acid composition containing approximately 25% basic and 30% acidic residues, and are easily eluted from chromatin in 0.35 M NaCl. They are present in amounts only approximately 5% of the nuclear DNA content and in, at most, 10–20% of the nucleosomes. They have been divided into two groups based on their solubility properties in trichloroacetic acid (TCA). HMGs 1 and 2 are soluble in 2% TCA but insoluble in 10% TCA; HMGs 14 and 17 are soluble in 10% TCA but insoluble in 20% TCA. The presence of HMGs in isolated mononucleosomes has been demonstrated by several biochemical means[26-28]. Furthermore, by the use of fluorescent antibodies, HMG-like proteins have been shown specifically to be associated with the transcriptionally active puffs in salivary gland polytene chromosomes[29].

Mononucleosomes enriched in nonhistone proteins have been prepared by limited digestion of nuclei with micrococcal nuclease[30-32]. Levy-Wilson and her co-workers[32], for example, have shown that a fraction enriched in active sequences, prepared by mild micrococcal nuclease digestion of trout testes nuclei and 0.1 M NaCl solubilization, is enriched in HMG T (analogous to HMGs 1 and 2), H6 (analogous to HMGs 14 and 17) and ubiquitin, and is depleted in histone H1. Analyses of these HMG-containing nucleosomes suggested that H6 was preferentially bound to the histone core while HMG T was associated with the internucleosomal linker DNA.

HMGs 14 and 17 can be eluted from chick erythrocyte chromatin with 0.35 M NaCl without any detectable change in the gross structure of individual nucleosomes; however, in this depleted chromatin the globin gene is no longer preferentially sensitive to digestion by DNase I[33]. Reconstitution of the depleted chromatin with either the entire 0.35 M NaCl fraction or purified HMGs 14 and 17 at a ratio of 1 mole HMG per 10 moles of nucleosomes results in the successful reconstitution of DNase I sensitivity on the globin gene (Fig. 1)[33]. Further reconstitution studies[34] have led to the following conclusions: (1) There is no tissue specificity associated with the HMGs; thus, HMGs 14 and 17 from brain nuclei are capable of restoring DNase I sensitivity to the globin gene when reconstituted with depleted red blood cell chromatin. (2) Most actively transcribed

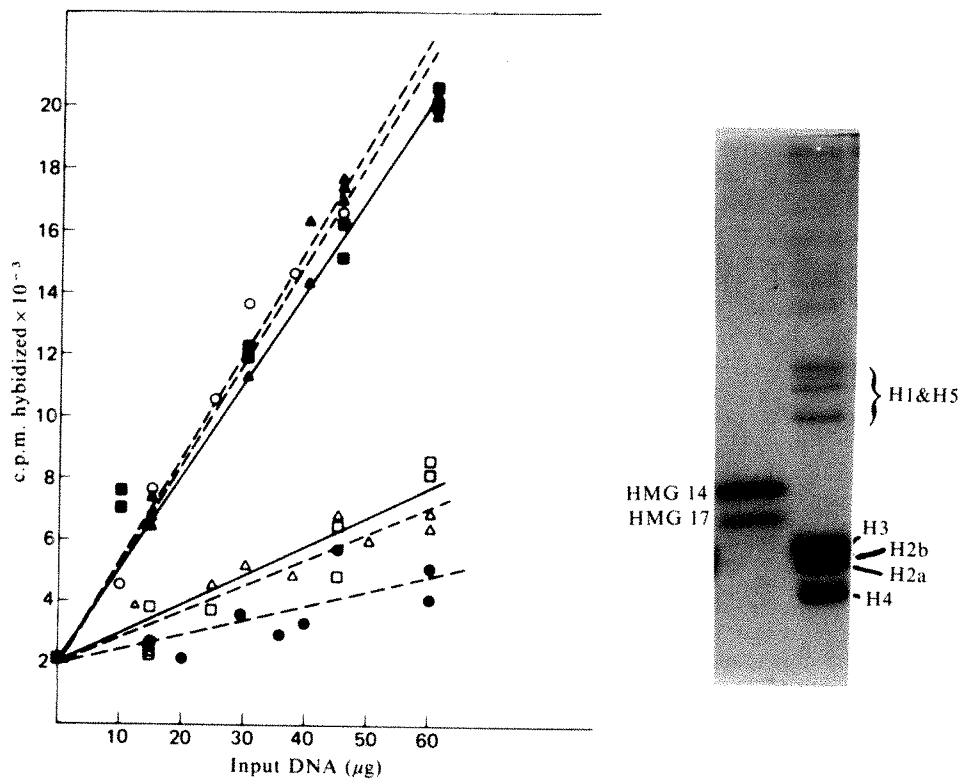

Fig. 1 Reconstitution of DNase I sensitivity of the globin gene in 14-day-old chick embryo red blood cells with 10% TCA-soluble HMG proteins. Chromatin was eluted with 0.35 M NaCl and separated into several portions. One portion was reconstituted with the 0.35 M NaCl eluate directly ▽); a second portion was reconstituted with 10% TCA-soluble fraction from the 0.35 M NaCl eluate containing mainly HMGs 14 and 17 (□); a third portion was reconstituted with the 0.35 M NaCl eluate previously treated with trypsin and then trypsin inhibitor (○); and a fourth portion was digested directly (▼). Each portion was then treated with DNase I so that 10–15% of the DNA was rendered acid soluble. The DNA was then purified and hybridized to an excess of globin cDNA. As controls, nuclei treated to 35% acid solubility with micrococcal nuclease (■) showed no preferential digestion, whereas nuclei treated to 10% acid solubility with DNase I (●) showed a significant loss of globin sequences. Reconstitution with 0.35 M NaCl alone or with neutralized and dialysed 10% TCA alone was unsuccessful in restoring DNase sensitivity (not shown). Input globin cDNA was 100,000 c.p.m. Also shown in an 18% SDS-polyacrylamide gel of total nuclear proteins and purified HMG 14 and 17 (from ref. 33).

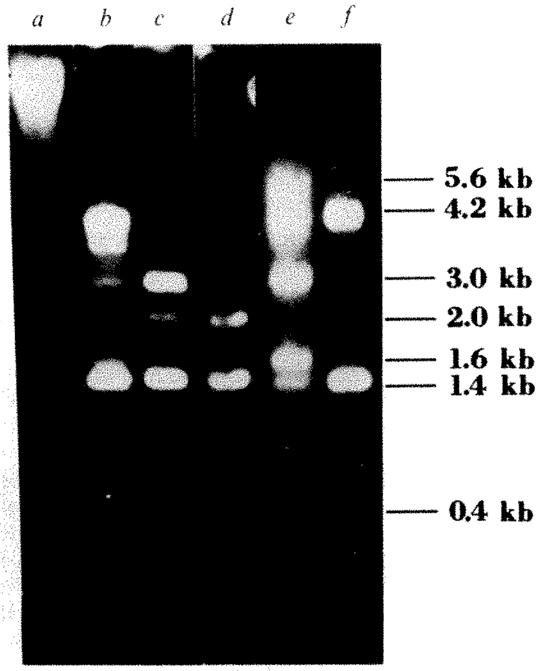

Fig. 2 The chicken adult β-globin gene is more methylated in 5-day embryos making embryonic haemoglobin than in 14-day embryos making adult haemoglobin. *a–d*, Partial digestion of adult erythrocyte DNA with *MspI*; *a*, no enzyme control; *b*, 2 units; *c*, 12 units; *d*, 100 units of enzyme; *e*, complete *HpaII* digest of 5-day erythrocyte DNA; *f*, complete digest of 14-day erythrocyte DNA. The DNA was electrophoresed on a 1% agarose gel. Southern blotted[80] and hybridized to an adult-specific β-globin probe, pHb1001. (From ref. 68.)

genes become sensitized to DNase I by HMGs 14 and 17. (3) Specificity for HMG binding seems to be in the recipient NaCl-depleted chromatin; thus, HMGs 14 and 17 from red blood cell chromatin fail to induce DNase I sensitivity to the globin gene when reconstituted with HMG-depleted chromatin from brain. (4) Either HMG 14 or HMG 17 can sensitize most actively transcribed genes to DNase I. (5) Genes transcribed at different rates have about the same affinity for HMGs 14 and 17. (6) HMGs 14 and 17 bind stoichiometrically to actively transcribed nucleosomes. (7) HMGs 14 and 17 can restore DNase I sensitivity to HMG-depleted nucleosome core particles containing 145 base pairs of DNA. And (8) as judged by sensitivity to DNase I, actively transcribed nucleosomes become associated with HMGs 14 and 17 within 3 minutes after these genes are replicated[35].

Taking advantage of the specific binding properties of HMGs described, an active nucleosome affinity column has been prepared, by coupling chicken HMGs 14 and 17 to agarose or glass beads, and used to map the DNA regions surrounding the chicken α-globin genes for their capacity to bind to HMGs 14 and 17[36]. The results indicated a direct correspondence between chromosomal regions which are capable of interacting with HMGs 14 and 17 and the regions which are highly sensitive to DNase I digestion. In contrast, the chromosomal regions of intermediate DNase I sensitivity which are adjacent to the highly sensitive regions did not bind HMGs 14 and 17.

The positioning of HMGs 14 and 17 in active nucleosomes has been investigated in a number of ways, both directly using nucleosomes enriched in active sequences, and indirectly by reconstitution. Electrophoretic studies[27,28,37,38] have indicated that HMGs 14 and 17 bind to a particle containing 150–160 base pairs of DNA, possibly replacing histone H1 and leading to a more open chromatin fibre. In contrast, HMG 14 (17)–H1 cross-linked products have been obtained[39] and it has been shown that total chick erythrocyte nucleosomes containing H1 or H5 are still able to bind HMGs 14 and 17[40]. This complication may be due to the ease with which H1 is displaced from mononucleosomes during preparation[41]. Mapping of DNase I cutting sites and thermal denaturation studies in nucleosome cores compared with HMG–nucleosome core complexes have suggested that the major sites of interaction of HMGs are located near the ends of the nucleosome core DNA[40]. Furthermore, the characterization of subnucleosome particles produced by extensive micrococcal nuclease digestion has suggested that the HMGs are (partly) associated with histone-free DNA[42]. Thus the general concensus is that HMGs 14 and 17 occupy two binding sites at each end of the nucleosome core and cover or interact with internucleosomal DNA.

Much less is known about other non-histone proteins associated with active chromatin. However, increasing attention is being paid to sequence-specific DNA binding proteins which might have as important a role in gene regulation in eukaryotes as they do in prokaryotes. For example, Engelke *et al.*[43] have isolated a protein of molecular weight 37,000, TFIIIA, from a *Xenopus* oocyte homogenate which binds to the intragenic control region of 5S DNA and appears to be required for transcription. Positive regulatory control has also recently been shown by the sequence-specific binding of the glucocorticoid–receptor complex to cloned fragments of murine mammary tumour virus DNA[44]. Conversely, repressor–operator control is shown by polyoma T antigen, which represses the synthesis of its own mRNA and the adenovirus DNA binding protein,

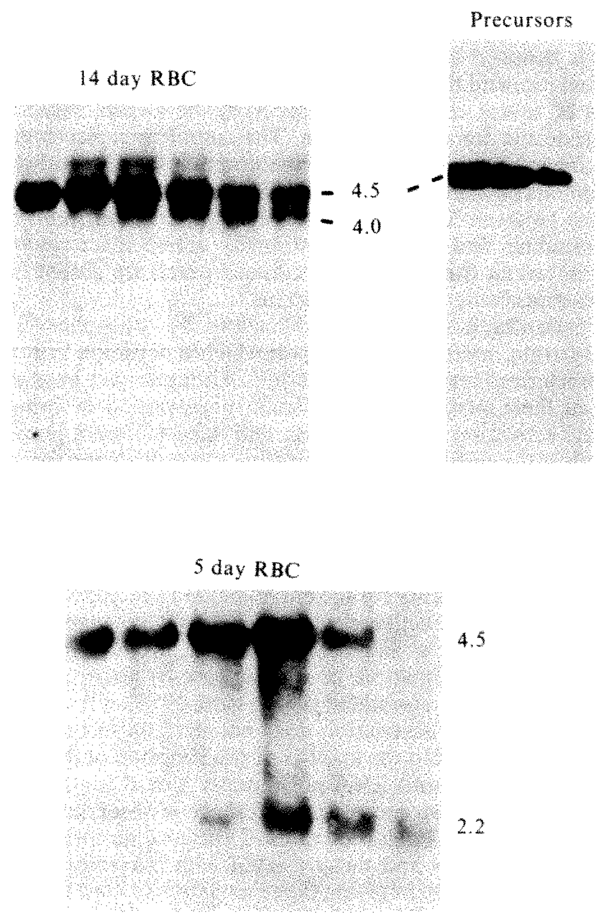

Fig. 3 Absence of DNase I-hypersensitive sites in globin chromatin from precursor cells. Nuclei from primitive erythroblasts (from 5-day embryos) making embryonic haemoglobin, definitive erythroblasts (from 14-day embryos) making adult haemoglobin, and precursor cells (500 embryos) were digested with increasing concentrations of DNase I. The DNA was purified, restricted with *Hin*dIII and blot-hybridized to an embryonic β-globin probe. Without DNase I digestion a 4.5 kilobase fragment is observed. In embryonic cells a discrete new band appears at 2 kilobases, whereas in adult cells the hypersensitive site disappears and a different region of hypersensitivity appears yielding a subfragment of about 4 kilobases. As a control the same precursor blot showed sub-bands after hybridization to a probe for the transcriptionally active actin gene. (From ref. 88.)

which represses the synthesis of adenovirus early region IV mRNA[45,46].

Modification of chromatin proteins

A fundamental manner in which chromatin conformation could be varied is by covalent modification of its histones or the DNA. Primary sequence variants of all five histones have been identified electrophoretically, especially with the use of Triton–acid–urea polyacrylamide gels[47]. Species-specific, tissue-specific and gene-specific subfractions have been described[48]. In most cases the role of histone variants in chromatin structure and function is unclear, but the occurrence of precisely timed staged-specific changes in histone subtypes during development[49,50] suggests that they are important in differentiation.

Direct evidence for the specific exchange of one histone subtype for another has been obtained by analysing male pronuclear histones from polyspermically fertilized sea urchin eggs[51]. Between fertilization and morula the sperm-specific histones of every sperm nucleus are completely replaced by cleavage stage histones. Inhibition of protein synthesis by emitine indicated that the cleavage-stage histones are stored and are of material origins. The replacement of the individual histones does not occur coordinately. The switch in histone H1 occurs almost immediately while the core histones are replaced at specific intervals during the first eight divisions. Since histone H1 is believed to play a role in the higher order structure of chromatin, and the switch occurs before any gross decondensation of sperm chromatin is observed, the switch might be a prerequisite for nuclear fusion. The complete replacement of the inner histones might serve to derepress the relatively transcriptionally inert sperm genome. Further evidence for a correlation between histone subtypes and transcription stems from the finding that the transcriptionally active macronuclei of *Tetrahymena* contains several variants which are absent in the transcriptionally inert micronucleus[52].

Postsynthetic histone modification by phosphorylation, acetylation, methylation and polyADP ribosylation is a well-characterized feature of chromatin[53]. Attempts have been made to link these modifications, particularly acetylation, to transcriptional activation and Yamamoto and Alberts[54] have proposed that histone acetylation–deacetylation can provide the flexibility needed to transduce laterally across an active gene the increased accessibility to RNA polymerase. However, even though there are numerous correlations between an increase in histone acetylation and increased RNA synthesis (ref. 55 for example), and considerable evidence for the enrichment of acetylated histones in transcriptional active chromatin[18,36,56–60], it seems unlikely that acetylation is sufficient either to produce an active chromatin conformation or to increase transcription rate. Studies of *in vitro*-assembled simian virus 40 (SV40) complexes have shown that acetylation does not destabilize or open up the nucleosome, and the kinetics of transcription of these complexes by calf thymus RNA polymerase A or B is not affected by acetylation[59]. Moreover, no difference is observed on comparing the DNase I digestion rates of nucleosome core particles from control cells and those treated with butyrate to inhibit cellular deacetylase implying that acetylation of core histones is not necessary for DNase I sensitivity[61]. So although histone hyperacetylation is a characteristic of active genes, its function, if any, in transcription, is not known.

HMG proteins also undergo postsynthetic modifications[61–65]. Recently, a careful analysis of the phosphorylation of HMGs 14 and 17 at different stages of the cell cycle in synchronized HeLa cells showed there to be a sevenfold increase in ^{32}P incorporation into HMG 14 in G_2 phase compared with G_1, and a twofold increase in incorporation into HMG 17 in early S phase[65]. In contrast, HMGs 1 and 2 were not phosphorylated. Therefore, phosphorylation of HMG 14 may be a prerequisite for the events which follow G_2—that is, chromatin condensation and cytokinesis. Perhaps of greater significance was the finding that the stage-specific phosphorylation of HMG 14 parallels that of histone H1, adding weight to the theory that HMGs 14 and 17 substitute for histone H1 in active regions.

DNA modification

The occurrence of a small fraction of modified bases in DNA has long been known (see ref. 66 for review). Over the past four years an inverse relationship has emerged between the presence of the most commonly modified base in eukaryotic DNA, 5-methylcytosine (m^5C), and gene activation. Bird and Southern[67] have shown that some type-II restriction endonucleases, whose substrate contains the dinucleotide sequence CpG, could be used to probe for m^5C by virtue of their inability to cut if the cytosine is methylated. Using these enzymes, specific sites have been shown to be undermethylated in the chicken β-globin gene in red blood cells (Fig. 2)[68], in the ovalbumin, ovotransferrin, and ovomucoid genes in the chicken oviduct[69], in amplified ribosomal genes in *Xenopus laevis*[67], in the human and rabbit globin genes[70,71], and in various integrated viral genes[72–74]. Furthermore, a direct correspondence between undermethylation, DNase I sensitivity and *in vivo* and *in vitro* transcription by endogenous RNA polymerase II has also been demonstrated[75]. A caveat to all of these correlations, though, has to be made because there are many sites within active genes which remain methylated in all tissues and other sites which remain unmethylated[69].

If undermethylation were sufficient for gene activation, inhibition of methylation should result in the expression of otherwise repressed genes. When a mouse/human hybrid cell line is grown in media containing the cytidine analogue 5-azacytidine, which is incorporated into DNA but cannot be methylated (due to the replacement of carbon 5 with nitrogen in the pyridine ring) the inactive X chromosome is reactivated[76]. Similarly, 5-azacytidine has been used to activate the metallothionein-1 gene in mouse lymphoid cells[77] and the endogenous retrovirus ev-1 in chicken lymphocytes[74]. In both cases activation has been shown to be coincident with demethylation of specific *Hpa*II sites in the coding regions of the respective gene. In the case of the retrovirus, the induction was also correlated to the acquisition of DNase I hypersensitive sites (see below) in both the 3′ and 5′ long terminal repeats. In contrast, the globin genes in the chicken lymphocytes are not

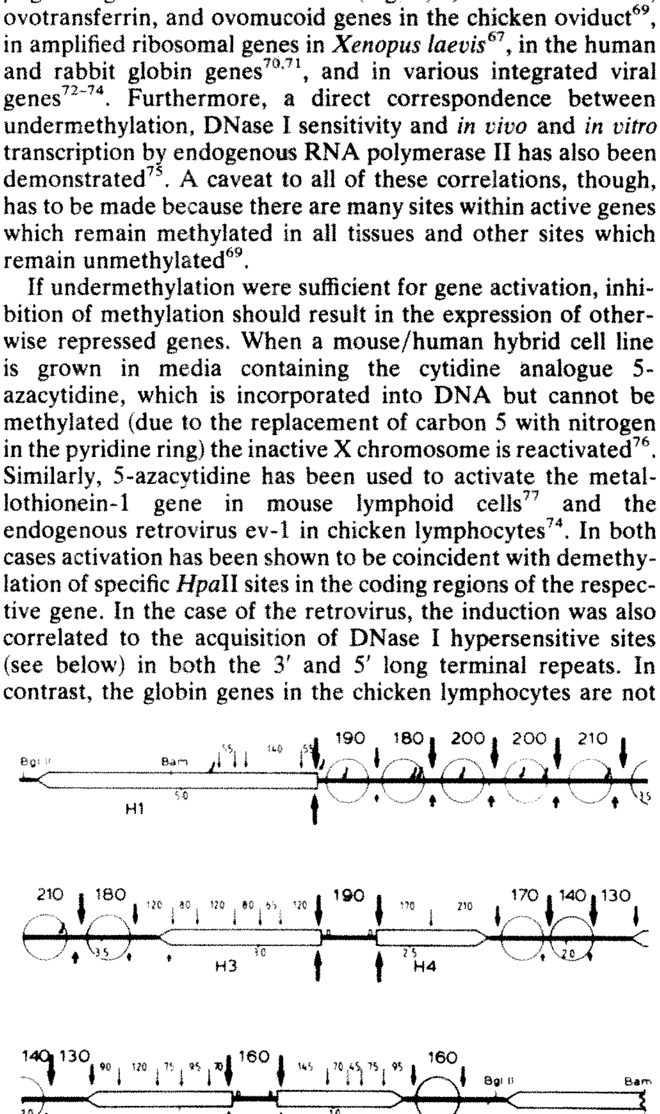

Fig. 4 Fine structure map of histone gene chromatin. Map of the 5.0 kilobase histone gene repeat, showing the transcribed regions as well as the direction of transcription for the five genes (large open rectangles with arrowheads). Numbers below the line, distance in kilobases from the *Bam*HI site on the extreme right. Small vertical rectangles above the line, TATA boxes. Arrows below the line, DNase I sites. Arrows above the line, micrococcal nuclease sites on the histone chromatin; the size of the arrows reflects the relative intensities of the corresponding bands on the autoradiograms. Curved arrows, micrococcal cleavage sites. Circles, static 146 base pair nucleosomes on the nontranscribed spacers. For clarity, 250 base pairs at the extreme left and right of the centre line are repeated on the upper and lower lines, respectively. (From ref. 84.)

activated by 5-azacytidine. Perhaps, then, the azacytidine-responsive genes are already distinct in some way from bulk chromatin. Supporting this is a finding that the inactive β-globin gene is about threefold less accessible to DNase I in *Xenopus* hepatocytes[78] than the inactive albumin gene is in erythrocytes or the vitellogenin gene is in either tissue. Therefore it seems that if demethylation is necessary for gene activation, it is not sufficient.

DNA of the transcriptionally active macronucleus of *Tetrahymena thermophila* is methylated at the N^6 position of adenine residues yielding N^6-methyladenine (m^6A)[79]. Approximately 1 in every 125 adenine residues is modified and there is no detectable m^5C. In contrast, the transcriptionally inert micronuclei contain m^5C and are devoid of m^6A. The m^6A-containing sequences are preferentially digested by both micrococcal nuclease and DNase I. Perhaps the function of these two types of modifications can be found in the differences in base pairing stability of the methylated and unmethylated pairs. The pair methyladenine·thymidine, characteristic of transcriptionally active regions, is more easily denatured than the non-methylated pair, while methylcytosine·guanine, characteristic of inactive regions, is more stable than the corresponding methylated pair.

Higher order chromatin structure

In addition to the high degree of DNase I sensitivity characteristic of active chromatin, there are also small regions of nuclease hypersensitivity, less than 200 base pairs, usually but not always 5′ to the coding region. The double-stranded cuts can be mapped by mildly digesting chromatin with either DNase I or micrococcal nuclease, purifying the DNA, redigesting with a restriction endonuclease and probing, by Southern blotting[80] with a short ^{32}P-labelled DNA fragment which abuts the restriction cut. DNA fragments smaller than the expected mapped restriction bands appear, the length of which defines the distance between the restriction site and the DNase I cut. Using this indirect end-labelling technique, Wu has demonstrated the presence of hypersensitive sites 5′ to the 70,000 and 83,000 molecular weight heat shock genes (*hsp* 70 and 83) in *Drosophila* embryos and tissue culture cells[81]. Since these sites do not exist on naked DNA, they must be a function of chromatin structure. After heat shock, the whole of the active hsp 70 coding sequence becomes sensitive to DNase I but to a magnitude less than the 5′ sensitivity, which is still partially retained. DNase I hypersensitive sites have also been demonstrated for the four small heat-shock genes[82], in the chick ovalbumin, conalbumin, globin and endogenous retroviral genes[22–24,74,75], in the rat preproinsulin gene[83], in the *Drosophila* histone gene repeat[84], and in the SV40 minichromosome[85–87]. In *Drosophila*, a pattern of micrococcal hypersensitive sites resembling that of DNase I was also observed. With both enzymes preferential cuts within the gene itself are seldom seen.

In an extensive set of experiments, the occurrence of DNase I hypersensitive sites has been correlated to β-globin gene activation in early chick development[88]. A comparison was made between a highly enriched red blood cell precursor population isolated from 20–23-hour chicken blastoderms deficient in globin transcription, embryonic red blood cells from 5-day old chicken embryos which express the embryonic β-globin gene and adult red blood cells from 14-day-old chicken embryos which express the adult β-globin gene. Hybridization of an embryonic β-globin probe to a *Hin*dIII digest of DNase-treated nuclear DNA is shown in Fig. 4. No hypersensitive sites were observed in the red blood cell precursors, whereas the embryonic and adult cells both had hypersensitive sites but different ones. It should be noted that the change in chromatin structure from embryonic to adult red blood cells does not occur directly; rather, the stem cell chooses one of two directions. In these experiments transcriptional activity was further correlated to undermethylation. Since the two globin genes exhibit the intermediate level of DNase I sensitivity in both cell types, it is attempting to conclude that the presence or absence of a hypersensitive site dictates which gene is transcribed. Other evidence suggests that this is not always true. The α and β major globin genes in murine erythroleukaemia cells show a high level of DNase I sensitivity and are transcribed at a low but detectable basal level. However, upon induction of globin synthesis with hexamethylene bisacetamide a new 5′ DBase I hypersensitive site is generated[89]. A possible problem with this result, however, is that the globin transcription detected before induction might only be occurring in a small subpopulation of cells.

Recent results have strongly suggested that the nuclease hypersensitivity of certain regions of chromatin is due to localized single-stranded regions of DNA in a nucleosome-free environment. Tissue-specific cleavages roughly corresponding to the known DNase I hypersensitive sites 5′ to the chick globin genes have been observed using the single-strand specific nuclease S_1 (ref. 90). When DNA regions containing these sites are subcloned into the pBR322 plasmid the cleavage sites are retained if the plasmid is supercoiled but lost if it is linearized. This suggests that the strain of supercoiling induces a change in DNA conformation which is sequence-specific. This supercoiling stress might be mimicking the natural effect of an altered nucleosome conformation or a sequence-specific binding protein in chromatin. Furthermore, it has recently been shown[24] that the 5′ hypersensitive site in the chick adult β-globin gene actually extends over 200 base pairs, 115 base pairs of which can be excised by *Msp*I digestion as protein-free DNA, suggesting the absence of a nucleosome.

DNA footprinting analysis of the interaction between the *lac* operator and repressor has shown that the binding domain of a protein can be 10- to 100-fold more sensitive to DNase I digestion when the protein is bound[91]. Therefore hypersensitive sites may represent regions of specific interaction with DNA sequence recognizing proteins. Consistent with this is the finding that the origin of replication and transcription of SV40 and polyoma which interacts with T antigen and the promoter region of the *Xenopus* 5S RNA genes which interact with TFIIIA[92–95] are preferentially nuclease sensitive. The presence of a specific DNA binding protein probably excludes nucleosome formation. Reconstitution studies[96] using calf thymus histones and *lac* operator DNA have indicated a preferred register of histones with respect to DNA sequence, demonstrating a further limit in the distribution of nucleosomes. Moreover, in the 250 Å chromatin fibre, the nucleosomes are arranged in a zig-zag fashion[97,98], the DNA in one nucleosome adjacent to the histones in the next enabling minor changes in position to be rapidly propagated along the fibre.

These studies have led to the postulate, and subsequent demonstration, that nucleosomes could be located in a unique or a small number of distinct positions relative to DNA sequence. This arrangement, termed phasing, has been the subject of two recent reviews[99,100]. It has led to a disagreement (perhaps semantic) of whether phasing is the result or the cause of the binding of regulatory proteins with respect to DNA sequence. There has also been some concern that phasing was an artefact of the marked specificity of micrococcal nuclease for A+T-rich regions. However, in carefully controlled experiments using both micrococcal nuclease and DNase I, it has been shown, for example, that nucleosomes are precisely positioned on the nontranscribed spacer region in the *Drosophila* histone

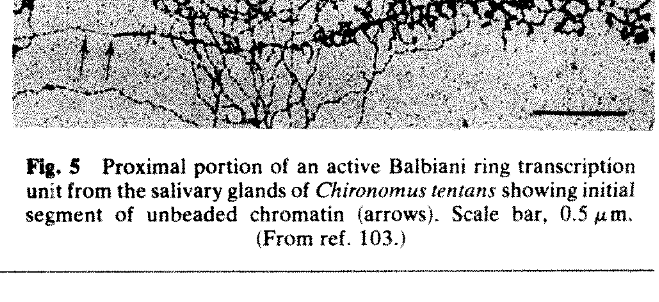

Fig. 5 Proximal portion of an active Balbiani ring transcription unit from the salivary glands of *Chironomus tentans* showing initial segment of unbeaded chromatin (arrows). Scale bar, 0.5 μm. (From ref. 103.)

gene repeat (Fig. 5)[84]. It was also shown that the nucleosome arrangement is established early in development and is retained throughout the remainder of the *Drosophila* life cycle.

Electron microscopic analysis

It is clear from the experiments described above that gene expression in eukaryotes is characterized by many levels of regulation. Most of the DNA in a nucleus, while packaged into nucleosomes, is further folded into an extremely compact and condensed higher order structure opaque to the transcriptional machinery. It might be that the features associated with active genes such as undermethylation, nuclease sensitivity, acetylation, HMGs 14 and 17 act coordinately to affect the degree in which individual genes are available to prokaryotic-type regulatory mechanisms. In the case of lampbrush and polytene chromosomes[101,102], gene activation is directly preceded by the chromatin fibre changing from a tightly packed state to a more open loop-like conformation. Specific active transcription units have been visualized for the Balbiani rings on chromosome IV in the salivary glands of *Chironomus tentans*[103] and on the ribosomal RNA genes in *Oncopeltus fusciatus* embryos[104] by an electron microscopy technique developed by Miller and Bakken[105].

Inactive chromatin exhibits a uniform beaded appearance in the electron microscope, while active transcription units are visualized as a gradient of ribonuclear protein fibres anchored to the base of the chromatin fibre by RNA polymerase molecules to yield the archetypical 'Christmas tree', the apex of which is coincident with the initiation of transcription. The Balbiani rings 1 and 2 transcription units generate 75S mRNAs coding for the salivary polypeptides. Careful measurement of the length of the transcribing chromatin has shown a marked extension of the fibre, the packing ratio going from 1.9 to 1.6 (defined as the length of B-structure DNA per unit length of chromatin)[103]. Nucleosome-size beads were observed in the active transcription units but with a frequency decreased to 4 per μm from the 28 per μm found in inactive chromatin. Furthermore, there appeared to be a smooth nonbeaded segment, 0.18 μm or about 500 base pairs in length directly preceding the RNP fibre gradient (Fig. 5). This could correspond to a 5' DNase hypersensitive region (see above), though it could also be an artefact of unusual tension during the spreading procedures.

Structural changes in ribosomal DNA transcription units, which can be identified morphologically, have been studied during early development in *Oncopeltus*[104]. At 32 hours after fertilization (late blastula) only beaded chromatin is seen, but 6 hours later, before ribosomal RNA synthesis is detected biochemically, nonbeaded stretches of ribosomal chromatin appear—many of them lacking transcripts. Again, there is a decrease in packing ratio in this case from 2.3 to 1.2. Importantly, the rDNA still exhibits a 200-base-pair repeat, though as transcriptional activity increases so does the accessibility to nucleases[106]. This result eliminates the possibility that the presence of numerous RNA polymerase molecules are responsible for the change in chromosome structure and indicates that the major change actually precedes transcriptional activation. This could occur by decondensation of a domain of the chromosome, and may possibly be equivalent to the preactivation state described by Weintraub and his colleagues[107].

Gene activation

Irrespective of the many characteristics of active genes described here, transcriptional activation still relies on the initial decondensation of a domain of the chromosome containing the gene to be transcribed. Recently, two possibly inter-related phenomena have been described which may be involved in this event. The yeast *Saccharomyces cerevisiae* can exhibit **a** or α mating type depending on the position in the chromosome where the mating type genes are located. There are three possible loci or cassettes which the genes could occupy: MAT, which is transcriptionally active, and HML and HMR, which are repressed through the action of several unlinked genes equivalently termed MAR or SIR[108]. When the cassettes are introduced into yeast on episomal plasmids by transformation they still exhibit normal regulatory control. Nasmyth and Abraham[109] have shown that the number of negative superhelical twists in a plasmid containing the HML locus is decreased when the plasmid is activated by being placed in a strain of yeast that is deficient in the MAR/SIR genes (Fig. 6). This raises the possibility that the MAR/SIR genes could function as type II topoisomerase molecules. Extrapolating back to the chromosome, decondensation could occur by the uncoiling of a 'lampbrush type' loop initiated by blocking of a sequence-or repertoire-specific topoisomerase.

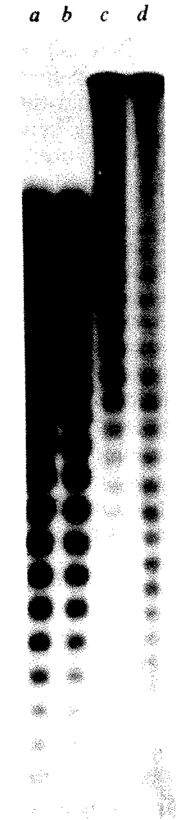

Fig. 6 Supercoiling difference in an active versus inactive yeast mating-type gene. A hybrid-yeast plasmid containing PBR, the centromeric region of chromosome 3, a selectable marker, TrP1, and either HMLα or MATa was transformed into a MAR$^+$ or a MAR$^-$ strain. The total DNA was purified and electrophoresed on a 0.7% agarose gel containing 2.5 μg ml^{-1} chloroquine. The gel was Southern blotted[9] and hybridized to pBR322. *a*, MATa in MAR$^-$ (K228 from A. Klar). *b*, MATa in MAR$^+$ (17-16 from A. Hopper). *c*, HMLα in K228. *d*, HMLα in 17-16. When the HMLα gene is repressed in 17-16 it is more negatively supercoiled than when it is active in K228. The MAT gene functions independently of MAR. (From ref. 109.)

Alternatively, decondensation/condensation may be associated with the formation of left-handed or Z-form DNA as occurs in the interband regions of *Drosophila* polytene chromosomes[110]. In physiological salt solutions Z-DNA is not stable and readily converts to the B conformation. It can be stabilized, however, by supercoiling, binding of specific basic proteins such as spermine and spermidine, or by the presence of 5-methylcytosine[111]. Rich and his colleagues[110] have proposed that selective demethylation of Z-DNA, thereby destabilizing it, would result in torsional stress. This stress can be overcome by positive supercoiling, which will result in an unwinding of the double helix at a position removed from the initial event, and yield a nuclease hypersensitive single-stranded region.

The primary events contributing to changes in higher order chromatin domains responsible for gene activation are just beginning to be investigated. Once known, secondary components directly involved in the act of transcription *per se*, such as the role of histone modification, HMGs and promoter/repressor control might be better understood. Only then may it become possible to answer some of the more fundamental questions of gene control and differentiation.

I thank Dr Ronald Laskey for suggesting that I write this review, Drs J. Hicks, K. Nasmyth, L. Silver, J. Strathern and H. Weintraub for critical comments on the manuscript, Drs B. Daneholt, J. McGhee, K. Nasmyth, H. Weintraub and A. Worcel for allowing me to reproduce figures, and M. Dermody-Weisbrod and M. Goodwin for assistance in preparing the manuscript.

ARTICLES

The range and unity of planetary circulations

Gareth P. Williams & J. Leith Holloway Jr

Geophysical Fluid Dynamics Laboratory/NOAA, Princeton University, Princeton, New Jersey 08540, USA

Altering the rotation rate, obliquity and diurnal period of an Earth-like model atmosphere produces a wide range of circulation forms, some of which resemble those observed on Venus, Mars, Jupiter, Saturn and (perhaps) on Uranus and Neptune. These unified solutions suggest: that Jupiter and Saturn resemble a larger, faster-spinning Earth and possess a stress-bearing or momentum-exchanging sublayer; that easterly winds prevail in Uranus' summer hemisphere; and that Venus resembles a slowly rotating Earth if diurnal heating variations are included.

FROM Venus to Neptune, the motions of the planetary winds are being explored and subjected to theoretical analysis and prediction. On Earth, Mars and Jupiter the winds appear to exhibit similar arrangements and to obey similar laws[1–3]. These affinities stem mainly from the constraints placed on large-scale motion by planetary rotation[4,5]. To learn more about the influence of rotation on the structure of the planetary winds and to determine the range of circulation forms, we evaluate in this article the response of a representative (Earth-like) model atmosphere to changes in rotation rate, obliquity and diurnal period.

Our numerical experiments show that an Earth-like atmosphere, when placed in the rotational configuration of another planet, displays that planet's form of motion: Jupiter, Uranus

0028-0836/82/210295—05$01.00

and Venus appear to behave like rapidly rotating, oblique and slowly rotating Earths, respectively—despite thermodynamical and other differences. This suggests that the basic meteorology of the Solar System is relatively simple, unified and Earth-like, even though more complex meteorologies are needed for understanding the finer details of individual planetary circulations. The solutions thus provide an elementary indication of the dynamical laws and processes acting in the various planetary atmospheres.

Modelling

Our standard climate simulation model (GCM) integrates the equations of atmospheric motion, thermodynamics and conservation of mass and moisture in space and time, using spectral

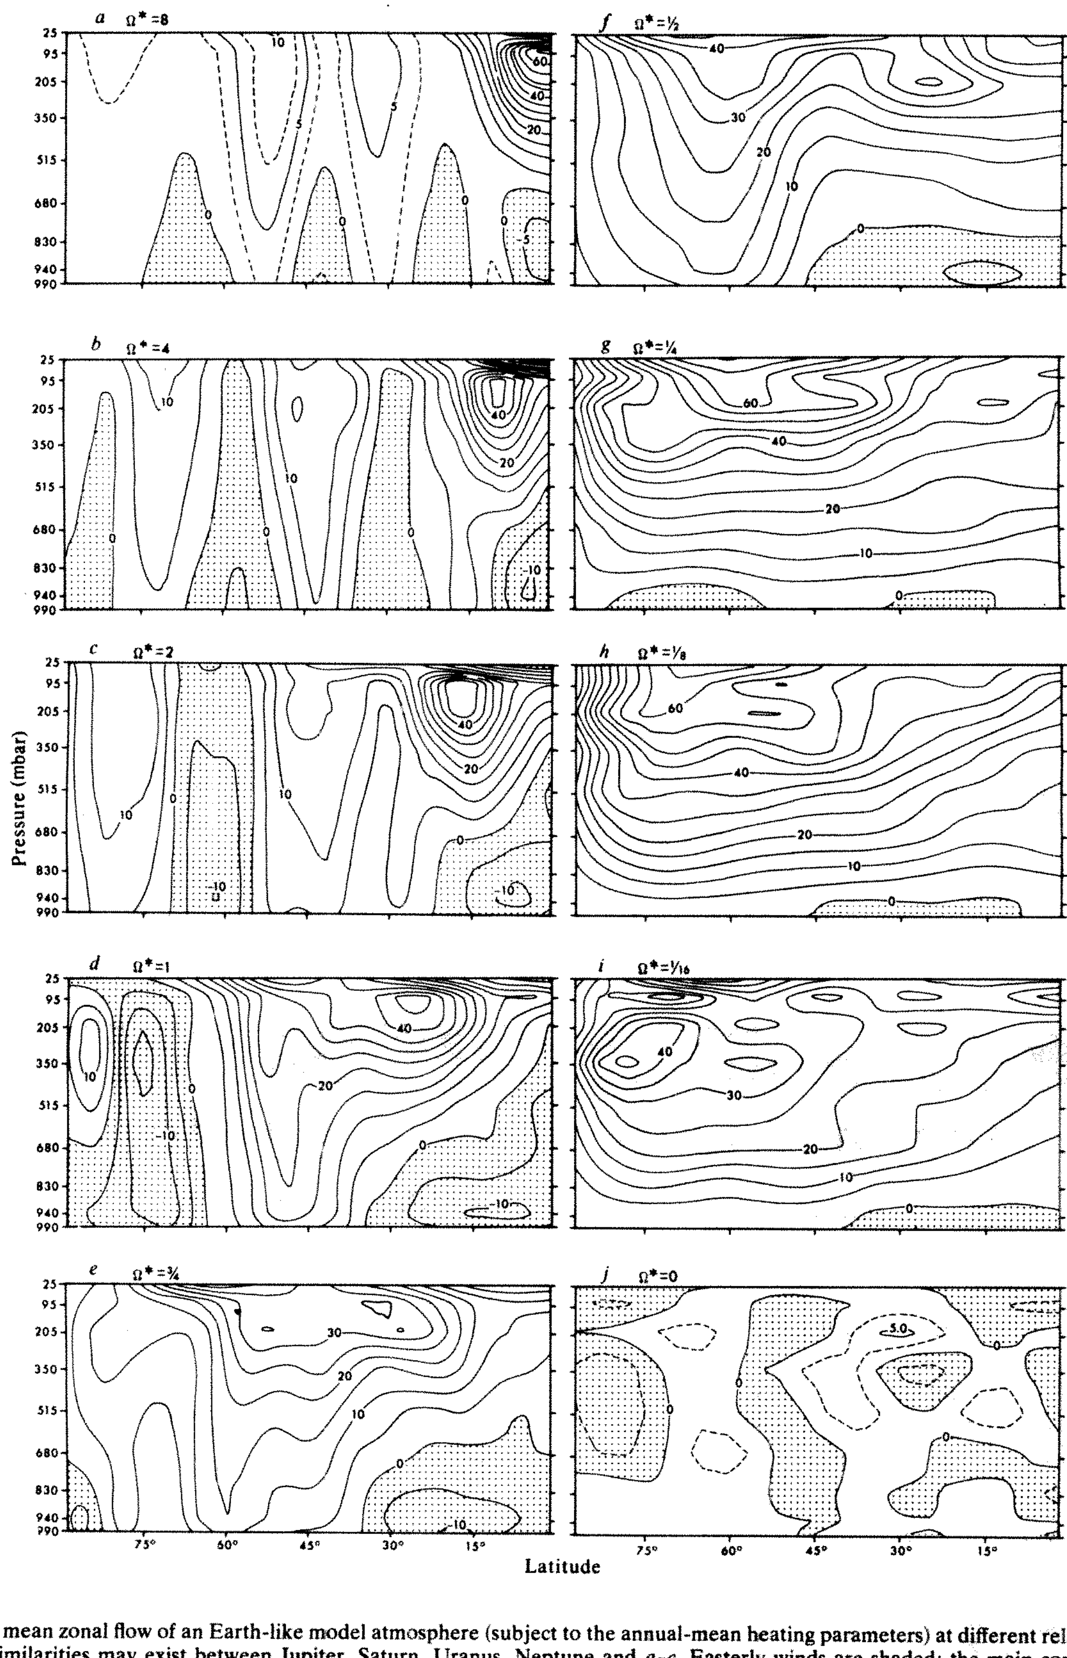

Fig. 1 The mean zonal flow of an Earth-like model atmosphere (subject to the annual-mean heating parameters) at different relative rotation rates, Ω^*. Similarities may exist between Jupiter, Saturn, Uranus, Neptune and *a–c*. Easterly winds are shaded; the main contour interval is 5 m s^{-1} and the supplementary one, 2.5 m s^{-1}. Pressure is used as the vertical coordinate. Calculations use a hemispheric sector, 120° in longitude, and horizontal rhomboidal spectral resolutions of 42 waves for the experiments in *a–e* and 15 waves for those in *f–j*.

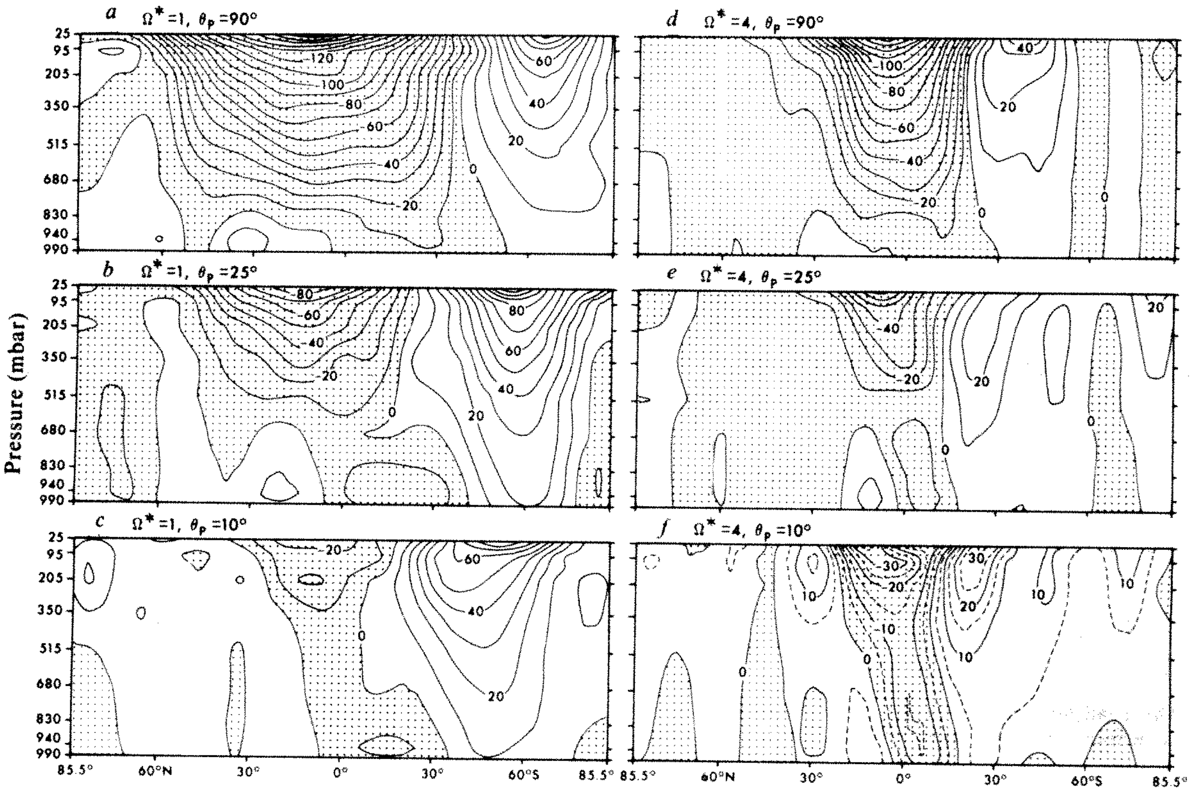

Fig. 2 The mean zonal flow of an Earth-like model atmosphere at different obliquities (θ_p) and relative rotation rates (Ω^*). Similarities may exist between Earth, Mars and *b*, between Uranus and *d*, between Saturn, Neptune and *e*. The solar constant is reduced to 3/4 or 1/2 its normal value when $\theta_p = 25°$ or 90°. The Sun is permanently at the northern hemispheric solstice (left side). Easterlies are shaded; the main contour interval is 10 m s^{-1} and the supplementary one, 5 m s^{-1}. Calculations use a global crescent, 120° in longitude, with a resolution of 15 waves (the solutions are preliminary and of reduced accuracy for the $\Omega^* = 4$ cases).

transform techniques in the horizontal and finite differencing in the vertical. For the radiative heating and cooling calculations, the normal annual-mean distribution of albedo, ozone, carbon dioxide and cloud cover are described as functions of latitude and height, while the variation of water vapour is predicted. The solar declination has its annual-mean values except when we examine obliquity and diurnal effects. For generality, the GCM has a simplified flat, uniformly moist (swamp) surface of zero heat capacity and excludes all ice-related processes. Moist convective adjustment represents small-scale convection and helps maintain vertical (hydrostatic) stability. A quadratic drag law determines the momentum and heat exchanges at the surface. (Full particulars of this GCM may be found in refs 6–9.) Solutions are discussed in terms of the relative rotation rate $\Omega^* = \Omega/\Omega_E$; where $\Omega_E = 7.292 \times 10^{-5} s^{-1}$ is the present terrestrial value. θ_p denotes planetary obliquity.

Dependence on rotation rate at equinox

Varying the rotation rate over a wide range of values ($\Omega^* = 0$–8) produces jets of diverse form and scale in the model atmospheres (Fig. 1). The jets are circumglobal and permanent in form, except at very low rotation rates ($\Omega^* < 1/64$).

The double maximum of the idealized terrestrial zonal flow stems from the overlapping of the tropical and extratropical jets at $\Omega^* = 1$ (Fig. 1*d*). These two basic jet forms are more independent and more obvious at higher rotation rates, because the baroclinic eddies are then smaller and more localized. Increased rotation rates also make the tropical jets narrower and the extratropical jets more numerous and more zonally aligned. At $\Omega^* = 8$, the tropical jet is centred on the equator (Fig. 1*a*).

In general, the mean meridional circulations consist of a direct (Hadley) cell equatorward of the tropical jet core, a weaker indirect cell in the poleward part of that jet, and assorted weaker cells in the extratropical jets. But at lower rotation rates ($\Omega^* \leq 1/4$) the baroclinic eddies cease to exist and a Hadley cell occupies the whole hemisphere (Fig. 1*g*–*j*). (The 'tropics' is defined as being that region influenced by the Hadley circulation. It extends from the equator to 15° N when $\Omega^* = 8$ and to 90° N when $\Omega^* \leq 1/4$.)

The equator-to-pole surface temperature difference generally increases with the rotation rate, from a minimum at $\Omega^* = 0$ to a maximum value (determined by the radiative equilibrium balance) approached at $\Omega^* = 8$, Table 1. A secondary minimum occurs at $\Omega^* = 3/4$ when baroclinic eddies peak in efficiency.

Dependence on obliquity at solstice

During solstice, a planet with a 10° obliquity and terrestrial rotation rate exhibits little latitudinal temperature variation, or motion, in its summer hemisphere (Fig. 2*c*). However, when the obliquity exceeds 20° the summer pole receives the greatest solar heating, resulting in strong pole-to-pole temperature gradients and extensive easterlies (with speeds up to 180 m s^{-1}) and eddies in the summer hemisphere (Fig. 2*a*, *b*). At $\theta_p = 90°$, a strong temperature inversion in the winter hemisphere excludes eddies from that region. Higher rotation rates reduce the width and amplitude of all currents and also reduce the tendency of temperature maxima to move to higher latitudes as obliquity increases (Fig. 2*d*–*f*). Consequently, the summer easterlies intrude less across the equator and the flow in the

Table 1 Surface temperatures (K) at the equator and pole of the model atmosphere as a function of relative rotation rate

Ω^*	0	1/8	3/4	1	2	4	8
T_s Equator	292	300	300	305	305	305	310
T_s Pole	280	255	275	270	265	235	230

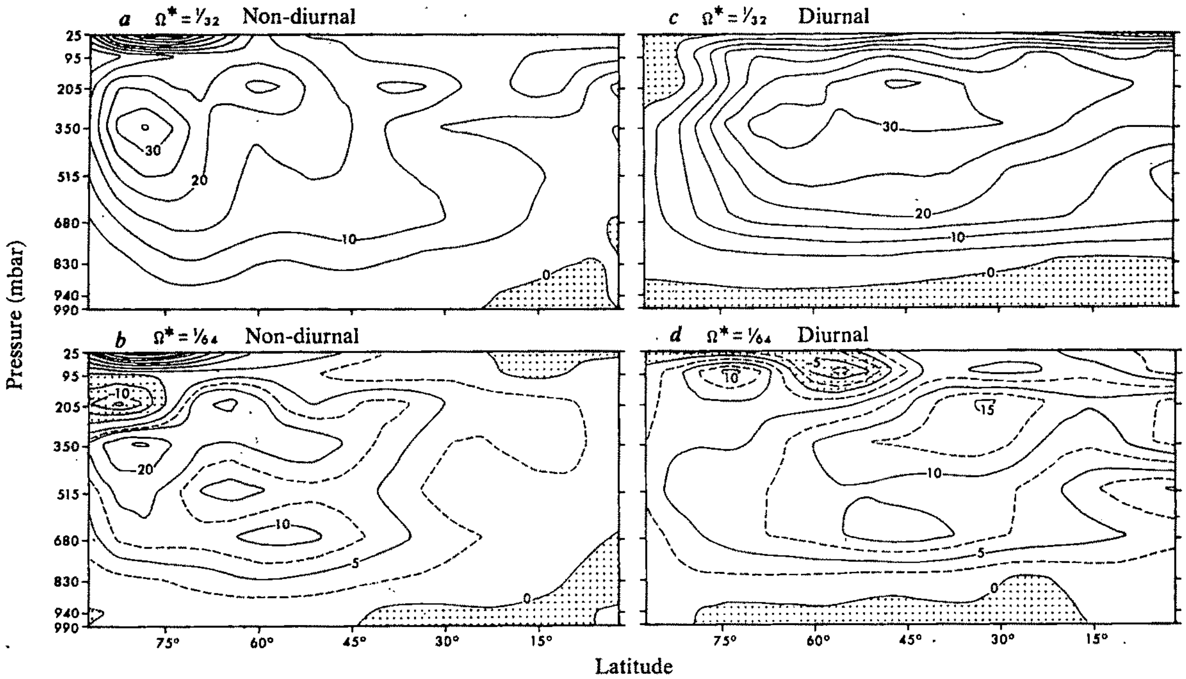

Fig. 3 The mean zonal wind of an Earth-like model atmosphere at two very low rotation rates, with and without diurnal variations in the solar heating. Similarities may exist with Venus. The main contour interval is 5 m s^{-1} and the supplementary one, 2.5 m s^{-1}. Calculations use a full hemisphere and a resolution of 15 waves.

winter hemisphere retains its equinoctal characteristics: a pre-eminent tropical jet and multiple extratropical jets. Interhemispheric heat transport, by the baroclinic eddies and the mean meridional circulation, balances radiative cooling in the unheated winter hemisphere (Table 2).

Dependence on diurnal period

The diurnal variation in the solar heating plays a fundamental role in shaping the circulation of an Earth-like planet only at low rotation rates ($\Omega^* \leq 1/16$).

As the rotation decreases towards these low rates in the nondiurnal system, the axis of the simple tropical (Hadley) jet that now constitutes the entire zonal flow moves poleward until a limit is reached at 80° latitude (Fig. 1*i*). At very low rates ($\Omega^* = 1/32$, $1/64$), geostrophy declines and the zonal flow weakens and becomes more complex (Fig. 3*a*, *b*).

Introducing diurnal variability into the very slowly rotating systems changes their narrow polar jets into broad global currents (Fig. 3*c*, *d*). The equatorial and subtropical westerly maxima (15 m s^{-1}) produced by the diurnal processes represent powerful currents for a planet whose surface rotates at <7 m s^{-1} (when $\Omega^* = 1/64$).

When $\Omega^* = 1/32$, the diurnal processes are wave-like and moderate; it may then be valid to regard the broad zonal current as being the result of the equatorward redistribution (by the waves) of momentum inherent in the polar jet of the nondiurnal state[10]. When $\Omega^* = 1/64$, the diurnal processes are so strong, and the nondiurnal jet so weak, that there may be no simple association between the diurnal and nondiurnal zonal flows[11].

Planetary implications

Earth: The hybrid mix of tropical and extratropical jets that occur at $\Omega^* = 1$ gives Earth the most complex of meteorologies. However, the thermal inertia of the oceans and ice caps reduces the strong seasonal variability normally associated with such an oblique planet. Only in the summer stratosphere are the warm polar temperatures and strong easterlies realized. The influence of obliquity may have been greater during Earth's ice-free-periods, when Ω^* and θ_p were perhaps double their present value[5], and the circulations were as depicted in Figs 1*c*, 2*b*.

Mars: Despite great differences in mass and composition, the martian and terrestrial atmospheres have similar forms of circulation. Lacking oceans, however, Mars has greater seasonal variation and, at solstice, the temperature and velocity distributions predicted by a Mars-like GCM[3] resemble those given by our simplified Earth model (Fig. 2*c*).

Venus: Venus' zonal circulation consists of a broad retrograde current that varies almost uniformly with latitude and step-like with height. Velocity maxima occur near the equator and in midlatitudes[12–14]. This form of circulation is also exhibited by our Earth-like model when the rotation is very

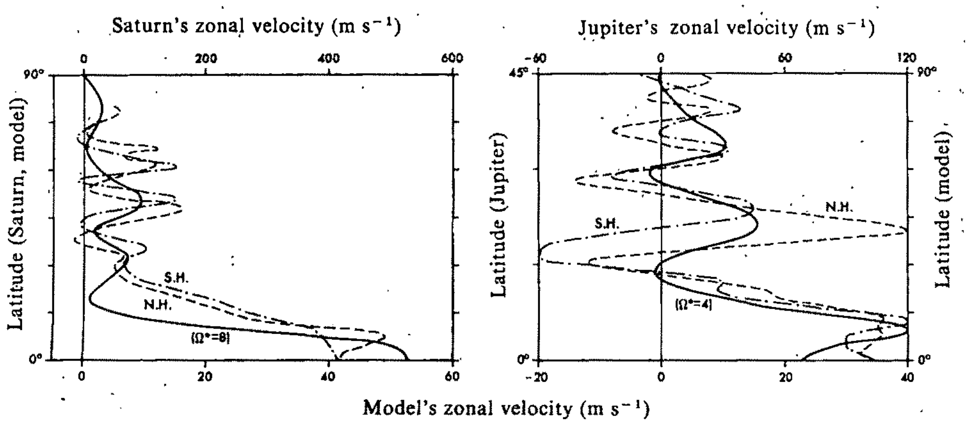

Fig. 4 Latitudinal profiles of the mean zonal velocities of northern and southern hemispheres (NH, SH) and rapidly rotating Earth-like model atmospheres. Adapted from Voyager data[17,18] and from Fig. 1*a*, *b* (at 205 mbar): *a*, Saturn and model at $\Omega^* = 8$; *b*, Jupiter and model at $\Omega^* = 4$. Scales are arbitrary.

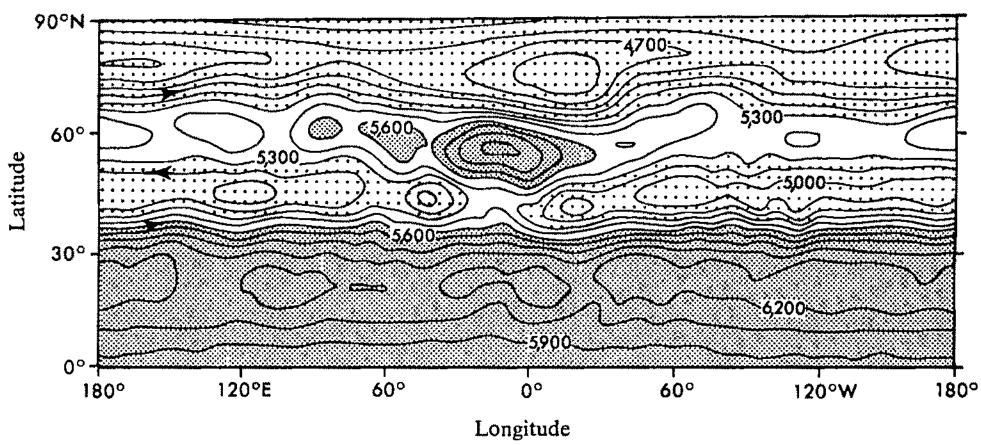

Fig. 5 The singular vortex resembling the Great Red Spot is produced by a topographic surface anomaly in a rapidly rotating ($\Omega^* = 4$) Earth-like model atmosphere. The 1-km high 'mountain' is centred near the latitude (53°) of zero mean flow (in a geostrophic, anticyclonic-shear zone) and at 0° longitude. Contours of the 500-mbar geopotential surface (a streamfunction) are plotted at intervals of 150 m with shading for values below 5,300 m and above 5,600 m.

slow and the diurnal heat cycle is included (Fig. 3*d*). Thus Venus seems to behave meteorologically like a slowly spinning, diurnally heated Earth. The diurnal heating component drives the quasi-horizontal turbulent exchanges that determine the form of the zonal wind[11] while the nondiurnal heating component drives the meridional exchanges that determine the amplitude of the zonal wind[10].

If we confine the solar heating more to the model's stratosphere, by inserting a high level opaque cloud, a more complex meridional circulation (multiple pole-to-equator cells) occurs but the zonal circulation remains basically unaltered. This suggests that the high level of heat deposition on Venus plays no fundamental role in determining the form of the zonal wind but is vital to the form of the meridional circulation. Stronger winds occur for Venus than for the model mainly because of the greater depth and density of its atmosphere[15].

Table 2 Surface temperatures (K) at summer and winter poles of the model atmosphere as a function of obliquity and relative rotation rate

Ω^*	1	1	1	4	4	4
θ_p	10°	25°	90°	10°	25°	90°
T_s Summer pole	300	310	310	280	320	310
T_s Winter pole	220	180	150	210	180	110

Reduced solar constants (Fig. 2) prevent the temperatures from exceeding 325 K at the summer pole.

Jupiter: Both Jupiter and the Earth-like GCM (when $\Omega^* = 4$) have circulations consisting of a pre-eminent tropical jet and multiple, highly zonal extratropical jets and assorted eddy fields (Fig 4*b*). If Jupiter does indeed resemble a larger, faster spinning Earth in its meteorology[2], then we predict that easterly trade winds occur in the lower tropical atmosphere and that Hadley and ageostrophic meridional circulations support the cloud band constituents.

Tropical jets cannot exist if the surface momentum exchange (drag) is excluded, so Jupiter must have a stress-bearing or momentum exchanging sublayer of some sort to be Earth-like in its tropical meteorology. The sublayer needed for tropical jet formation may not be uniform. Solitary topographic bumps (representing magnetic loops, rafts, icebergs, mountains or whatever)[16] inserted into the anticyclonic shear zones of the analogue circulations produce a long-lived anticyclonic vortex, together with a stagnant wake, a current reversal and secondary vortices (Fig. 5). This flow arrangement resembles that of the Great Red Spot (GRS). Topographic vortices of GRS scale are highly stable because they obey the planetary geostrophic (Burger) equations which, in contrast to the more familiar quasi-geostrophic equations, do not admit dispersive linear-wave solutions (Williams, G. P. and Pacanowski, R., in preparation). Thus, in this Earth-like meteorological view, the existence of the tropical jet and the genesis and permanence of the GRS all point (consistently) towards the presence of some sort of (irregular) sublayer on Jupiter. Such a possibility seems remote but is not inconceivable.

Saturn, Uranus and Neptune: Similar physical configurations should give all the outer planets similar meteorologies and, at least near equinox, zonal circulations like Jupiter's. Observations of Saturn's equatorial circulation reveal some basic differences from Jupiter that may be due to seasonal or other parametric differences (Fig. 4*a*). A velocity maximum at or near the equator, and a smaller relative amplitude to the extratropical jets, imply that Saturn resembles more an Earth-like atmosphere with $\Omega^* = 8$, than one with $\Omega^* = 4$. The greater strength and extent of Saturn's all-powerful equatorial jet may be due to the wider Hadley cell favoured by a deeper atmosphere.

At solstice, the large obliquity of Saturn and Neptune could lead to easterly winds dominating their summer hemispheres, if the internal heat sources do not reduce the seasonal variations. The extreme obliquity of Uranus and its lack of internal heat sources make the onset of a polar hot spot and powerful easterly winds and eddies inevitable in its summer hemisphere.

Conclusions

The element of unity seen in the above set of solutions suggests that relatively simple principles govern all the known planetary circulations and that these laws can be deduced best by evaluating a comprehensive atmospheric model rather than by trying to reason from individual facts of nature. The extent of planetary unity can be explored relatively simply: by looking for easterly winds deep in Jupiter's tropics or in the summer hemispheres of the other major planets.

We thank S. Manabe for guidance, and B. G. Hunt for stimulating correspondence. The study was initiated while G.P.W. was a visitor at the Department of Applied Mathematics and Theoretical Physics and Darwin College, Cambridge. P. Tunison, W. Ellis, M. Zadworny drafted the figures; B. M. Williams typed the manuscript.

Size and shape in raised mire ecosystems: a geophysical model

H. A. P. Ingram

Department of Biological Sciences, The University, Dundee DD1 4HN, UK

Raised mires are ecosystems in which waterlogged peat accumulates above the level of the surrounding stream system. It has been suggested that waterlogging is maintained by matric forces, but a model involving impeded drainage is in better accord with the structure of the peat and with basic tenets of soil physics. At one site from which enough hydrological and soil physical data are available to conduct a preliminary test, the elliptical shape and proportions of the mire surface profile are in agreement with this model.

RAISED mires or raised bogs[1] which were distinguished from fens by Lesquereux in 1844 [2], were among the earliest types of peatland ecosystem to be recognized, and are known to be one of the world's most widespread types of mire[3,4]. Their development is marked by the accumulation of peat deposits which, in surface profile, resemble inverted clock glasses[5]. The growth of such a deposit is made possible because it remains perennially waterlogged almost to its upper surface: a feature as paradoxical as it is fundamental, seeing that the central parts of the surface may lie at altitudes up to 10 m above the marginal lagg streams into which the deposit drains. I shall consider here how saturation is maintained in the cupola-like peat deposits of raised mires and, having identified impeded drainage as the mechanism, shall then discuss implications for the shapes of these ecosystems.

Capillary hypothesis

Moore and Bellamy[6] suggested that domed peat deposits retain their water by matric forces (capillarity), while Gosselink and Turner[7] believed that 'capillary action' draws water up into raised mires. However, Granlund[8] had earlier shown experimentally that the zone of saturation would not rise beyond about 0.5 m in *Sphagnum* peat from the higher parts of a raised mire south of Stockholm and this roughly agrees with the maximum rise of 0.3–0.4 m found in a similar situation near Leningrad[9].

Application of the capillary model of soil pore structure[10]

$$h_c = \frac{2\gamma \cos \alpha}{\bar{r} \rho_w g} \qquad (1)$$

(where h_c is the height of capillary rise; γ the surface tension of water; α the contact angle, taken to be zero; $\bar{r}$ the mean pore radius, ρ_w the density of water; g the acceleration due to the Earth's gravity) suggests mean pore radii of the order of 30 μm. But to account for a deposit exceeding 5 m in height, the mean pore radius would need to be <3 μm, implying complete alteration (maximal humification[11]) of peat right up to the surface, rather than the more moderate humification generally experienced.

The capillary hypothesis is also unsatisfactory on theoretical grounds. First, it suggests no mechanism for generating a consistent shape, lower at the edges than the centre. Thus it fails to explain the clock-glass profile. Second, it misinterprets the nature of saturation in these deposits. Soil horizons where saturation is maintained by matric forces contain water under tension: they experience negative hydraulic potentials such that, if all water in a raised peat deposit were retained in this way, the water table or surface of zero potential displayed in a dip well would lie at the level of the lagg streams (Fig. 1, A). However, pools frequently occur on raised mire surfaces and, even in their absence, water tables commonly lie within a few tens of centimetres of the surface (Fig. 1, B). Most of the deposit accordingly experiences a positive hydraulic potential. Any saturated region above the water table is merely a shallow capillary fringe.

Soil structure

Pedologically, an intact raised mire where the peat-forming vegetation has not been destroyed by reclamation or peat extraction may conveniently be described as 'diplotelmic'[12]. It comprises two layers of material, namely a core of humified peat known as the 'catotelm' which occupies most of the deposit, overlain by a thin (25–50 cm) 'acrotelm' or 'active layer'[13–15]. Most of the soil's biological activity and exchange of matter and energy are concentrated in the acrotelm[16]. In Holarctic raised mires the top of the acrotelm comprises growing plant material, especially *Sphagnum*, which undergoes alteration by humification below, where it becomes transformed into the partly colloidal material of the catotelm. Because colloidal peat undergoes irreversible alteration on de-watering[17], a condition of the stability and growth of raised mires is that their water tables must stay sufficiently close to the surface to maintain perennial saturation of the entire depth of the catotelm. Thus the thickness of the acrotelm and the maximum depth of the water table (Fig. 1, C and WT) are roughly the same[18], seldom exceeding ~0.5 m.

Hydraulics and hydrology

Because matric forces alone are inadequate, it will be clear from Fig. 1 that the body of water saturating the catotelm is inherently unstable. Without atmospheric precipitation it would in time disperse either by evaporation or else sideways into the lagg streams by seepage through the peat. Water bodies of this kind, maintained 'by impeded drainage', or, more accurately, through a dynamic equilibrium between recharge and seepage, are common both in artificially drained land[19] and in more natural situations[20]. They are conveniently termed 'groundwater mounds'[21]. When developed in a homogeneous, isotropic porous medium through which water flows in accordance with Darcy's law

$$\mathbf{v} = -K \text{ grad } \phi \qquad (2)$$

(where $\mathbf{v}$ = bulk flux density; K = hydraulic conductivity; ϕ =

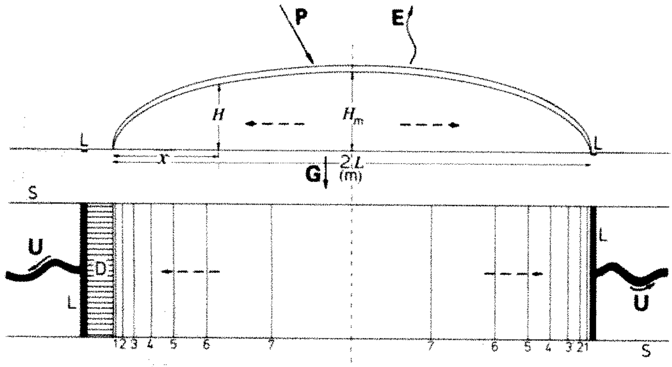

Fig. 2 Groundwater mound in a raised mire, in sectional profile (above) and in plan (below). D, L as in Fig. 1; m, summit and catchment boundary between the two lagg streams; S, parallel sides of confining valley with level floor; 1–7, contours of the water table (equipotentials according to the Dupuit–Forchheimer approximation) spaced at equal intervals of altitude. Thick arrows and bold letters: fluxes of water and flux densities (equation (5)). Thin arrows: dimensions of groundwater mound (equations (3) and (4)).

hydraulic potential), the potential distribution must conform with Laplace's equation which can be used, where the geometry is simple, to predict the relationship between height and width of the groundwater mound for any combination of discharge with hydraulic conductivity[22]. The shape of the mound can also be approximated using Dupuit–Forchheimer theory, which assumes that flow is approximately horizontal, that the equipotentials are vertical surfaces and that grad ϕ is given by the slope of the water table. Thus Childs[23] gave solutions which apply to mounds with equipotentials that are parallel, circular or elliptical in plan. The first case is simplest. Its application to an idealized deposit, shaped like a raised mire and confined in a parallel-sided valley, is shown in Fig. 2. Here the net recharge appears as **U**, the lateral discharge by seepage towards the lagg streams, which are assumed to be at bed level and of negligible depth. The permeability of the deposit is characterized by K and the quotient $\mathbf{U}/K$ is related to the dimensions of the groundwater mound by the expression

$$\frac{\mathbf{U}}{K}=\frac{H^2}{2Lx-x^2} \tag{3}$$

which takes the form of the equation of an ellipse. By setting $x=L$, the maximum height H_m of the mound is given by

$$\frac{\mathbf{U}}{K}=\frac{H_m^2}{L^2} \tag{4}$$

which corresponds to one limit of the exact solution of Laplace's equation.

Table 1 Water balance, Dun Moss, May 1972–April 1973 [26]

Method	Item	Flux density (mm yr^{-1})
Array of standard gauges, diameter 127 mm, exposed at 305 mm above ground level	**P**	530*
High water tables: lysimeter, checked against U.S.W.B. Class A evaporation pan. Low water tables: short term mass balance when **U** = 0 (dry periods)	**E**	317
Short term mass balance when **U** = 0 (dry periods)	**G**	26†
By difference	**U**	187‡
Selection of appropriate period	ΔW	0§

* Compares with $\bar{\mathbf{P}}=951$ mm yr^{-1} for decade May 1970–April 1980.
† Mott's revised estimate.
‡ Equivalent to 5.9×10^{-7} cm s^{-1}.
§ Water levels same at start and finish.

Supposing that the trough of Fig. 2 has a leaky floor, the groundwater discharge **U** becomes one item in a water budget written

$$\mathbf{P}-\mathbf{E}-\mathbf{U}-\mathbf{G}-\Delta W=0 \tag{5}$$

in which all terms are flux densities except ΔW and where **P** = precipitation, **E** = evapotranspiration, **G** = leakage and W = storage. (**G** ≪ **U** for valid application of the Dupuit–Forchheimer approximation).

Groundwater mound hypothesis

These considerations lead to the hypothesis that shape and size in raised mires are controlled by soil physics and hydrology. The hypothesis has the following elements: (1) a diplotelmic soil structure, (2) with perennial saturation of the catotelm, (3) maintained by a groundwater mound, (4) whose dimensions are governed by the water balance, (5) and by the permeability characteristics of the peat, (6) and whose surface, the water table, is confined within a thin acrotelm, (7) so that both acrotelm and ground surface assume an elliptical profile.

It follows from elements (2) and (3) that, with a thin capillary fringe, the catotelm will be coextensive with the groundwater mound when the latter is at its smallest. From elements (4) and (5) it further follows that the critical water balance is that of the driest period through which the mire survives without irreversible desiccation, when the permeability characteristics in question are those of the catotelm alone.

Testing the hypothesis at Dun Moss

To qualify as a test site for the groundwater mound hypothesis a raised mire must meet several criteria. First, human interference with its ecology and hydrology should be minimal. Second, its situation should resemble the model of Fig. 2. Third, its catotelm should have known water transmission characteristics. Finally, relevant hydrometeorological records should be available for several years, including an exceptionally dry period.

Few raised mires are likely to fulfil these stringent requirements completely, but they are met in part by Dun Moss, a small raised mire in east Perthshire (National Grid ref. NO167 558)[24]. The situation of the mire may be inferred from

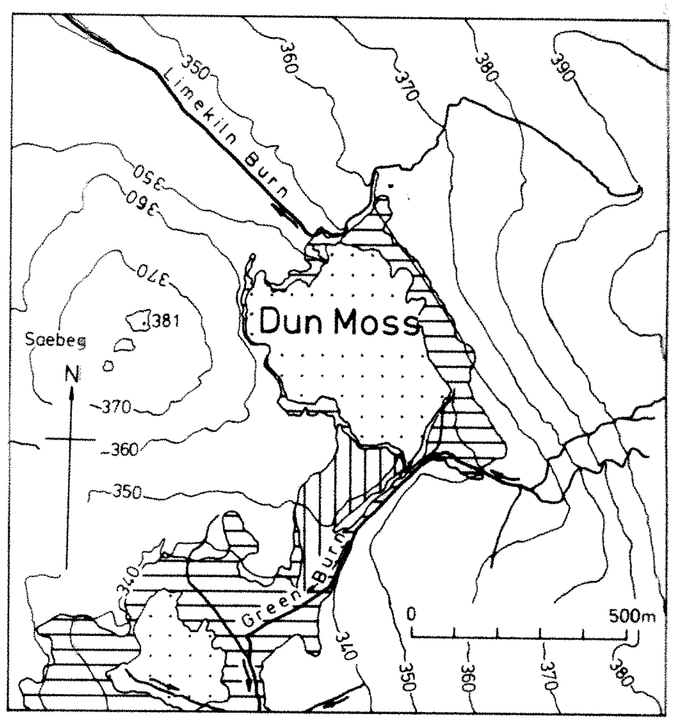

Fig. 3 Physiography and mire types in the vicinity of Dun Moss. ▩, Mire expanse; ▤, marginal lagg fens and so on; ▥, lines, area formerly exploited by peat cutting; arrows, perennial surface streams. Altitudes in m above OD, reproduced from the Ordnance Survey map, Crown copyright reserved.

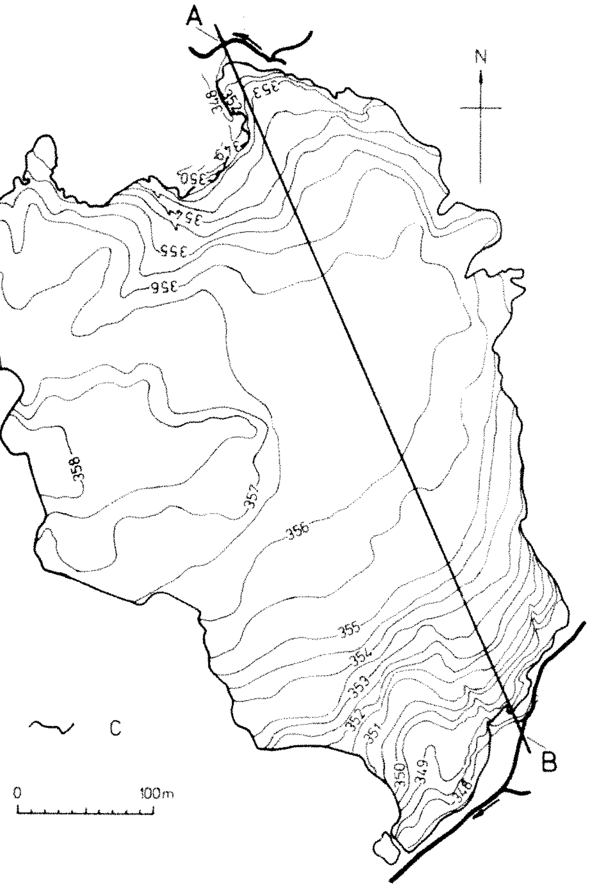

Fig. 4 Physiography of the mire expanse at Dun Moss. AB, line of profile transect connecting the captured headwaters of the Green Burn with the SE–NW reach of the Limekiln Burn. C, boundary of mire expanse. Arrows, lagg streams and so on. Contours in metres, based on a theodolite survey of the hollows on the uneven surface.

Fig. 3. It lies in a north-west trending valley with roughly parallel sides, whose headwaters were deflected south-west across the low ridge south of Saebeg through an overflow channel: a fluvioglacial feature probably eroded in late Weichselian times. Lagg streams now drain northwards to the Limekiln Burn and southwards to the Green Burn, both with beds at 348.0 m altitude where they touch the mire boundary. The surface of the raised peat deposit is a mosaic of *Sphagnum* hummocks with intervening hollows. Its general shape is shown by the contours in Fig. 4. The profile transect AB is drawn along the axis of the valley, which stratigraphical studies[25,26] have shown to continue beneath the peat deposit. On this transect the highest point of the mire surface lies at an altitude of 356.2 m, whence $H_m = 8.2$ m. The contour intersections are plotted in Fig. 5. The distance along AB between the lagg streams is 547 m, but of this 27 m is occupied by surfaces of seepage supporting *Carex rostrata* fern communities, mainly adjacent to the Green Burn. Taking 520 m as the correct value of $2L$ for substitution in equation (4) gives a morphologically based estimate of $\mathbf{U}/K = 9.95 \times 10^{-4}$ which, when substituted in equation (3), generates the thick curve drawn in Fig. 5. Except near the ends, where the Dupuit–Forchheimer approximation is likely to be weakest, and around the 100-m point on AB where the contours indicate flow diverging from the transect, the points lie close to the hypothetical ellipse.

The site has also yielded data for a preliminary estimate of $\mathbf{U}/K$ based on hydrodynamics. There are at present no sophisticated criteria for choosing the time period most appropriate for an estimate of $\mathbf{U}$, but 1 yr is the shortest period during which all the relevant seasonal biological and geophysical processes are represented and which can be selected so that $\Delta W = 0$. Since investigations began at Dun Moss, the driest year experienced has been May 1972 to April 1973, for which a provisional water balance was drawn up by Mott[26] as shown in Table 1. This suggests 5.9×10^{-7} cm s^{-1} as a tentative minimal estimate of $\mathbf{U}$. Extensive field studies of water transmission through the top of the catotelm at Dun Moss were carried out by Rycroft[25,27,28]. The results of numerous tests with seepage tubes[29] suggested that Darcy's law is only an approximate description of flow in humified peat, but that K values determined in the latter parts of long tests ($t \to 10^3$ s) give a reasonable indication of the permeability characteristics. Stratigraphical analysis showed that the raised peat deposit comprised varying amounts of the remains of *Eriophorum vaginatum* and *Calluna vulgaris* in a matrix of *Sphagnum* species (mostly *S. imbricatum* and sect. *Acutifolia*), generally humified to about H4 on von Post's scale. Consistent sets of results were obtained from H4 *Sphagnum* peat with traces of *Eriophorum* at depths of 70–80 cm at sites C510F and C520F: neighbouring positions within 60 m of the centre of the mire expanse. Variable head tests showed $\bar{K} \to 2.1 \times 10^{-4}$ cm s^{-1} while constant head depletion tests showed $\bar{K} \to 7.9 \times 10^{-4}$ cm s^{-1}, suggesting 5.0×10^{-4} cm s^{-1} as a modal value which we may tentatively accept for the catotelm as a whole, there being no seepage tube technique yet available for use at peat depths exceeding about 1.5 m. Taking these tentative values as best available estimates, we obtain

$$\mathbf{U}/K = 1.2 \times 10^{-3}$$

as a hydrodynamically based estimate of the quotient for the driest year experienced. This exceeds the morphologically based estimate by 20% and corresponds with the thin curve in Fig. 5.

Discussion

Ecosystems are entities in which biological, geochemical and geophysical processes interact. Conceptual models of ecosystems may, as with feeding or foraging studies, be fundamentally biological. When concerned with nutrient cycling they are basically geochemical. When dealing with energy capture or water movement their essence may be geophysical. All three elements may be involved in models of phenomena like succession and may contribute to our understanding of whole ecosystems[30]. Peatlands owe their existence to peculiar soil water regimes. It follows that we should look especially to soil physics and hydrology in our early efforts to build conceptual models of mire ecosystems.

In the present instance, precise conformation between the profile of Dun Moss and its hydrodynamics is scarcely to be expected. Among other complications, it is unlikely that our estimate of $\mathbf{U}$ for the driest year for which we happen to have data is actually the lowest discharge experienced. Furthermore the deposit merely resembles the model envisaged in Fig. 2, and its geometry in plan suggests that seepage is neither rectilinear nor parallel to the valley axis throughout the groundwater mound. However, the similarity of the profile to an ellipse whose parameters are in reasonable accord with what is known

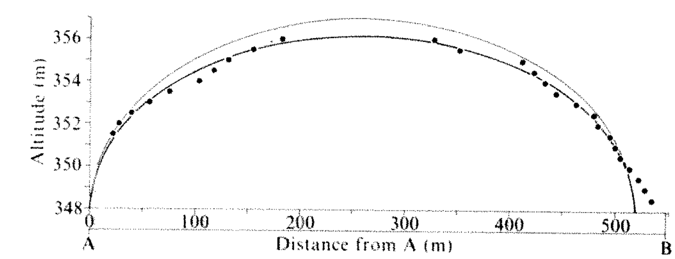

Fig. 5 Profile of mean hollow altitudes on the surface of Dun Moss in the vicinity of transect AB (Fig. 4). Plotted points: contour intersections from Fig. 4. Thick line, Dupuit–Forchheimer ellipse for $\mathbf{U}/K = 9.95 \times 10^{-4}$, the morphometric estimate, denoting the shape predicted on the groundwater mound hypothesis. Thin line, the same for $\mathbf{U}/K = 1.2 \times 10^{-3}$, the hydrodynamic estimate for the driest year in a decade. (Vertical scale exaggerated 20-fold.)

of the hydrodynamics of the catotelm seems to support the groundwater mound hypothesis.

This hypothesis accords with work by Weber[31], whose early systematic studies of raised mire ecosystems led him to conclude that they were sustained by meteoric water and impeded drainage. It also postulates a mechanism for the close control of the shapes of these ecosystems. Given that the permeability of moderately altered *Sphagnum* peat (H3–H6) varies rather little with humification[32], equation (4) predicts that damper climates will support raised mires of more pronounced convexity (higher ratios of $H_m:L$). Such trends have been reported for Southern Sweden[33] and the Federal German Republic[34], while a comparison of the convexity of raised mires in two regions of Finland with similar climates showed little difference[35]. Equation (3) suggests that growth at all points on the surface of a raised mire is likely to proceed at synchronal rates, even under fluctuating climates. This agrees with stratigraphical findings such as those of Aaby[36], and with evidence from pollen analysis of cores from various parts of Dun Moss[26] which suggests that its shape has remained remarkably constant during some 5 millennia of accumulation.

As a conceptual model, the groundwater mound hypothesis has a secure physical foundation and seems consistent with evidence from various sources. To explore it further we need data on the permeability of the deeper catotelm and on groundwater discharge as a water budget item, not only from Dun Moss but also from other raised mires of relatively simple geometry.

I thank P. J. Mott for permission to quote his water balance computation; R. G. Crawford for help in compiling Fig. 4; D. J. A. Williams for discussions; owners and tenants D. W. Rycroft, R. S. Clymo and Olivia M. Bragg for comments and for access to the site. The data from Dun Moss were obtained during work supported by the NERC.

Acumentin, a protein in macrophages which caps the 'pointed' end of actin filaments

Frederick S. Southwick & John H. Hartwig

Hematology–Oncology and Infectious Disease Units, Massachusetts General Hospital, Department of Medicine, Harvard Medical School, Boston, Massachusetts 02114, USA

Macrophages have a calcium-insensitive protein which binds to and inhibits monomer addition at the 'pointed' end of actin filaments labelled with heavy meromyosin. This protein, in concert with calcium-sensitive proteins already shown to bind the 'barbed' end of filaments, can lead to complete control of actin filament length in the cytoplasm. The blocking of actin filament ends in low as well as high calcium concentrations would prevent treadmilling in living cells.

HUXLEY[1] first recognized a polarity in actin filaments, and showed that heavy meromyosin bound to actin filaments, giving the appearance of arrowheads attached to the filaments. The direction of the arrowheads defines a 'pointed' and a 'barbed' end of the filaments, and during the contraction of striated muscle, actin moves in the direction of the pointed end. Subsequently, several investigators demonstrated that the association constant for monomer addition is greater at the barbed end of actin filaments decorated with heavy meromyosin than at the pointed end[2–4]. The barbed and pointed ends of actin filaments labelled with heavy meromyosin have therefore been called the preferred and unpreferred assembly ends, respectively. An observed inequality in dissociation to association rate constant ratio at the opposite ends of filaments at steady state[4] has given weight to the concept called treadmilling[5], which refers to a process in which actin monomers in equilibrium with actin polymers cycle within the filaments from the ends having the lower to the ends having the higher critical concentration. If such treadmilling exists it could cause rearrangement of actin-based structures in the cytoplasm of non-muscle cells[6]. The concept of treadmilling also predicts that anything which prevents an exchange of monomers with the barbed filament end would shorten the filament, and such capping at the pointed end would cause filament elongation.

Another manifestation of actin filament polarity is the binding of different molecules to one end of the filament. Recent work has identified several molecules that bind to the barbed end of actin filaments: these include gelsolin[7–10], a protein found in a wide variety of mammalian cells[11]; villin, a protein very similar to gelsolin and present only in the microvilli of intestinal and

0028-0836/82/210303—05$01.00

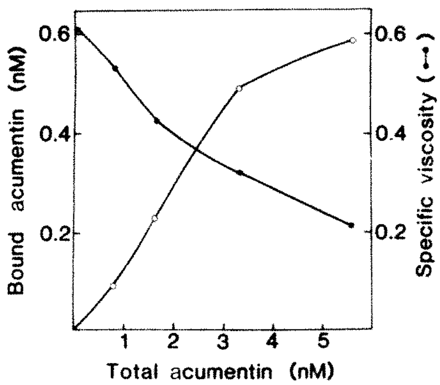

Fig. 1 Binding of acumentin to F-actin and correlation of its binding with changes in the final viscosity of actin. Rabbit skeletal muscle actin[30] 0.65 mg ml^{-1}, in 0.8 mM EGTA, 1.25 mM dithiothreitol, 0.05 mM $MgCl_2$, 0.5 mM ATP and 5 mM imidazole-HCl, *p*H 7.5, was gel-filtered on Sephadex G-150 and polymerized in the presence of increasing concentrations of acumentin by the addition of 3 M KCl to a final concentration of 0.1 M at 25 °C for 2 h. The specific viscosity of actin was determined in Cannon–Manning capillary viscometers and was 0.61 in the absence of acumentin. The outflow time for water in these viscometers was 48–50 s. The binding of acumentin to G-actin was determined by centrifuging 175 μl of the various actin solutions at 30 p.s.i. in a Beckman airfuge for 1 h to pellet all F-actin present. The amounts of acumentin in the pellet and supernatant fractions were determined by densitometry of Coomassie blue-stained polyacrylamide gels after electrophoresis in the presence of SDS. Acumentin alone did not sediment. Macrophage acumentin migrates as a single polypeptide band of molecular weight 65,000 (Tatsumi *et al.*, manuscript in preparation). This molecular weight was used to calculate the molar concentration of bound acumentin (○).

renal brush border epithelial cells[12–14]; a protein of *Acanthamoeba*[15]; and the cytochalasins[4,16,17]. Such molecules, in addition to binding to the barbed end of F-actin, stimulate nucleation of actin assembly and shorten the filaments whether added to actin during or after polymerization. The activities of gelsolin and villin are modulated by calcium. Gelsolin and villin bind to actin much more efficiently in the presence of micromolar calcium concentrations than in lower concentrations. The calcium-dependent shortening of actin filaments by gelsolin and villin provides a mechanism by which changes in calcium levels can regulate the length of actin filaments. However, to maintain total control over the filament length, it would be advantageous to cap both ends of the filaments because otherwise some filament annealing and monomer exchange might occur.

Table 1 Effect of macrophage acumentin and gelsolin on the direction of filament growth from F-actin decorated with heavy meromyosin

Type	—◄◄	◄◄—	-◄◄-	◄◄	—	(*n*)
F-actin alone	2.6 (2)	13 (10)	52 (40)	7.8 (6)	25 (29)	77
F-actin + acumentin	3.0 (2)	38 (26)	4.5 (3)	16 (11)	37 (25)	67
F-actin + gelsolin	20 (15)	1.3 (1)	1.3 (1)	52 (40)	26 (20)	77
F-actin + gelsolin + acumentin	2.0	—	—	84 (88)	24 (25)	102

Actin[30], 1 mg ml^{-1}, in 0.2 mM, $CaCl_2$, 0.5 mM 2-mercaptoethanol, 2 mM Tris-HCl *p*H 7.5, was polymerized in the absence or presence of gelsolin (molar ratio of 1 gelsolin to 50 actins) by the addition of 0.1 M KCl for 1 h at 25 °C and then incubated with or without acumentin (1 mol acumentin to 25 actins) for an additional 30 min at 25 °C. The filaments formed were then incubated with 1 mg ml^{-1} skeletal muscle heavy meromyosin for 10 min at 25 °C. 25 μm ml^{-1} of each was then mixed with 100 μg ml^{-1} of G-actin and the KCl concentration adjusted to 0.1 M and incubated at 25 °C for 5 min. The protein solutions were then placed in microtitre wells, and a strip of mica previously coated with carbon inserted such that the carbon layer floated on the surface of the solution but was not freed from the mica strip. The mica was then removed, allowing the carbon to re-attach, and inserted in a 1% uranyl acetate solution. The carbon was freed from the mica, Formvar–copper grids were dropped on to the carbon, and the grids were removed from the uranyl acetate solution with a strip of parafilm. The dried grids were photographed in a Philips 301 electron microscope and the negatives enlarged to a final magnification of ×60,000. Data are expressed in per cent with the number of filaments observed in parentheses. —◄◄, Growth of actin from the pointed end only, ◄◄—, barbed end only, -◄◄-, both ends, or ◄◄, lack of assembly onto heavy meromyosin-labelled nuclei, and —, filaments that did not have labelled nuclei attached.

β-Actinin, a protein isolated from skeletal muscle, is the only agent thus far suggested to bind the pointed end of actin filaments[18,19]. This protein inhibits the annealing of actin filament fragments. When annealing of a mixture of sonic fragments of actin decorated with heavy meromyosin and undecorated fragments occurred in the presence of β-actinin, Maruyama *et al.* had the impression that, compared with controls, more bare filaments attached to the barbed end of decorated segments than to the pointed end[19]. However, the barbed end of the decorated filament is in any case preferred for assembly, and therefore it is difficult to show an increase in assembly or annealing from that end. The existence of agents that block the barbed end of filaments makes it possible to ascertain blocking of the pointed end with more certainty. Using this approach we have found that a protein purified from human granulocytes[20] and rabbit lung macrophages binds to the pointed end of actin filaments. We propose to name this protein acumentin, from the Latin *acumen* meaning the point.

Acumentin binds and caps the pointed ends of actin filaments

Binding of acumentin to the pointed or unpreferred end of heavy meromyosin-labelled actin filaments was demonstrated indirectly in the electron microscope by observing the assembly of actin nucleated by actin filaments decorated with heavy meromyosin[2,3] in the presence and absence of acumentin. As shown in Table 1, the addition of decorated actin filaments to a solution of monomeric actin resulted in the growth of filaments from both ends of the nuclei, an observation in agreement with previous findings[2,3]. In some filaments growth was limited to only one end of the nuclei, with a bias of 5 to 1 favouring the barbed ends of the actin nuclei, the end known to have the most rapid assembly rate[4]. The addition of acumentin to actin nuclei markedly decreased the instances of actin assembly from the pointed ends of the nuclei. Although the findings are consistent with binding and capping of the pointed end of a filament by acumentin, this could also have been due to a second mechanism. The presence of unbound acumentin in the system could potentiate the formation of actin nuclei. Rapid filament assembly from these acumentin would decrease the actin monomer concentration, a condition that would favour the assembly of actin from the barbed or preferred assembly end of actin filaments decorated with heavy meromyosin. As demonstrated in Table 1, acumentin did increase the number of bare filaments.

Experiments using gelsolin ruled out this alternative. The gelsolin–calcium complex prevents assembly at the barbed end[8] and increases the actin monomer concentration, a condition which favours growth at the pointed end (Table 1). Addition

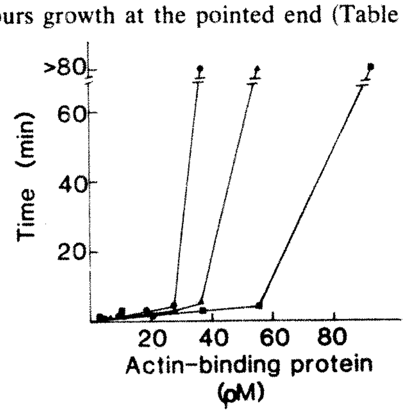

Fig. 2 Effect of increasing concentrations of acumentin on the critical concentration of macrophage actin-binding protein required for incipient gelation of F-actin. Actin, 5 mg ml^{-1}, in buffer A was polymerized by the addition of 3 M KCl to a final concentration of 0.1 M for 1.5 h at 25 °C. The F-actin was then diluted to 1 mg ml^{-1} in the presence or absence of acumentin and increasing concentrations of macrophage actin-binding protein. The solutions were mechanically mixed before being drawn up into capillary tubes. The final concentrations of acumentin were 0 (●), 20 (▲) and 30 (■) μm ml^{-1}, respectively. Gel points were determined as described by Yin *et al.* using a rolling ball viscometer[23].

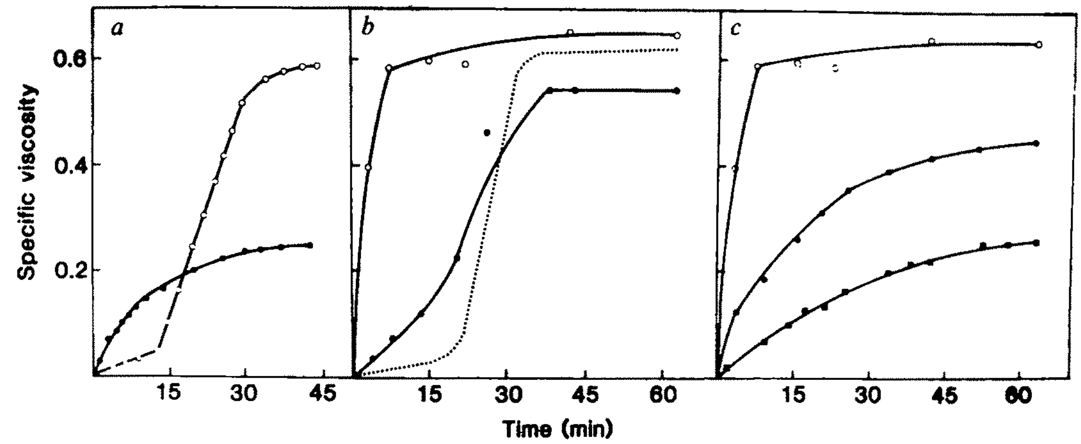

Fig. 3 Effects of acumentin on the kinetics of actin polymerization as determined by viscometry. *a*, Effect of acumentin on the nucleation of actin. Actin, gel-filtered on Sephadex G-150, was polymerized at a concentration of 0.65 mg ml^{-1} in 1.5 mM dithiothreitol, 0.175 mM ATP, 0.1 mM EGTA, 0.02 mM $MgCl_2$ and 5 mM imidazole-HCl, *p*H 7.5, in the presence (●) or absence (○) of 0.122 mg ml^{-1} of acumentin by the addition of 3 M KCl to a final concentration of 30 mM. *b*, Effect of acumentin on actin filament elongation. Gel-filtered actin, 0.5 mg ml^{-1}, in buffer A was polymerized by the addition of 1 M $MgCl_2$ to a final concentration of 1 mM in the presence (●) or absence (○) of 0.55 mg ml^{-1} of acumentin for 1 h at 25 °C. The filaments formed were used to nucleate actin assembly; 33 µl of each was then added to 300 µl of 0.5 mg ml^{-1} of G-actin in buffer A. The solution was immediately made up to 20 mM with 3 M KCl and 0.4 mM with 2 M $MgCl_2$ and its viscosity followed with time at 25 °C. The dotted line shows the polymerization of 0.5 mg ml^{-1} of actin in the absence of added acumentin F-actin nuclei. *c*, Additive effects of acumentin and gelsolin on actin filament elongation. 0.5 mg ml^{-1} of actin in the buffer detailed in Fig. 4*b* legend was polymerized in the presence of 33 µg ml^{-1} of gelsolin by the addition of 2 M $MgCl_2$ to a final concentration of 1 mM. The gelsolin–F-actin complexes were then incubated with or without acumentin, 0.55 mg ml^{-1}, for 1 h. 50 µg ml^{-1} of F-actin alone (○), gelsolin–F-actin (●) or gelsolin–F-actin–acumentin solution (■) were added to 0.5 mg ml^{-1} of G-actin. The solutions were immediately made 20 mM and 0.4 mM in KCl and MgCl (ref. 2) by addition of 3 M KCl and 2 M $MgCl_2$, respectively.

of acumentin to the preparation of labelled nuclei almost completely abolished growth from the labelled filaments, and there was no increase in the number of unlabelled filaments. The data establish that acumentin caps the pointed end. Experiments described below using biophysical techniques are all consistent with the conclusion that acumentin binds to the ends of actin filaments.

Assembly of actin with acumentin shortens the filament length distribution

When actin is polymerized in the presence of acumentin, its final viscosity is decreased relative to that of actin assembled in its absence[20]. Figure 1 shows the correlation between the capacity of acumentin to bind to actin during polymerization with its ability to reduce the final equilibrium viscosity of actin after assembly. The binding of acumentin to actin filaments increased in proportion to the decrease in final viscosity of the actin solution. This effect of acumentin on the viscosity of actin resulted from the formation of shortened actin filaments, because acumentin does not increase the fraction of monomeric actin in equilibrium with actin filaments. Although the ability of acumentin to reduce the final viscosity of actin was independent of calcium concentration (10^{-8}–10^{-4} M), its effects on actin viscosity could be inhibited by KCl concentrations above 0.1 M, complete inhibition occurring at 0.3 M KCl (ref. 20). Binding was determined by co-sedimenting acumentin bound to filaments polymerized in its presence. In this assay, the amount of acumentin bound to actin correlated with the degree of filament shortening, and binding increased in almost direct proportion to the concentration of acumentin added. At any given acumentin concentration only 12.6±2% (mean±s.d.) of the added acumentin was bound. As acumentin was present during actin assembly, each molecule theoretically could have bound monomers to form nuclei, suggesting that low affinity rather than a limited capacity was responsible for this low level of binding. The observed linear increase in binding is consistent with the conclusion that acumentin stimulates actin nucleation (Fig. 3*a*), thereby increasing filament number. Therefore, the amount of acumentin bound will be directly related to the number of filament ends.

The conclusion that filaments were shortened is further supported by the finding that acumentin increased, in a concentration-dependent fashion (Fig. 2), the critical amount of cross-linker required to gel a solution of actin. As the critical gel point is inversely related to filament length[21], acumentin must decrease the average length of actin filaments. The weight-average lengths of actin filaments polymerized in the presence of 20 and 30 µg ml^{-1} of acumentin can be calculated directly from the gel point determinations, using the Flory equation: $V_c = C/X_w$, where V_c is the critical gel point in mol^{-1}, C is the polymer concentration in g l^{-1} and X_w is the weight-average molecular weight of the actin filaments[21]. The calculated length of actin filaments polymerized in the absence of acumentin was 2.44 µm, and 1.78 and 1.2 µm in the presence of 20 and 30 µg ml^{-1} of acumentin, respectively.

A comparison of the gel point values with the binding data supports the idea that one acumentin molecule is bound per actin filament. Assuming that 12.6% of the added acumentin was bound to actin filaments, then for 1.0 mg ml^{-1} of actin, 1 mol of acumentin would be bound for every 609 and 409 actin monomers in filaments for 20 and 30 µg ml^{-1} of acumentin added, respectively. Dividing these values by the known number of monomers per unit filament length (370 monomers per µm (ref. 22)) gives respective lengths of 1.64 and 1.11 µm. The values are in reasonable agreement with those determined from the gel point values.

We studied the effect of acumentin on the nucleation and elongation steps of actin polymerization and on filament annealing to analyse the mechanism by which acumentin affects filament length. As shown in Fig. 3*a*, acumentin accelerates the onset of actin polymerization; this suggests that acumentin promotes the nucleation of actin monomers. Growth of filaments from these nuclei may result in the formation of a larger number of shortened filaments relative to actin assembled by spontaneous nucleation, because more nuclei are competing for the monomer pool[8]. However, this effect alone is insufficient to maintain the filaments in a shortened state because such filaments would reanneal with time to a normal length distribution. Short filaments are stabilized at equilibrium by the fact that acumentin binds to their ends (Fig. 3*b*) and prevents annealing and redistributing to a longer length distribution, as amplified below.

To study the elongation phase of filament assembly, nucleation was stimulated maximally by adding nuclei in the form of actin filaments to solutions of monomeric actin. The addition of the F-actin nuclei to monomeric actin resulted in a rapid polymerization of actin, as judged by an immediate increase in the viscosity of the solution (Fig. 3*b*). On the other hand, the addition to monomeric actin of nuclei in the form of actin filaments which had been assembled in the presence of acumentin, promoted a slower initial rate of assembly than did the addition of actin nuclei alone. Therefore, nuclei capped with acumentin, like nuclei reacted with other agents which bind to the end of actin filaments[8,10,14–16], are less effective than

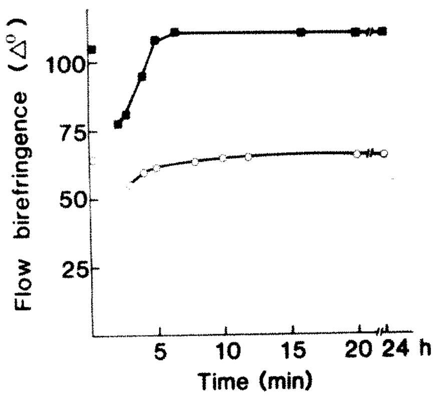

Fig. 4 Effect of acumentin on the annealing of F-actin fragments. F-actin, 0.25 mg ml^{-1}, in 0.1 M KCl, 0.2 mM $CaCl_2$, 0.5 mM ATP, 0.5 mM 2-mercaptoethanol, 2 mM Tris-HCl, *p*H 7.5, was mixed on a mechanical mixer with (■) or without (○) 32 μg ml^{-1} of acumentin. The flow birefringence and extinction angles of the two solutions were determined as described by Maruyama[31]. The solutions were then sonicated for 40 s on ice and the recovery of birefringence from sonication was then followed with time. F-actin had a final extinction angle of 3°. Acumentin increased the extinction angle to 8°. Velocity gradient was 100 s^{-1}.

actin nuclei in stimulating the growth of actin. This effect is a consequence of the decrease in the number of ends on the nuclei available for binding of actin monomers.

Acumentin and gelsolin have additive inhibitory effects on filament elongation (Fig. 3*c*). When actin filament fragments capped with gelsolin were added to G-actin solutions, the onset of actin assembly was immediate as judged by the increase in the viscosity of the solution. However, the initial rate of filament assembly was lower than that of polymerization nucleated by addition of actin filaments alone. The addition of acumentin to the nuclei capped by gelsolin further depressed the rate of filament assembly without affecting the onset of polymerization. The combination of the two proteins might at first glance be expected to block both ends of the nuclei, thereby causing actin to assemble as if no nuclei were added. There are two reasons this result was not observed. First, gelsolin affects actin polymerization in several ways. It reduces the number of free nuclei ends by binding to the barbed end of actin filament nuclei. However, gelsolin also 'severs' actin filaments, thereby creating new pointed ends[23,24]. Moreover, free gelsolin nucleates actin monomers. Second, acumentin also reduces the number of free filament ends by binding to the pointed end of the filaments. However, free acumentin can also nucleate actin monomers. Therefore, as free molecules of acumentin and gelsolin were not removed in the conditions of the experiment shown in Fig. 3*c*, unbound gelsolin and acumentin would be present in the solution. These molecules could nucleate actin monomers, producing new filaments with one free end. In addition, gelsolin would be expected to produce new ends by cutting filaments. Therefore, the combined effect of gelsolin and acumentin is explained most simply by a reduction in, but not a complete removal of, filament ends.

As shown in Fig. 4, acumentin inhibits the annealing of broken actin filaments. When actin was disrupted by sonication in the absence of acumentin, flow birefringence values recovered rapidly. Shearing of actin filaments in the presence of acumentin on a mechanical mixer or sonication caused an immediate and persistent decrease in the flow birefringence value of the actin, indicative of filament shortening. The decrease in birefringence after shearing is consistent with binding of acumentin to the ends of actin filaments which had been fragmented by shear and with the inhibition of annealing of these capped fragments.

Biological implications

Acumentin binds and caps the pointed end of actin filaments, and potentiates the nucleation step of actin assembly. This effect increases the number of nuclei available for addition of actin monomers and distributes the resulting polymer mass over more filaments, thus shortening the filament length distribution. The filaments elongate more slowly and remain short because acumentin caps one of their ends. Whether acumentin shortens filaments by actively severing them or by inhibiting broken filaments from annealing is unknown. All experiments involved mechanical shearing of the filaments, and transient filament fragmentation invariably results from these manipulations[25].

Phagocytic leukocytes have a layer of distinct cytoplasm located just beneath their plasma membrane, and this cortical cytoplasm is redistributed during cell movement. Electron micrographs of the cortex of these cells reveal the presence of short actin filaments 100–300 nm long[26–29].

The abundance of acumentin in leukocytes may in part explain the existence of these short filaments. The molar ratio of acumentin to actin in cytoplasmic extracts is 1 to 5 (ref. 20). Assuming that 10% of the acumentin in the cortex were bound to actin, 1 acumentin molecule would cap a filament containing 50 actin molecules or one which was 135 nm long. We presume that acumentin would be constitutively bound to actin filaments, the amount bound being determined solely by its affinity for actin, because its binding to actin is equivalent in high and low calcium concentrations. The gelsolin–calcium complex confers the remaining control and the fine regulation of filament length.

Exchange of actin monomers with the ends of filaments would be totally inhibited if both ends were capped by acumentin and gelsolin, a condition that would occur in the cell when the free calcium level is greater than micromolar. When the free calcium concentration decreases below micromolar concentrations gelsolin dissociates from the barbed end of the filament. Filaments with freed barbed ends would compete with acumentin for the pointed ends of the filaments. Our binding data suggest that the affinity of acumentin for the pointed end of actin filaments is lower than that of actin monomers for the barbed end of filaments[4], and probably lower than the affinity of filament ends for each other during annealing. High concentrations of actin filaments with free barbed ends could displace acumentin from the pointed ends of other filaments. In these conditions the average filament length would increase.

When the free calcium concentration rises sufficiently, gelsolin would split actin filaments and remain bound to their barbed ends. This would decrease the number of barbed and increase the number of pointed filament ends. In the absence of acumentin, residual free barbed filament ends would anneal with the pointed ends of other filaments and free monomers could also bind to the pointed ends. Capping of the pointed ends by acumentin would prevent either this filament annealing or monomer addition, thereby conferring a greater degree of precision to the control of actin filament length by the calcium–gelsolin complex.

Furthermore, the interaction of acumentin and gelsolin with actin could permit rapid changes in legnths of existing filaments without concomitant alterations in a pool of monomeric actin which might cause the uncontrolled formation of new filaments. Finally, the presence of an agent that constitutively blocks a filament end, renders unlikely the existence of actin treadmilling in the living cell.

Department of Surgery, Children's Hospital Medical Center and the Departments of Anatomy and Surgery, Harvard Medical School, Boston, Massachusetts 02115, USA

Protamine is shown to be a specific inhibitor of angiogenesis. The compound inhibits the capillary proliferation observed in embryogenesis, inflammation, certain immune reactions and the growth of solid tumours.

ANGIOGENESIS, the growth of new capillary blood vessels, is important in normal processes such as development of the embryo, formation of the corpus luteum and wound healing. It is also a component in pathological processes such as chronic inflammation, certain immune responses and neoplasia[1–3]. Furthermore, angiogenesis is a property of most solid tumours and is necessary for their continued growth[4]. Consequently, we have hypothesized that an angiogenesis inhibitor might be used to control tumour growth[5].

During our early studies of angiogenesis we observed that mast cells accumulated at a tumour site *before* the ingrowth of new capillary sprouts, but that mast cells alone could not initiate angiogenesis[6]. We later postulated that mast cells might facilitate the continuous migration[7] of capillary endothelial cells towards the solid tumour. When capillary endothelial cells were cloned and carried in long-term culture[8], and a quantitative assay was devised to measure their migration rate[9], we found that heparin released by mast cells increased the migration (chemokinesis) of capillary endothelial cells *in vitro*[10]. Protamine, an arginine-rich basic protein of 4,300 molecular weight (M_r), found only in sperm and known for its capacity to bind heparin, blocked the ability of mast cells and heparin to stimulate migration of capillary endothelial cells[10].

We now show that protamine is a specific inhibitor of stimulus. Protamine released locally prevents the neovascularization induced by an inflammatory agent or by an immune reaction and it inhibits capillary proliferation in the embryo. Protamine also inhibits tumour angiogenesis and subsequent tumour growth when it is applied locally, but in only a few cases when it is administered systemically. It has no effect on established capillaries that are not proliferating. We further show that heparin can enhance the intensity of angiogenesis induced by tumour extract *in vivo* but that heparin alone cannot initiate angiogenesis.

Inhibition of angiogenesis in the embryo

The effect of protamine on growing embryonic vessels was investigated using chick embryos of different ages. Capillaries appear in the yolk sac at 48 h and grow rapidly over the next 6–8 days. Protamine in methylcellulose disks applied locally inhibited capillary growth and produced a large avascular zone in the yolk sac (Fig. 1), whereas control embryos implanted with empty disks did not develop avascular zones.

Heparin added to the protamine disk prevented the development of the avascular zone (Fig. 1). The non-anticoagulant fraction of heparin[11] was equally effective in this action, while heparin alone did not cause an avascular zone.

In contrast, protamine had no effect on mature, non-growing[12] vessels studied on the chorioallantoic membrane at day 10. However, protamine applied to younger proliferating vessels of the day 5 or 6 chorioallantoic membrane produced a large avascular zone within 48 h.

Inhibition of tumour angiogenesis

The first indication that protamine could inhibit tumour angiogenesis came from studies of heparin on the chick chorioallantoic membrane (CAM). When 100 μg of tumour extract (partially purified for angiogenesis activity from human hepatoma cells)[9] was placed on the CAM, new capillary growth was elicited within 48 h in 90% of the eggs. Addition of heparin (6 μg, that is, 1 unit) reduced to 25 μg the amount of tumour extract required to elicit neovascularization in 100% of eggs, and reduced the interval between implantation and capillary growth to 24 h (Fig. 2). Heparin alone had no effect. Addition of protamine just sufficient to neutralize heparin (12 μg) eliminated the angiogenesis enhancing effect of heparin. However, when protamine was increased to 20 μg, it prevented all angiogenesis induced by tumour extract (25 μg) (Fig. 2).

A further test used a sustained release pellet[13] of protamine positioned between tumour and normal vessels in the rabbit cornea[14], allowing quantification of the inhibition of new capillary proliferation as a function of the rate of linear capillary growth. A protamine pellet juxtaposed to a V2 carcinoma implant almost completely inhibited capillary growth. In contrast, in the untreated eyes, tumours were vascularized by hundreds of new capillary sprouts and grew rapidly. Tumours in the protamine treated eyes did not become vascularized until the protamine pellet was removed. The mean vessel growth rate in the protamine-treated eyes was 0.02 ± 0.01 mm per day compared with 0.25 ± 0.07 mm per day in the untreated eyes (Figs. 3*a*, *b* and 4).

A more rigorous test of an angiogenesis inhibitor is to implant tumour directly into vascular tissue. Thus when V2 carcinoma and protamine pellets were implanted in a subcutaneous pouch[15] in the rabbit ear, the density of neovascularization (observed by transilluminating the ear) was markedly reduced in comparison with tumour in the opposite ear not exposed to protamine. Although vessel growth rates could not be quantified, tumour growth could be. Protamine-treated tumours grew at a mean rate of 8 ± 1 mm^3 per day compared with 68 ± 5 mm^3 per day for untreated tumours (Fig. 5). By histological section, the protamine-treated tumours, while still

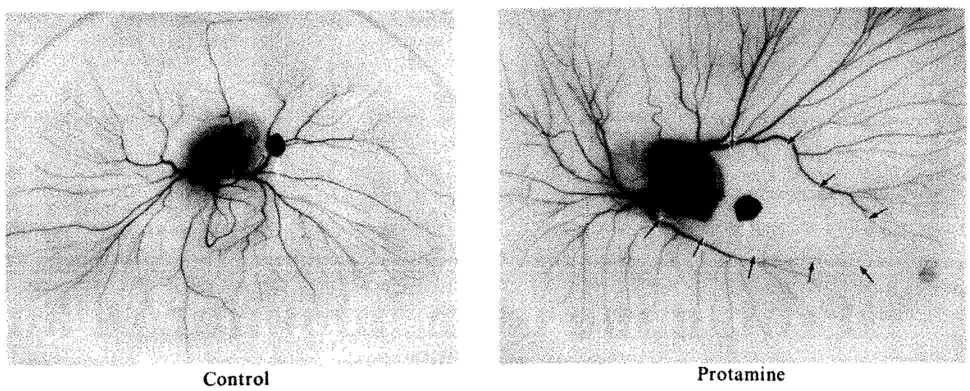

Fig. 1 Inhibition of angiogenesis by protamine in the chick embryo yolk-sac vascular membrane. Fertilized embryos are placed in a Petri dish on day 4 and cultured in a humidified incubator in 5% CO_2 as previously described[32]. Protamine sulphate (Calbiochem) is dissolved in distilled H_2O to make 14.3 $\mu g\ \mu l^{-1}$. 500 μl of this solution is added to 500 μl of 1% (w/v) methylcellulose (in distilled water, previously sterilized by autoclaving). Aliquots (7 μl) of this mixture are pipetted onto Teflon moulds of 3.2 mm diameter and allowed to dry (J. Barlow and J.F., unpublished). The resulting methylcellulose disk contains 50 μg protamine and can be peeled away from the Teflon mould. For control disks, 500 μl H_2O is substituted for the protamine. For photographic purposes, India ink can be added to the methylcellulose (2 μl per 100 μl). A methylcellulose disk (white arrow) was placed at the advancing edge of the vascular membrane on day 4 and the resultant avascular zone (black arrows) measured on day 6. The outlines of the yolk sac and of the avascular zone were traced on top of the Petri dish cover and converted to area with a Zeiss MOP-3 digital image analyser (Carl Zeiss). Forty-three embryos were implanted with protamine disks. The mean area of the vascular membrane on day 6 was $24.8 \pm 1.0\ cm^2$. The mean area of the avascular zones produced by protamine was $3.0 \pm 0.4\ cm^2$, or 12.5% of the original vascular area. In 43 control embryos implanted with empty disks, the mean area of the vascular membrane was $23.6 \pm 1.0\ cm^2$. There was no avascular zone in these embryos. Heparin (25 μg) added to the protamine disk prevented the development of the avascular zone. The non-anticoagulant fraction of heparin[11] was equally effective in preventing the protamine-avascular zone. Heparin alone did not cause an avascular zone. While the size of the avascular zone was dose related to protamine, it was not specific for protamine. Extremes of pH and osmolarity could also produce an avascular zone.

viable, were either avascular or were penetrated only sparsely by capillaries. In contrast, the untreated tumours were pervaded by a dense capillary network.

Inhibition of inflammatory angiogenesis

To determine whether protamine could inhibit inflammatory angiogenesis[16], a focus of chronic inflammation was established in the rabbit cornea by implanting silica particles. In each of six rabbits, a protamine pellet (prepared as described in Fig. 3 legend) was implanted between the silica and the normal vascular bed. An empty pellet was implanted in the opposite eye. New capillaries appeared at 2 days in the untreated eyes and grew towards the silica at a mean rate of 0.2 ± 0.02 mm per day. By contrast, in the protamine-treated eyes the mean vessel growth rate was 0.06 ± 0.01 mm per day. When the protamine pellet was exhausted or removed, new capillaries advanced towards the silica at the same rate as in untreated eyes.

Inhibition of immune angiogenesis

To determine whether protamine could block immune angiogenesis[17], fragments of rabbit lymph node were implanted in corneal pockets of nine outbred rabbits. Either a protamine pellet or an empty pellet was implanted between the node and the normal vascular bed. In the absence of protamine, new capillaries entered the cornea by day 4 and advanced towards the lymph node at a mean rate of 0.20 ± 0.03 mm per day. In the presence of protamine, angiogenesis was suppressed completely until day 8, when a few vessels began to grow at 0.05 ± 0.03 mm per day.

Systemic administration of protamine

Although the systemic administration of protamine was limited by its toxicity at high doses (lethargy, weakness and occasionally sudden death), it has, within the tolerated doses, been used to test the inhibition of growth of four types of lung metastases and three of their subcutaneous primary tumours.

Protamine concentrations in the lung were fivefold greater than in the subcutaneous tissue, and 40-fold greater than in the skin.

Lung metastases. To test whether systemically administered protamine was an effective inhibitor of tumour growth, mice with lung metastaases were treated with subcutaneous protamine at 12-h intervals (Fig. 6). When mice which had received Lewis lung tumour cells, B16 melanoma cells (subcutaneous strain) or B16 melanoma (tissue culture strain) either intravenously (i.v.) or subcutaneously (s.c.) were treated with a well tolerated dose of protamine (60 mg per kg, s.c., every 12 h), there was 77–92% inhibition of mean lung metastases tumour volume compared with saline-treated animals. The number of lung metastases did not differ significantly between protamine- and saline-treated animals with the exception of the two strains of melanoma.

Similarly, when rats which had received Walker 256 carcinoma cells i.v. were treated with a well tolerated dose of protamine (120 mg per kg, s.c., every 12 h), there was 97% inhibition of mean lung metastases tumour volume compared with saline-treated animals (Fig. 6). The number of metastases was also reduced: there were 3 metastases per rat in the protamine-treated animals compared with 64 metastases per rat in the saline-treated animals (Fig. 6).

Subcutaneous tumours. The growth of neither Lewis lung carcinomas nor B16 melanoma (subcutaneous strain) when implanted s.c. was significantly inhibited by protamine except for some inhibition of the former at highly toxic doses (135 mg per kg). However, systemic protamine did inhibit the growth of subcutaneous tumours of B16 melanoma (tissue culture strain), as will now be described.

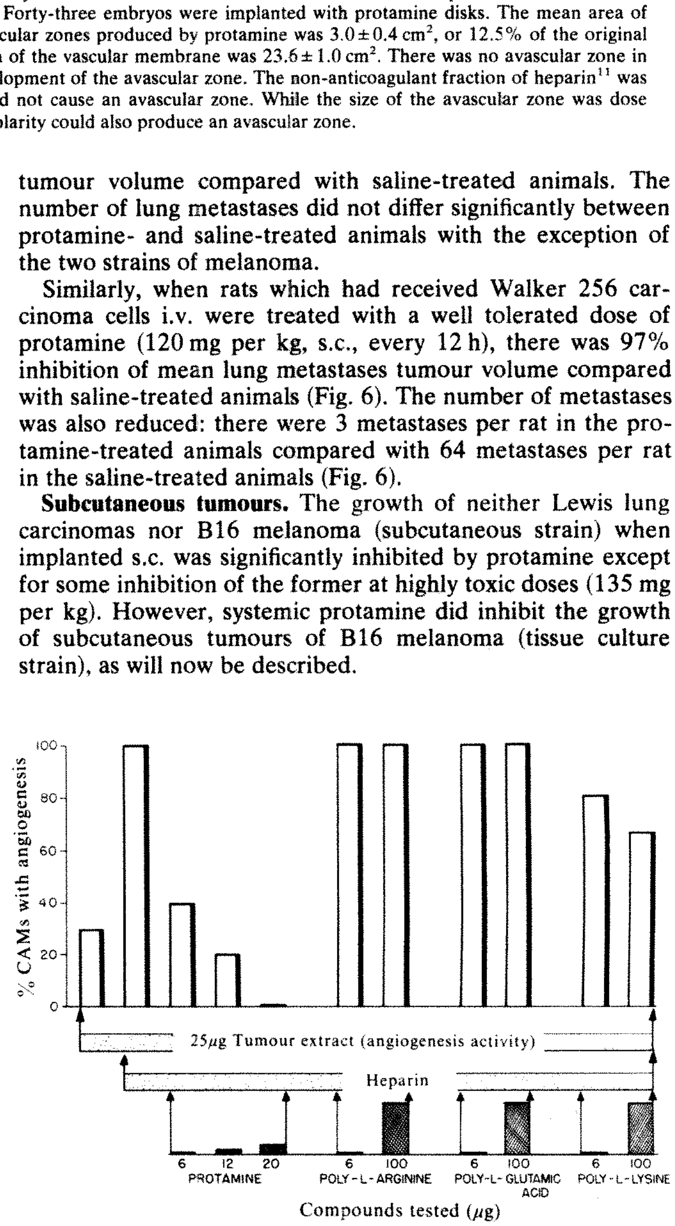

Fig. 2 Angiogenesis on the chick chorioallantoic membrane (CAM). Tumour extract (25 μg, from hepatoma cells[9]) in 5 μl H_2O was placed on the centre of a round plastic coverslip (Thermanox, 15 mm diameter) (J. Barlow and J.F., unpublished data). To each disk was added another 5 μl aliquot containing either heparin (6 μg) or one of the test compounds. The coverslip was allowed to dry, placed on the CAM of 9-day-old embryos and viewed 24 h later with a $\times 12$ stereomicroscope. Angiogenesis was present if new capillaries converged on the spot in the centre of the coverslip. Controls were poly-L-arginine (M_r 130,000, Sigma), poly-L-glutamic acid (M_r 10,000) and poly-L-lysine (M_r 3,000). The five bars on the left represent 50 eggs each. The remaining six bars to the right represent 15 eggs each.

Fifty-two C57BL/6 mice received 4.6×10^7 melanoma tissue culture strain F2[18] s.c. (smaller inocula of 10^3, 10^4 and 10^5 cells also produced tumours, although much later). Half of the mice received protamine 60 mg per kg, s.c., every 12 h in a remote site and the other half received saline.. All tumours took and grew at approximately the same rate in both protamine- and saline-treated animals until day 5 when the tumours were nearly 0.05 cm^3 and had become vascularized. The protamine-treated tumours then slowed their growth (0.05 cm^3 per day) until day 18 when they either stopped growing or began to regress. The saline-treated tumours continued to grow rapidly over the same period (0.23 cm^3 per day). In 13 (50%) of the protamine-treated mice, tumour regressed completely. It was necessary to lower the protamine dose by approximately one-half once regression was complete. These mice remained tumour free after protamine was discontinued. Eight (30%) died while the tumour was undergoing rapid necrosis. Two mice died with melanoma ascites after the primary tumour had disappeared. In three mice, tumours underwent incomplete regression and remained as small, barely visible lesions. Their tumour growth resumed whenever protamine was discontinued, and they were dead by day 68. The saline-treated animals died with massive tumours (17.8 ± 0.4 cm^3) by day 30. Using the same strain of melanoma, this experiment was repeated eight times over a 2 yr period with essentially similar results (tumour regression in ~50% of the animals). After a large tumour had regressed to become no longer visible, it was necessary to continue the lower dose of protamine for at least 2 more weeks, otherwise the tumour recurred. When mice that had been tumour free and not receiving protamine for 1–11 months received a second s.c. inoculation of the same strain of melanoma cells, new tumours developed and were also susceptible to protamine inhibition.

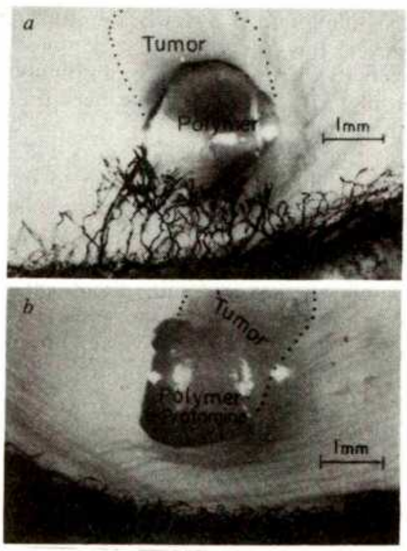

Fig. 3 Inhibition of tumour angiogenesis in the rabbit cornea by protamine. Polymer pellets of ethylene vinyl acetate (EVA) copolymer, of ~1 mm diameter were impregnated with 1,000 μg protamine sulphate as previously described[13]. The pellets were coated with 2% EVA in methylene chloride, dried for 3 h and sterilized by UV light for 2 min. The pellets were implanted in a pocket in the rabbit cornea, 1 mm from the limbus. A 1 mm^3 piece of V2 carcinoma was implanted distal to the polymer, 2 mm from the limbus[14]. In the opposite eye of each rabbit, control polymer pellets that were empty were similarly implanted in juxtaposition to the tumour. By spectrophotometric analysis *in vitro*, the pellets released 400 μg protamine on day 1. This sustained release declined exponentially until day 4, when the pellets released an average of 15 μg per day thereafter, for the next 15 days. As capillary blood vessels grew towards the tumour implant, maximum vessel length was measured every 3 days with a stereoscopic slit-lamp at ×10 (±0.1 mm). At day 10 a typical rabbit was killed and India ink was injected into each carotid artery. The corneas were removed and photographed with a stereoscope. *a*, New capillary blood vessels growing towards the tumour and passing over the blank polymer. *b*, In the presence of the protamine pellet (opposite eye), new capillary vessels at the edge of the cornea do not enter the cornea. Histological sections showed viable tumour in each cornea.

Thus, the first tumour regression apparently was not accompanied by a strong immune reaction.

Controls

To control for the specificity of protamine as an angiogenesis inhibitor, compounds similar in structure or charge density to protamine were tested against tumour angiogenesis in the CAM and against growing embryonic vessels on the yolk sac. Poly-L-arginine, poly-L-glutamic acid and poly-L-lysine produced no inhibition of angiogenesis at concentrations two to four times the protamine concentration that was inhibitory (Fig. 2). At five times the protamine concentration, poly-L-lysine weakly inhibited tumour angiogenesis in the CAM but did not inhibit the growth of yolk sac vessels. These compounds were all lethal when applied at concentrations greater than five times the protamine concentration. Platelet factor 4 and major basic protein from eosinophils have a high affinity for heparin. They both produced avascular zones at approximately one-half the concentration of protamine.

As another control of protamine specificity, mixtures of heparin and protamine (1:2) were assayed in the chick embryo (Fig. 1). Both the commercial anticoagulant heparin (Sigma) and the non-anticoagulant fraction[11] (courtesy of Dr Robert Rosenberg) neutralized the anti-angiogenesis activity of protamine in the yolk sac and on the CAM. Heparin (Sigma) was also injected into tumour-bearing mice simultaneously with protamine (but at a different site). Inhibition of tumour growth was abolished; tumour size and mouse mortality were the same as for mice injected with saline alone (data not shown).

To exclude the possibility that protamine inhibition of tumours might be caused by direct cytotoxicity, tumour cells were exposed to protamine *in vitro*. Protamine was neither cytostatic nor cytotoxic to V2 carcinoma, B16 melanoma (tissue culture strain), Lewis lung or Walker cells at concentrations of 50–500 μg ml^{-1}. Growth suppression began at 500 μg ml^{-1} for Walker cells, but melanoma, V2 and Lewis lung cells were not suppressed at 1,000 μg ml^{-1}. In fact, growth of V2 carcinoma was stimulated to 55% above control by a protamine concentration of 100 μg ml^{-1}, and Lewis lung cells were stimulated to 37% above control by a protamine concentration of

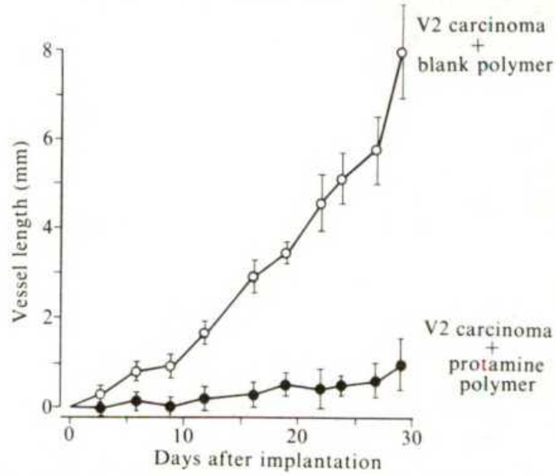

Fig. 4 Measurement of capillary growth rate in the rabbit cornea. Series of nine rabbits with V2 carcinoma in each cornea accompanied by a protamine pellet (●) or empty pellet (○) were used as described in Fig. 3 legend. In the presence of protamine, capillary growth is suppressed until the week 3 (when protamine release from the polymer pellet declines). In the eyes containing a blank pellet, tumours all became vascularized and grew to a large exophytic mass, necessitating the death of these animals by about 30 days. In a parallel experiment (data not shown), in which both eyes of an animal were treated with protamine, capillary growth resumed within 3 days of removal of the pellet. There was subsequent rapid tumour growth. Protamine pellets implanted in the absence of tumour did not induce neovascularization. Measurements are expressed as mean ±s.e.m. here and in all subsequent figure legends. Eyedrops of protamine in Ringer's solution (100 mg ml^{-1}) applied three times per day, did not inhibit capillary growth. The eyedrops caused no detectable irritation in the normal eyes of rabbits. Systemically administered protamine failed to inhibit capillary growth in the cornea.

500 μg ml^{-1}. These concentrations exceed any local concentrations of protamine achieved *in vivo* by sustained-release pellets. Furthermore, when protamine was administered systemically, its peak uptake in subcutaneous melanoma was 70 μg per 100 mg of tumour at 1 h. This is equivalent to 0.001 μg per 1,000 cells (assuming that a 100 mg tumour contains at least 10^7 cells). The melanoma cells *in vitro* grew maximally at 2 μg per 1,000 cells, that is, at more than 2,000 times the protamine concentration achieved *in vivo*.

To determine if protamine was cytotoxic to rapidly dividing cells *in vivo*, melanoma-bearing mice treated with protamine or saline for 11 days received 80 μCi ^{3}H-thymidine and were killed 5 h later. The percentage of ^{3}H-thymidine labelled cells in the bone marrow was similar for the protamine-treated (20%) and saline-treated mice (17%). In the saline-treated tumours, 17% of the tumour cells were labelled. There was no necrosis. In contrast, the regressing protamine-treated tumours were marked by a large necrotic centre and a few outer layers of viable cells. The labelling index of the rim of viable cells was 16%, not significantly different from the saline-treated tumour.

To exclude the possibility of cumulative toxicity at the 60 mg per kg dose, 10 non-tumour-bearing mice received protamine (60 mg per kg, s. c., every 12 h) for 1 yr, beginning at age 6 weeks. Their weight gain and activity were the same as for 10 saline-treated mice throughout this period, and all 20 mice were alive at the end of 1 yr.

Discussion

These studies show that protamine is an inhibitor of angiogenesis in the four species tested, irrespective of whether the angiogenic stimulus is embryological, neoplastic, inflammatory or immunogenic.

The mechanism by which protamine inhibits angiogenesis is unclear. However, previous *in vitro* studies suggest that heparin modulates the rate of migration of capillary endothelium[10]. The specific binding of protamine to heparin could block the linear migration of capillary endothelial cells, thus interfering with a crucial step in capillary formation[7]. The anticoagulant function of heparin apparently is not involved in this reaction, because the non-anticoagulant fraction of heparin is capable of reversing the anti-angiogenesis activity of protamine. Although coagulation studies remained normal in animals treated with protamine, it is possible that protamine may modify fibrin deposition in the neovascular bed induced by tumours[19,20]. Furthermore, the disparity between the effect of protamine on lung metastases and subcutaneous tumours seems to be due to differences in the tissue uptake of protamine (unpublished data).

These experiments do not prove unequivocally that the angiogenesis-inhibitory activity of protamine is responsible for its anti-tumour effect. However, indirect evidence in support of this conclusion is based on four observations: (1) when protamine is removed from the cornea, capillary growth resumes *before* tumour regrowth begins; (2) histological sections from protamine-treated animals show many microscopic lung metastases that remain avascular, in contrast to saline-treated animals where vascularized tumours predominate; (3) tumour regression in mice does not seem to be immunologically mediated, because lymphocytic infiltration is minimal or absent, and when animals taken off protamine after complete tumour regression are re-inoculated with melanoma cells, tumours grow as before; (4) protamine is neither cytostatic nor cytotoxic to tumour cells *per se* at the doses used.

Four lines of evidence argue that protamine does not act directly on tumour cells: (1) tumour cells in culture grow well at protamine concentrations greater than the peak concentrations of protamine in tumour; (2) the early growth of the protamine-susceptible strain of melanoma (before neovascularization) in protamine-treated mice is not significantly different from that of melanomas in saline-treated mice; (3) the ^{3}H-thymidine-labelling index of bone marrow and viable tumour cells does not differ significantly between protamine- and saline-treated mice; (4) melanoma cells in ascites proliferate during protamine treatment even while the solid primary tumour regresses.

The effectiveness of protamine in inhibiting the growth of lung metastases and its relative ineffectiveness against many subcutaneous tumours might be partly explained on the basis of differential protamine uptake by the two tissues. However, there is no explanation for the finding that strains of tumour implanted s.c. should have different susceptibility to protamine. Some tumours have been found to contain two subpopulations of neoplastic cells—those that can stimulate angiogenesis and those that cannot[21]—and it is possible that the ratio of these two subpopulations dictates the intensity of angiogenesis for a given tumour mass. A second possibility is that different tumour strains might secrete different amounts of glycosaminoglycans that would bind protamine in competition with heparin. A third speculation is that in protamine-resistant tumours there may be more mature vessels. Little is known about the extent to which new capillaries within a tumour convert to mature capillaries and venules (that is, with intact basement membrane, and accumulated pericytes or smooth muscle). Finally, there may be important differences in mast cell content of tumours that would account for different responses to protamine.

Angiogenesis inhibition is a newly found property of protamine. However, this is not the first demonstration of the antitumour activity of protamine, as antitumour activity of protamine or mixtures containing it has been previously found in mice and humans[19,22–26].

It is possible that angiogenesis inhibitors will eventually be used clinically in those diseases common to ophthalmology, dermatology and rheumatology where neovascularization is the dominant pathology, and in certain neoplasms that are the most highly angiogenic, such as brain tumours. It is, however, much too early to know whether protamine or any other inhibitor of angiogenesis, conceivably including some of endogenous origins[27–31], will be of any clinical value. Protamine is toxic

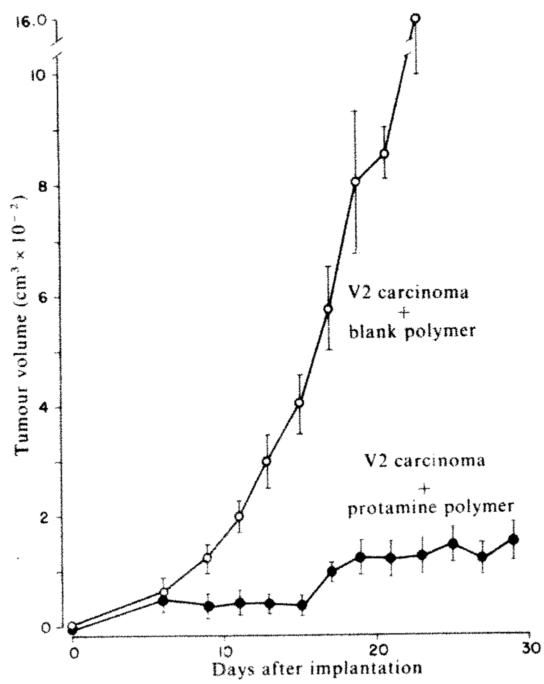

Fig. 5 Inhibition of tumour growth by locally applied protamine when the tumour is implanted directly into the vascular bed. Eight rabbits received a subcutaneous implant of V2 carcinoma in each ear by a method developed by Bronsther *et al.*[15]. One ear received two polymer pellets impregnated with protamine as described in Fig. 3 legend. In the opposite ear, two empty polymer pellets were implanted with the tumour. In both ears, tumour growth formed a hemisphere, the dimensions of which were measured with a micrometer caliper. Tumour growth in the protamine-treated pocket (●) was markedly suppressed compared with tumour in the control ear (○). Although capillary growth rate could not be quantified as in the cornea, the extent of vascularization could be observed by transillumination of the ears. The untreated tumours became vascularized on about days 6–7, and rapid growth ensued. In contrast, the protamine-treated tumours generally did not become vascularized, and their growth was slow or undetectable.

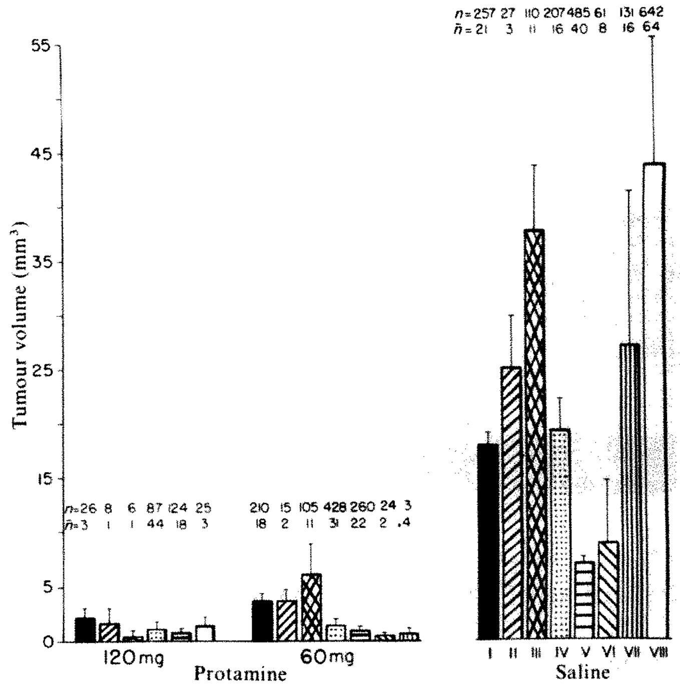

Fig. 6 Effect of protamine of pulmonary metastases in mice and rats, ■, Expt I: 36 C57BL/6 male 42-day-old mice received 1.2×10^6 Lewis lung carcinoma cells i.v., and either protamine, 120 or 60 mg per kg, s.c., every 12 h or saline. All mice were killed on day 15. Mice surviving to that day were: 120 mg, 9/12 (3 mice died free of lung metastases on day 2 presumably from a too rapid step-up to the full dose); 60 mg, 12/12; saline, 12/12. The standard error of the differences in means between all groups was significant at $P<0.001$. In all experiments n = total number of metastases represented by the mean, and $\bar{n}$ = average number of metastases per animal. In this and all subsequent experiments, the mice were weighed twice weekly and the dose of protamine revised upward by increasing the volume according to the average weight of each treatment group except for expts IV and VII where doses were individually calculated. The lungs were fixed in 10% formalin and the lobes separated. The volume and number of metastases were determined with a ×12 stereoscope (eyepiece micrometer 1 unit = 0.064 mm). Two diameters were measured in mm and the volume calculated using the formula[33], vol = $(d_1\ d_2\ d_3\ \Pi)/6$, where the width of the metastasis is used twice as d_1 and d_2 and the length as d_3. The measurements were made by two readers on different days who did not know how each specimen was treated. All mice were housed individually. A stock solution of protamine sulphate (Calbiochem) of 10 mg ml^{-1} in saline was warmed to 37 °C and filtered (0.45 μm Millipore). The amount of protamine lost in the filter was always less than 4% of the original concentration as measured spectrophotometrically at 230 nm. The protamine solution was stored at 4 °C in a sterile 50 ml polyethylene centrifuge tube and warmed to 37 °C before use. Treatment began 24 h after tumour inoculation, and only one injection was given on day 1. The twice daily injections began on day 2. Injections were made with a 30-gauge needle in a shaved area over the iliac crest that had been cleaned with a small amount of Betadine solution. Precautions: if one or two doses of protamine are omitted, resumption of the full dose may be highly toxic or lethal. Stepwise resumption to the full dose is necessary. Male mice comfortably tolerated 60 mg per kg, s.c., 12 hourly for 1 yr without signs of toxicity or without showing differences from saline-injected animals. However, at 120 mg per kg 12-hourly, toxicity appeared after 2–3 weeks in 50% of mice. Tumour-bearing mice show less toxicity for a given dose of protamine than do mice without tumours. If a skin ulcer appears, protamine may leak, resulting in non-therapeutic levels of protamine. If a s.c. injection is given too quickly or forcibly, some protamine will enter the venous system and (with doses > 60 mg per kg) cause sudden toxicity or death. The maximum tolerated single i.v. dose for a mouse is ~6 mg per kg. ▨, Expt II: 56 mice received 6×10^5 Lewis lung carcinoma cells i.v., were placed in three treatment groups and killed on day 17. Surviving mice were: 120 mg, 9/25; 60 mg, 10/16; saline, 10/15. Lung metastases were measured in formalin-fixed lungs as described above. In the protamine-treated mice that died before the end of the experiment, the mean volumes of the pulmonary metastases were less than the mean volumes of the metastases in the killed mice. The s.e. of the difference in means of the 60 mg versus saline groups was significant at $P<0.001$ and that of the 60 mg versus 120 mg groups was significant at $P<0.05$. ▩, Expt III: this experiment was designed to determine the maximum size that could be reached by pulmonary metastases before 50% of the saline-treated host animals had died. Thirty mice received 5.8×10^6 Lewis lung carcinoma cells i.v. and were separated into three groups of 10 mice each. One mouse chosen at random from each protamine group was killed whenever a saline-treated mouse died of tumour, until day 21 when 50% of saline-treated mice had died, and then all the remaining mice were killed. ▒, Expt IV: this experiment was designed to determine the effect of protamine on pulmonary metastases shedding from a primary tumour. Seventy-one mice received a s.c. implant (1 mm³) Lewis lung carcinoma; 25 received protamine, 120 mg per kg every 12 h, 25 received 60 mg and 21 received saline. By day 21 the mean volume of the s.c. primary tumour in the saline-treated mice was 5.4 ± 0.2 cm³; it was 2.4 ± 0.2 cm³ and 2.9 ± 0.6 cm³, respectively, 120 mg and 60 mg groups. All surviving mice were killed on day 24. The survivors were 2/25 in the 120 mg group, 11/25 in the 60 mg group and 7/21 in the saline group. In the protamine-treated mice that died before the end of the experiment, the mean volumes of the pulmonary metastases were less than the mean volumes of the metastases in the killed mice. The s.e. of the difference in means of the 60 mg group versus saline was significant at $P<0.001$. There was no difference between the 60 mg and 120 mg groups. ▤, Expt V: in this repeat of expt IV, 45 mice received s.c. implants of Lewis lung carcinoma and were divided into three groups of 15 mice each. On day 22 the mean volume of the s.c. primary tumour in the saline-treated mice was 6.1 ± 0.3 cm³; it was 3.2 ± 0.2 cm³ and 2.9 ± 0.5 cm³ in the 60 mg and 120 mg groups, respectively. All surviving mice were killed on day 26. The survivors were 7/15, 12/15 and 12/15 for the 120 mg, 60 mg and saline groups, respectively. In the protamine-treated mice that died before the end of the experiment, the mean volumes of the pulmonary metastases were less than the mean volumes of the metastases in the killed mice. The s.e. of the difference in means of the 60 mg group versus saline was significant at $P<0.001$. There was no significant difference between the 60 mg and the 120 mg groups. ▧, Expt VI: this experiment was designed to determine the effect of protamine on pulmonary metastases shedding from a primary tumour which was unresponsive to protamine in the subcutaneous position. Twenty mice received a s.c. inoculation of 10^7 B16 melanoma cells (subcutaneous strain); 12 mice received protamine, 60 mg per kg, s.c., 12 hourly, and 8 received saline. Lung metastases were measured whenever a mouse died. By day 50 three protamine mice and two saline mice were alive and these were killed to end the experiment,. The mean volume of the s.c. tumour at the last measurement before death was 14.4 ± 2.0 cm³ for saline-treated mice and 11.2 ± 1.5 cm³ for protamine-treated mice. The bar graph represents the metastases from all mice. The s.e. of the difference in means between the two groups was significant at $P<0.001$. ▥, Expt VII: a parallel experiment to expt VI except that the primary tumour was responsive to protamine in the subcutaneous position. Sixteen mice received 10^7 B16 melanoma cells (tissure culture strain); 8 mice received protamine, 60 mg per kg 12-hourly, and 8 received saline. Lung metastases were measured whenever a mouse died. By day 50 three mice were alive in each group and they were killed to end the experiment. The mean volume of the s.c. tumour at the last measurement before death was 13.5 ± 1.0 cm³ for the saline-treated mice and 0.3 ± 0.2 cm³ for the protamine group. The protamine-treated tumours underwent either complete or partial regression, but in this experiment, the protamine dose was not lowered during the regression in order to maintain the dose constant for pulmonary metastases. The s.e. of the difference in means between the two groups was significant at $P<0.001$. □, Expt VIII: a test of protamine against pulmonary metastases in a different species. Nineteen CD rats (age 21 days) received 5.1×10^6 Walker carcinoma cells i.v.; nine rats received protamine, 120 mg per kg, s.c., every 12 h and 10 received saline. On day 9, 8 of the 10 saline rats died (due to massive pulmonary metastases) and therefore all remaining rats were killed and lung metastases were measured as before except that Bouin's solution was used for fixation. The bar graph represents the mean volume of metastases from all rats. The s.e. of the difference in means between the two groups was significant at $P<0.001$.

when administered systemically above doses of 60 mg per kg in mice and 120 mg per kg in rats, and this toxicity is unrelated to its angiogenesis-inhibitory activity. This toxicity may severely limit or prevent the clinical use of systemically administered protamine as an antitumour agent. However, in the experimental situations where the appropriate tissue concentration can be achieved, protamine inhibits angiogenesis with the resulting effect on tumours. Furthermore, if the mechanism of the anti-angiogenesis activity of protamine can be determined, this may lead to the discovery of other angiogenesis inhibitors.

We thank Dr Christian Haudenschild for reviewing histological sections; Dr Robert Rosenberg for the non-anticoagulant fractions of heparin; Drs Bruce Zetter and Anthony Bellvé for helpful discussions; Dr Dean Hsieh for the polymer pellets; Ms Martha Potts, Mr Ronald Pelletier, Mr Paul Wesley, Ms Nancy Healy, and Mr Henoy Sims for technical help; Mr Janis Cirulis for art work; Mr Carl Cobb and Ms Jane Dittrich for editorial assistance; Mrs Pauline Breen for typing; Ms Margo Cantor for help in measuring Lewis lung metastases; and Drs Robert Handin for platelet factor 4 and Gerald Gleich for the major basic protein. The B16 melanomas, Lewis lung carcinoma and Walker 256 carcinoma were obtained by courtesy of Dr Randall Johnson and Mr Isidore Wodinsky of Arthur D. Little Co. This work was supported by a grant provided to Harvard University by Monsanto Company and by USPHS grant RO1-CA14019 from the National Cancer Institute.

Note added in proof: Female C57BL/6 mice tolerate higher doses of protamine (up to 120 mg) without toxicity.

Observation of additional low-degree 5-min modes of solar oscillation

Philip H. Scherrer*, John M. Wilcox*, Jørgen Christensen-Dalsgaard† & Douglas Gough‡

By measuring the difference between the shifts in the Fe 5,124 spectrum line from light integrated from a central circular portion of the solar disk and from an annular portion exterior to it, we have detected high-order solar oscillations with degrees $l = 3$, 4 and 5. The frequencies of the octupole modes agree well with the values obtained from whole-disk measurements at the South Pole[1]. A least-squares fit of the observed frequencies to values interpolated between and extrapolated from the predictions of a sequence of solar models with different chemical compositions selects two models. One of these is almost identical to that obtained by a previous fit[15] of modes with $l \leq 2$, and has a helium abundance somewhat greater than 25% by mass.

Most previous observations of low-degree 5-min solar oscillations have been made with light integrated from the entire solar disk. Claverie *et al.*[2–5] and Grec *et al.*[1,6,7] have measured spectrum line shifts, and Deubner[8] and Woodard and Hudson[9] have measured radiant intensity. Such measurements are most sensitive to modes of degree $l = 0$, 1 and 2; the long continuous Doppler observations made at the South Pole have also isolated octupole modes[1].

Our observations are based on a method used by Severny *et al.*[10]. A Babcock solar magnetograph[11] at the Stanford Solar Observatory, which is normally used for measuring Zeeman splitting, was converted into an instrument that measures Doppler shifts with equivalent sensitivity. For this purpose one selects a magnetically insensitive Fraunhofer line (with $g = 0$). Light from a central circular area of the solar disk, with radius $0.5\ R_{\odot}$, is filtered with a right-hand circular polarizer, and light from the annulus between $0.55\ R_{\odot}$ and $0.80\ R_{\odot}$ is filtered with a left-hand polarizer. The wavelength difference between the right and left polarized spectrum lines is measured by the magnetograph. It is interpreted, using the Doppler formula, as the difference between the averaged line-of-sight velocities from the circular and annular portions of the solar disk[12].

Because our apparatus convolves the Doppler signal with a function whose length scale is less than the radius $R_{\odot}$ of the solar disk, the degrees of the modes of oscillation to which it is most sensitive are higher than for whole-disk observations. Our signal should be dominated by modes with $l = 3$, 4 and 5, though contributions from modes with $l = 2$, 6, 9 and 10 should also be detectable[13]. Here we concentrate on the dominant modes.

We obtained good-quality data on 15 days from 17 June to 14 July 1981. The observations were made with 0.1 s time resolution, and were subsequently averaged into 15 s bins. A slow drift, typically of magnitude $1\ \mathrm{ms^{-1}\ h^{-1}}$, was then removed with a high-pass filter. This left data sets over intervals of average duration 9.6 h. Harmonic-amplitude spectra were computed from each data set using a simple least-squares method for finding Fourier coefficients in the frequency range 2.0–4.5 mHz in steps of 1.0 μHz.

Figure 1 shows the average of the 15 spectra. In common with previous observations, power is found to be concentrated between 2.5 and 4.0 mHz, and seems to be generated by a series of oscillators with uniformly spaced frequencies. But whereas whole-disk observations with comparable resolution[2–4,8] display two peaks per interval of ~136 μHz (corresponding to a mode with $l = 1$ and an unresolved pair with $l = 0$ and $l = 2$), here, as expected, there are three; we infer that they correspond to modes with $l = 3$, 4 and 5.

By selecting every third peak (taking due account of peaks that are obviously missing), one might hope to collect sets of modes of like degree. There are no obvious distinguishing differences between the amplitudes and frequencies of the three sets so obtained, as one would expect theoretically. Therefore we cannot identify the modes using our data alone. It is possible, however, to identify the modes in the data obtained at the South Pole, by comparing the uneven frequency distribution and variable peak heights with theoretical expectations[1,6,7,13–16]. The frequencies of the modes inferred to have $l = 3$ are indicated by vertical lines in Fig. 1. They can be seen to correspond with some of the peaks of our spectrum.

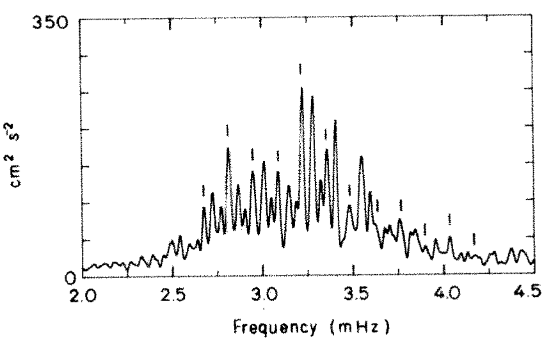

Fig. 1 Average of 15 squared velocity amplitude spectra of data collected in June and July 1981. The vertical lines mark the frequencies of octupole modes measured by Fossat *et al.*[1] at the South Pole.

0028-0836/82/210312—02$01.00

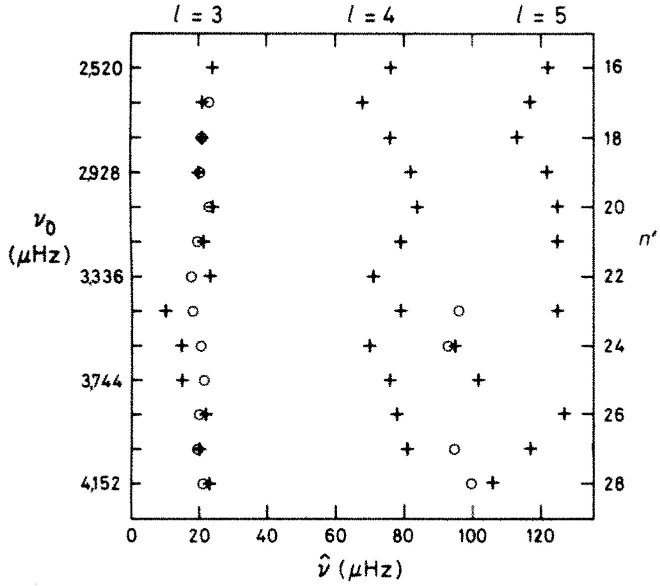

Fig. 2 Echelle diagram of the frequencies between 2.5 and 4.3 mHz of low-degree modes, constructed with $\nu_1 = 72\ \mu$Hz and $\Delta\nu = 136.0\ \mu$Hz. The frequencies ν of the modes represented in the diagram are given by $\nu = \nu_0 + \hat{\nu}$. +, Frequencies of the peaks in Fig. 1. ○, Octupole modes (with $\hat{\nu}$ near 20 μHz) and some dipole modes (with $\hat{\nu}$ near 100 μHz) observed from the South Pole by Fossat *et al.*[1]. Thus by comparing our results with the South Pole data and with theory we identify the degrees of the modes responsible for the three principal columns; these are indicated at the top of the figure. We presume the frequencies 3,703, 3,846 and 4,258 μHz correspond to dipole modes. The ordinate scale n' on the right is the order n or modes with $l \geq 3$, and is $n-1$ when $l = 2$. This identification was obtained by the least-squares comparison with theory described in the text. Fitting regression lines $\alpha + \beta(n - n_0)$, with $n_0 = 22 - \frac{1}{2}l$, to the three principal columns of Stanford frequencies ν yields $(\alpha, \beta) = (3{,}152 \pm 1, 135.7 \pm 0.3)$, $(3{,}140 \pm 1, 136.2 \pm 0.4)$ and $(3{,}117 \pm 1, 136.5 \pm 0.3)$ for $l = 3$, 4 and 5 respectively.

To facilitate identification of the modes responsible for our data, we present, following Grec[17], an echelle diagram (Fig. 2) of the frequencies of the peak maxima in Fig. 1. Each frequency ν is reduced to a frequency $\nu_0 + \hat{\nu}$ where ν_0 is an integral multiple of $\Delta\nu$ plus some constant ν_1, and $\hat{\nu}$ is in the range $(0, \Delta\nu)$. Figure 2 shows a plot of $\nu_0 \equiv \nu - \hat{\nu}$ against $\hat{\nu}$, the spacing $\Delta\nu$ having been chosen to give roughly the same values of $\hat{\nu}$ to modes of like degree. Thus $\Delta\nu$ is representative of the mean frequency differences between modes of adjacent order and like degree. More accurate estimates of these differences are given in the legend.

Included in Fig. 2 are the octupole modes identified in the South Pole data. Because these agree well with one of our columns of frequencies, we deduce that this column also results from octupole modes. The degrees of the new modes producing the other two principal columns are then inferred by comparison with theory[13]. Further comparisons with theory and with other observations will be reported elsewhere[18].

The addition of these new modes to the helioseismological data should impose tighter theoretical constraints on solar models. Here we simply compare the frequencies we have measured with the frequencies ν_λ interpolated between and extrapolated beyond the frequencies ν_A, ν_B, ν_C of the three solar models A, B, C of Christensen-Dalsgaard *et al.*[19] according to the formula

$$\nu_\lambda = \begin{cases} \lambda\nu_A + (1-\lambda)\nu_B & \lambda > 0 \\ (1+\lambda)\nu_B - \lambda\nu_C & \lambda < 0 \end{cases} \quad (1)$$

Model A is a standard solar model with initial helium and heavy-element abundances $(Y, Z) = (0.25, 0.02)$; models B and C have initial abundances (0.19, 0.004) and (0.16, 0.001) respectively, and have suffered contamination by heavy elements in and above the convection zone at a rate chosen to yield a present surface abundance: $Z = 0.02$. The least-squares fit of ν_λ with our frequencies ν represented in Fig. 2 yields $\lambda = -0.29$ and $\lambda = 1.26$ as the two best solutions. The r.m.s. difference between ν_λ and the observations is ~8 μHz for both solutions. The helium-rich solution agrees with that of similar analyses of whole-disk data[15] and low-order modes apparently detected as oscillations in the limb-darkening function[20]. Therefore we select this as our best estimate. We are then able to infer the orders n of the modes; these are indicated in Fig. 2. Our extrapolated solution has a relatively deep convection zone, and is thus consistent with analyses of 5-min oscillations of high degree[21,22].

We thank E. Fossat, G. Grec and M. Pomerantz for communicating observations before their publication and for suggesting the format of Fig. 2. Jovimagnetic secular variation

J. E. P. Connerney & M. H. Acuña

NASA/Goddard Space Flight Center, Laboratory for Extraterrestrial Physics, Planetary Magnetospheres Branch, Greenbelt, Maryland 20771, USA

Long-term variations of a planetary magnetic field are one of the few observables available for the study of planetary interiors and dynamo theory. Although variations of the geomagnetic field have been accessible to direct measurement for centuries, knowledge of the secular variations of other planetary dynamos is limited. We report here new limits on jovimagnetic secular variations found by comparison of a jovian internal field model[1] obtained from the Voyager 1 magnetic field observations at epoch 1979.2 with the epoch 1974.9 Pioneer 11 O_4 model[2]. No significant secular variation of either the magnitude or position of the jovidipole was found for the years 1974.9 to 1979.2, although a small Earth-like variation cannot be ruled out.

A gradual decrease in the Earth's dipole moment at a rate of ~5% per 100 yr has been established from observations of the geomagnetic field over the past 150 yr (ref. 3). Less well established but still generally accepted is the slow westward

drift of certain features of the geomagnetic field at a rate of ~0.1° or 0.2° long. yr^{-1}. From the palaeomagnetic records it is well known that the Earth's dipole field has a rich history of wanderings and polarity reversals. The irregular and unpredictable switching of the geodipole occurs with varying frequency, a rate of several reversals per Myr being typical of the past 200 Myr.

Geomagnetic secular variations are an important source of information about the Earth's deep interior and the dynamo presumed responsible for the geomagnetic field[4-6]. Within the context of modern dynamo theory, secular variations can provide constraints on material properties deep within the planet's otherwise inaccessible interior. Comparative studies of planetary dynamos may prove invaluable in unravelling the complexities of the self-sustaining dynamo. Thus the history of Jupiter's planetary magnetic field is of great interest, especially because it represents the first real opportunity to observe secular variations of a planetary dynamo other than the Earth's.

Indirect observations of the jovian magnetic field began with the discovery of non-thermal radio emissions by Burke and Franklin[7] in 1955 and are still in progress[8]. Continued observations of jovian radio emissions have precisely established the rotation rate of the planet and have suggested the occurrence of secular variations of the jovimagnetic field. Berge[9] has suggested that the 30% decrease in Jupiter's integrated flux density occurring from 1961 to 1973 may be a result of a decrease in the jovian magnetic dipole moment. An upper limit on the variation of magnetic field strength between epochs 1967 and 1970 of ~5% yr^{-1} was obtained from observations of the circular polarization of decimetric radiation[10]. From observations of the maximum frequency of jovian decametric radiation, J. K. Alexander (personal communications) concludes that the magnetic field magnitude at high northern latitudes has changed by <0.1% yr^{-1}. Observations relating to the inclination of the jovidipole with respect to the planet's rotation axis have been interpreted as evidence of a secular decrease of the inclination angle by $0.07 \pm 0.05°$ yr^{-1} (ref. 10) but have not been confirmed[11].

In situ observations of the jovian planetary magnetic field are limited to the Pioneer 10 and 11 flybys at epochs 1973.9 and 1974.9 and the Voyager 1 and 2 flyby encounters at epochs 1979.2 and 1979.5. Comparison of spherical harmonic models of the jovimagnetic field obtained from the Pioneer observations[12] suggested a decrease in the dipole moment of ~6% during the intervening year. The decrease was, however, attributed to other effects although the possibility of a secular change as large as 6% per year was explicitly not excluded[13].

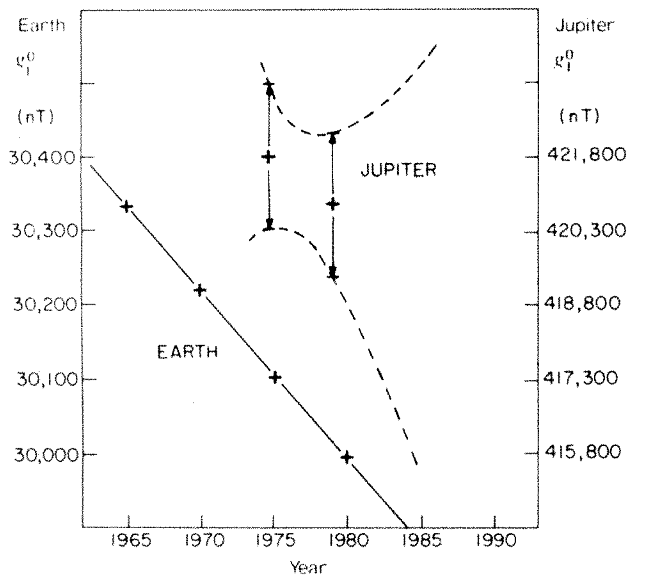

Fig. 1 Secular decrease of the Earth's main dipole g_1^0 term compared with estimates of Jupiter's main dipole term. One vertical division represents ~0.033% of the main dipole term in each case.

* Ref. 1. † Ref. 2 rotated to 1965 system III. ‡ Ref. 16. § Ref. 12 rotated to 1965 system III.

A preliminary jovimagnetic field model based on Voyager 1 observations[14] yielded a similarly reduced dipole moment attributed not to a secular decrease of the jovian field but rather to the presence of a large-scale current system in the jovian magnetosphere. This azimuthally directed 'magnetodisk' current is confined to an equatorial annular disk extending from ~5R_J (jovian radii) to >50R_J (ref. 15) and appears to be a permanent feature of the voluminous jovian magnetosphere. The relative contribution of this ~3×10^8 A current system to the magnetic field observed by Voyager 1 near closest approach is greater than that of previous flybys by virtue of the larger periapsis of the Voyager 1 encounter (4.9 R_J) relative to those of Pioneer 10 and 11 (2.8 and 1.6 R_J).

A more recent estimate of the jovimagnetic field has been obtained from the Voyager 1 observations[1] through the use of new modelling and inversion techniques[16] which facilitate the separation of externally generated fields from those generated within Jupiter's core. The Schmidt normalized spherical harmonic coefficients of this recent Voyager 1 internal field model are listed in Table 1 along with some previous estimates obtained from the Pioneer 11 vector helium[12] and fluxgate magnetometer observations[2]. The parameters which have no corresponding entry in the V1 list are not determinable from the Voyager 1 magnetic field observations alone and are therefore not available at epoch 1979.2. There is general agreement among the Pioneer 11 and V1 models, and the correspondence between the dipole terms of the V1 and O$_4$ models is particularly good. Here we consider only a comparison of the V1 and Pioneer 11 O$_4$ model parameter estimates and the associated estimated parameter uncertainties (in parentheses in Table 1). (Davis and Smith[13] estimate that uncertainties in the dipole terms of the SHA 23 model quoted in Table 1 are as large as 5% of the g_1^0 term, that is, ~0.2 G. They estimate that uncertainties in the quadrupole and octupole terms range from 0.2 to 0.8 G. Since these uncertainties are approximately an order of magnitude greater than those estimated for the O$_4$ and V1 models we do not consider the SHA 23 model.)

In Fig. 1, the time dependence of the magnitude of the g_1^0 coefficient for both the Earth[17] and Jupiter are compared, scaled such that a major division represents ~0.33% of the field magnitude. A linear fit to the jovian g_1^0 estimates shown in Fig. 1 is

$$g_1^0(t) = 4.218\ (\pm 0.015) - 0.0023\ (\pm 0.0050)t \qquad (1)$$

where g_1^0 is given in G, and t is the time difference in yr from

1974.9. No significant secular variation of the magnitude of the g_1^0 term is found. The observations are consistent with a modest secular increase of ~0.06% yr (at 1 s.d. in the rate) or a decrease of as much as ~0.17% yr^{-1}. For comparison, the observed secular decrease of the magnitude of the Earth's g_1^0 term is ~0.075% yr^{-1}. The dashed lines in Fig. 1 correspond to a 1 s.d. error in an estimate of g_1^0 calculated using equation (1), illustrating the deterioration in predictive capability for epochs far removed from the 1977 median epoch.

A comparison of the two remaining dipole terms g_1^1 and h_1^1 leads to a negligible inferred drift of the magnetic dipole axis of 0.025° (±0.22) yr^{-1} in longitude. The estimated uncertainty in the drift rate is comparable with the uncertainties in Jupiter's rotation rate[18]. The inclination of Jupiter's dipole axis has decreased by an insignificant ~0.01° (±0.03) yr^{-1}. These conclusions are not substantially altered if an alternative model[16] derived from the Pioneer 11 fluxgate magnetometer observations is used in place of the O_4 model. The uncertainties quoted here are largely the result of uncertainties in the position of the dipole axis at epoch 1974.9. Some of the V1 quadrupole and octupole parameters (in particular the g_2^0, h_2^1, g_3^2 and h_3^2 terms) depend on the details of the model used to represent the jovian magnetodisk currents[1,15] and therefore we will not discuss higher order terms at present.

The *in situ* magnetic field observations are consistent with no secular variation of the jovimagnetic dipole field from 1974.9 to 1979.2. They are also consistent with a modest Earth-like secular variation in both the magnitude of the main dipole g_1^0 term and the drift of the dipole axis in longitude. Earlier suggestions of relatively large secular variations in the dipole moment and inclination[10] are thus not substantiated. Current theoretical estimates of jovimagnetic secular variations based on free hydromagnetic oscillations of the liquid core[19] range from days to centuries. Assuming the Voyager 1 and O_4 models do not represent a chance agreement of two samples of an aliased time sequence, jovimagnetic secular variations must have a time scale of centuries and not decades. It is also clear that the differences in the Pioneer 10 and 11 internal field models reflects more the influence of unmodelled current systems than a real secular variation of the jovimagnetic field. Estimates of the size of Jupiters' conducting core[20] based on Hide's method[21] and the large secular variations inferred from the Pioneer models need to be critically reassessed.

Finally, the methods used to obtain an estimate of the jovian internal field from the Voyager 1 observations[1] should be equally applicable to flybys planned for the near future with similarly large periapses. A similar determination of Jupiter's internal field from either the International Solar Polar Mission (to ~6 R_J) in 1987 or the Galileo encounter (~5 R_J) scheduled for ~1990 could in principle distinguish between an Earth-like and no secular variation of Jupiter's main field.

Molecular relaxations in a glass of cholesteric liquid crystal

G. P. Johari*, J. W. Goodby & G. E. Johnson

Bell Laboratories, Murray Hill, New Jersey 07974, USA

Glasses, in which the orientations of molecules have a long-range order, can be obtained by supercooling the mesophases of liquid crystals. Such mesophases may be: (1) nematic, when the centres of their rod-, or lath-like molecules do not lie on a regular lattice, but there is a long-range order in the alignment of their long axes, called the director; (2) cholesteric (or twisted nematic) when the alignment (due to steric asymmetry of the individual molecules) of the nematic type is such that the local director rotates at a steady rate as one moves normal to it; and (3) smectic, when there is also a partial ordering in the positions of the molecules in planes related to the local direction of orientational order. The situation in the nematic and cholesteric phases is clearly akin to magnetic ordering and the glassy states of these phases are useful, as our models of disorder, in understanding the behaviour of structurally isotropic glasses. A study of molecular motions in the glassy cholesteric phase of cholesteryl hydrogen phthalate, given here, shows features which have a striking resemblance to those observed in the (positionally ordered) glass-like state of plastic crystals[1,2] and the (grossly disordered) molecular and polymeric glasses. This suggests that the characteristic features of the molecular motions in glasses must be explained in terms of the non-equivalence of the molecular environment, rather than in terms of the complexity of the molecule, its internal degrees of freedom, or the state of aggregation. This has implications for our concept of the microstructure of a glass.

Cholesteryl hydrogen phthalate melts to an isotropic liquid at 431 K. The liquid readily supercools and undergoes an isotropic→cholesteric transition at 367 K. On further cooling the turbid cholesteric phase becomes increasingly more viscous and undergoes a glass transition at 297 K, as indicated by differential thermal analysis. In the cholesteric phase[3] the alignment of the molecular axes has a long-range order as in a nematic phase, but this order is restricted to within the plane and each subsequent plane has molecular orientations (or local director) twisted by an angle of <1°. Thus the arrangement acquires a helical pattern with the optical axis coincident with the helical axis, which is normal to the planes. Measurements were made on unoriented samples contained in a parallel-plate, three-terminal dielectric cell whose temperature was controlled from 77 to 440 K. The distance between the highly polished surfaces of the electrodes was ~2 mm and the strength of the electric field was 20–25 V cm^{-1}. The cholesteric phase between the electrodes had no preferred orientation; the symmetry of the sample was helical over distances of, say, a few micrometres and spherical over longer distances, because the order induced by the surface of electrodes extends to a distance of a few hundred micrometres, and thus the helical axes for the domains may assume all possible orientations. The capacitance and conductance, or dielectric loss factor, were measured from 0.1 to 100 Hz, using a low-frequency bridge[4], and from 10^2 to 10^5 Hz, using a GR 1615A capacitance bridge. No change in capacitance or conductance occurred with a change in the electric field strength from 2.5 to 25 V cm^{-1}.

The dielectric loss tangent, tan δ, at 1 kHz of the supercooled and glassy cholesteric phase is plotted against temperature in Fig. 1. The two peaks are due to molecular relaxations, in the supercooled liquid at 321 K and in the glass at 155 K whose

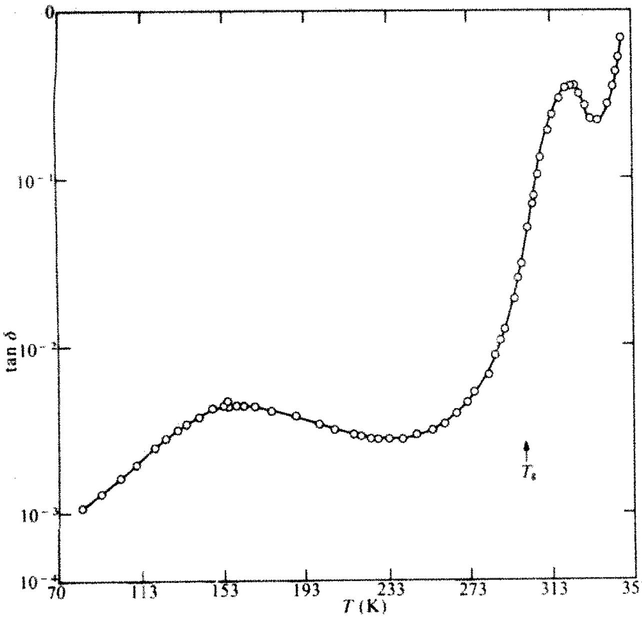

Fig. 1 The dielectric loss factor, tan δ, at 1 kHz of the unoriented samples of cholesteric phase of cholesteryl hydrogen phthalate in the supercooled liquid and glassy states plotted against temperature. T_g is the calorimetric glass transition temperature.

rates correspond to the frequency of 1 kHz. These are referred to as main and secondary relaxations respectively. The presence of a secondary relaxation indicates that, even in the otherwise rigid matrix of a cholesteric glass, configurational states which involve changes in the electric polarization are available to the structure. The lower magnitude of its dielectric loss, or orientation polarization, also suggests that either the number of molecules contributing to the secondary relaxation and/or the dipole moment associated with the molecular reorientations is much lower than that in the main relaxation.

The spectrum of the main relaxation in a frequency plane is asymmetric and is broader at the high-frequency than at the low-frequency side of the peak. The half-width of the peaks is ~2 decades of frequency, which is significantly higher than 1.14 decades characteristic of a single Debye-type relaxation. The spectrum of the secondary relaxation given in Fig. 2 is also broad. Here the half-width of the peaks increases from 4 decades at 190 K to 5 decades at 139 K. Thus both the main and secondary relaxations have a distribution of relaxation times, but the distribution changes significantly with temperature only for the latter. The relaxation rates, which are given by the frequency, f_m, of the peaks in the spectrum, are plotted logarithmically against the reciprocal temperature in Fig. 3. The rate of the main relaxation follows the Vogel–Fulcher–Tamman equation of the type, $f_m = A \exp(-B/(T-T_0))$, where A, B and T_0 are empirical contants. The extrapolated relaxation rate at the calorimetric T_g (= 297 K) is $10^{-4}\ s^{-1}$. Thus the molecular degrees of freedom causing the dielectric relaxation of the cholesteric phase are undoubtedly the ones whose freezing out causes the decrease in the heat capacity at T_g. The rate of the secondary relaxation in Fig. 3 follows the Arrhenius equation, $f_m = f_0 \exp(-E/RT)$. This gives an activation energy, E, of 19.8 kJ mol^{-1} for the molecular processes in the cholesteric glass.

The aforegiven features of both the main and secondary relaxations in the cholesteric liquid crystal are strikingly similar to those observed in amorphous polymers[5,6], rigid molecular glasses[7] and orientationally disordered crystals[2]. This similarity suggests that the potential energy barriers resisting the molecular motions, whose freezing out causes the glass transition, are independent of the internal degrees of freedom and the state of aggregation of molecules, and that the molecular mobility is intrinsic to the nature of the glassy state.

In terms of the models for the structure of a glass, which involve dense random packing[8,9], microcrystals[10], dislocations[11–14], mixed clusters of competing polymorphs[15,16], disclinations[17] and dislocations[18], the secondary relaxation may arise from hindered rotations of molecules in localized regions of loose molecular packing[19] (referred to as 'islands of mobility') bounded by the relatively immobile close-packed structures. The localized regions may consist of the interstitial packing[20] between the amorphous clusters, or polyhedra, if the structure of a glass consists of regions of varying molecular density. In such a case only a fraction of the total number of molecules in a glass may contribute to its secondary relaxation. Although such localized regions may exist due to the freezing-in of the short range structures corresponding to the density fluctuations in the liquid at T_g, it is also believed that the secondary relaxation indicates small angle movement of each molecule[2] in the essentially equivalent molecular environments of a dense random packed structure of a glass. In this case all molecules in a glass contribute to the relaxation but each by a small amount.

Owing to the nature of the packing of the rod- or lath-like molecules fewer regions of relatively loose structure would exist in a glass obtained from a cholesteric liquid than in one obtained from an isotropic liquid. Consequently, the magnitude of tan δ in the secondary relaxation relative to the main would, in general, be lower in the former than in the latter type of glass. But, if the small angle movement of all molecules were responsible for the secondary relaxation, as is expected in the dense random packed structure of a glass, the aforementioned relative magnitude of tan δ would be similar in the two types of glasses. The ratio of maximum tan δ at 1 kHz of the secondary to the main relaxation in Fig. 1. is 1 : 58 in the cholesteric glass, which is much lower than the corresponding ratio of 1 : 10 or less, observed in most molecular[2,7] and polymeric glasses[5]. Therefore, the secondary relaxation is likely to be associated with the regions of relatively loose interstitial packing in the strucure of a glass.

These results are significant for our understanding of the molecular processes in disordered solids, for it seems that the features of molecular motions in them must have their origins in the non-equivalence of the molecular environment, rather than in the complexity of the molecules, their internal degrees of freedom, or the state of their orientational or positional disorder. The results also support a model for the structure of a glass as an assembly of polyhedra connected by loose interstitial packing, where molecular motion is possible even when the polyhedra are fixed in place. Because supercoooled thin

films of cholesteric glass in our experiments are found to be anisotropic, we maintain that the polyhedra in the structure are not microcrystals or crystal nuclei arrested in various stages of their growth, for a random arrangement of such polyhedra would produce a macroscopically isotropic, not anisotropic, structure.

The results have a further implication for our understanding of the glass transition in metal alloys and of the computer simulation of hard sphere glasses, for the configurational restrictions that lead to the formation of a glass in a mesomorphic phase involve mainly the positions (centres of mass) of the molecules and not the orientations or the local director, as no change in the order parameter occurs at T_g. In this respect the glass transition in them is similar to the glass transition in metallic alloys and in the computer simulated experiments on aggregates of hard spheres, where the choice of spheres precludes the possibility of an orientational disorder.

A 2-D model calculation of atmospheric lifetimes for N_2O, CFC-11 and CFC-12

Malcolm K. W. Ko & Nien Dak Sze

Atmospheric and Environmental Research, Inc.,
840 Memorial Drive, Cambridge, Massachusetts 02139, USA

Accurate values for the atmospheric lifetimes of N_2O, $CFCl_3$ (CFC-11) and CF_2Cl_2 (CFC-12) are vital[1–3] for studies of their life cycles and in attempts to forecast their future atmospheric levels. These gases are known to be removed mainly by stratospheric photolysis. The lifetimes set by these removal processes are usually inferred from one-dimensional (1-D) models. Using a two-dimensional (2-D) zonal-mean model together with recent observations, we argue here that the stratospheric removal rates may also depend on certain latitudinal features, including latitudinal variations of the gas concentrations, photolysis rates and their correlations, features that cannot be included in the 1-D models. Our discussion also considers the validation of 1-D model results, particularly regarding predictions of atmospheric lifetimes.

The atmospheric lifetime (τ) of a trace gas in steady-state condition can be defined as

$$\tau = \frac{\langle \text{global burden} \rangle}{\langle \text{global removal} \rangle} = \frac{\langle \int fN \, dv \rangle}{\langle \int LNf dv \rangle} \qquad (1)$$

where N is the air number density, f and L are the steady-state volume mixing ratio and loss frequency of the trace gas respectively, and the bracket represents an annual average over time. For gases like CFC-11 and CFC-12 which have not yet attained their steady-state concentrations in the contemporary atmosphere, one may also define a present state lifetime by the ratio of the current burden to current removal rate[4]. This lifetime is in general time dependent and may differ from the steady-state lifetimes defined by equation (1). (Unless stated otherwise, the term 'lifetime' here will refer to the steady-state lifetime.)

The global burden of N_2O, CFC-11 and CFC-12 may often be estimated from the observed concentrations at a few ground stations because the bulk of these gases reside in the troposphere where they are well mixed[2]. The calculation of the global removal rate is, however, less straightforward as it involves the integral of the product of f, L and N. The major contribution to the integral arises from the stratospheric region where the quantities f, L and N vary significantly with altitudes and latitudes. A common approach is to approximate the integral (which may be interpreted as a spatial and temporal average of the product) by the product of the corresponding averaged quantities. This approach clearly ignores the correlation between the quantities f, L and N and hence its contribution to the integral. The neglect of this correlation may introduce significant errors[5,6] in the calculation of certain reaction rates. We now show that the global removal rate depends not only on the vertical structure of f, L and N in the stratosphere, but also on their latitudinal distributions and correlations.

Three approaches are used to determine the atmospheric lifetimes of the above gases. The first requires empirical knowledge of the source strength and burden. The second approach is to calculate the global removal rate in equation (1) with the spatial distribution of f constructed from available field data, an approach used by Johnston *et al.*[7] in their analysis of N_2O budget. The limitation of these two approaches is that an extensive set of global data is often needed.

In the absence of sufficient data coverage, one must resort to the third approach which uses models to calculate f and τ while using the limited amount of observations to validate the computed gas distributions. A favourable comparison between calculated and observed f may be used as support for the predicted lifetime.

Among the hierarchy of models, the 1-D models are most

0028–0836/82/210317—03$01.00

widely used[1,2]. The problems with 1-D models concern the interpretation of their simulated vertical profiles which are considered to represent some sort of global longitudinal and latitudinal averages. Strictly, 1-D model results should be compared with the observed global averages defined by a large set of spatial and temporal data. Acquisition of such a data set for any trace gas is clearly an enormous task. Even if such global data are available, difficulty still remains in the assessment of the 1-D model predicted lifetimes. Specifically, the global removal rate calculated using the 1-D vertical profiles of f, L and N may still be in error due to the neglect of the zonal and latitudinal correlation between f and L even if the calculated profiles agree with globally averaged observations.

Recent data on N_2O, CFC-11 and CFC-12 (refs 8–14) show that at each given altitude above tropopause, higher concentrations are always found in the tropical stratosphere, a region where the solar UV radiation which dissociates the gases is most intense. Thus, the contribution from the covariance of f and L to the global removal rate could be significant. To account for the covariant effect, multi-dimensional models are needed.

Ideally, a three-dimensional (3-D) model should be used in the lifetime calculation as the spatial and temporal correlations between different quantities (such as L and f) appearing in equation (1) can be properly treated in the integrals. A 3-D study for N_2O has been made by Levy *et al.*[15]. The main disadvantage of using a 3-D model is that it uses a lot of computer time.

The distribution of f calculated from the 2-D zonal-mean model is representative of the zonal average concentrations. If one assumes that the zonal deviation of f is small, the global removal rate can be accurately approximated by integrating the product of the zonal-mean f and zonal-mean L. This assumption is supported by 3-D model simulation of the N_2O distribution[15], and seems to be appropriate for CFC-11 and CFC-12. We shall now use a 2-D model to demonstrate that the latitudinal covariance often exists and may not be negligible for gases such as N_2O, CFC-11 and CFC-12.

Figure 1 shows the N_2O observations[8–14] at different latitudes together with profiles from our 2-D model[16]. Both the data and the model reveal significant vertical as well as latitudinal variations in the N_2O mixing ratio. The overall agreement between model and observation is good.

Figure 2 shows the model calculated column removal rate of N_2O as a function of time and latitude. Note the strong latitudinal gradient, a feature reflecting the important effect of the latitudinal variations in local concentration and local solar flux. During spring and autumn, the maxima occur around the Equator, whereas during summer and winter, they occur about 15° above and below the Equator respectively. Our calculation shows that the net contribution to the global removal rate from the covariance of f and L is positive. The annual average column removal rate for N_2O is 1.2×10^9 molecules cm^{-2} s^{-1}. With a calculated column abundance of 6×10^{18} molecules cm^{-2}, a lifetime of 159 yr is derived. This value may be compared with values of 175 and 150 yr calculated by Johnston *et al.*[7] and Levy *et al.*[15] respectively.

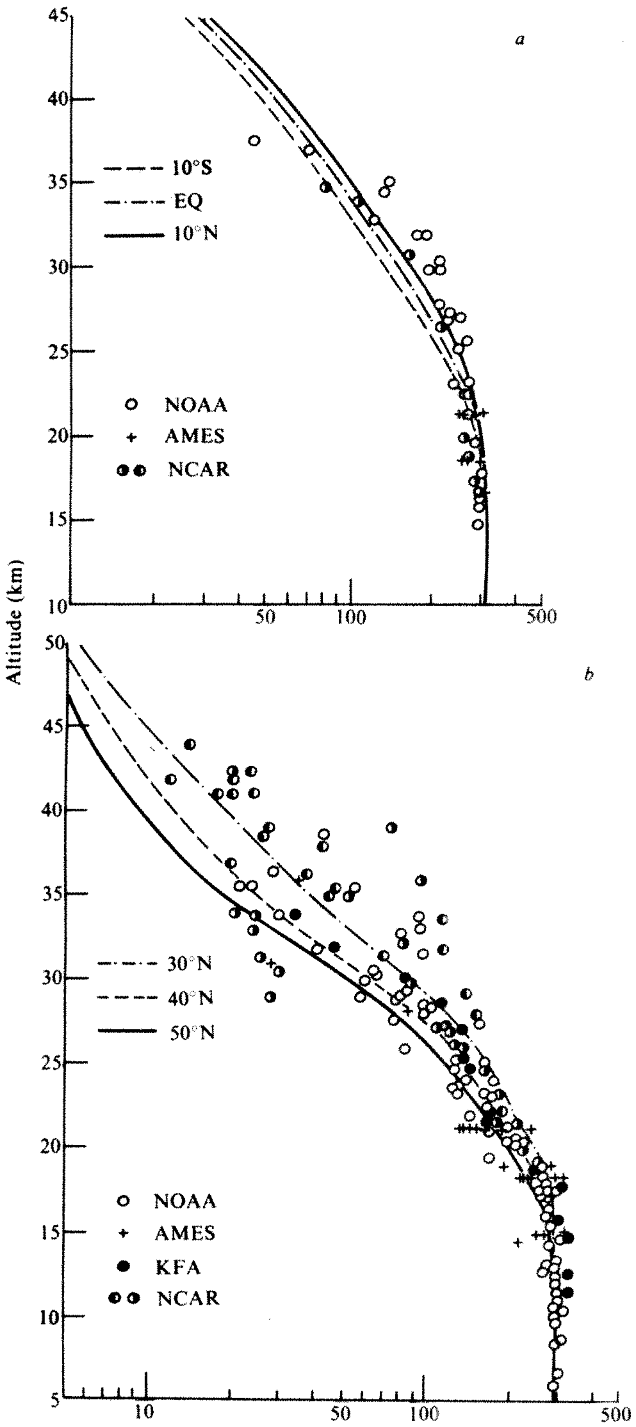

Fig. 1 Calculated N_2O profiles together with observations for equatorial (*a*) and mid-latitude (*b*) regions. The profiles are calculated using the 2-D zonal-mean model described in ref. 16. Dynamic transports in the model are simulated by advection from zonal-mean wind plus eddy transport parameterized by a symmetric eddy diffusion tensor. The wind fields are from ref. 20, while the values of the eddy diffusion tensor are from ref. 21. The reaction rates are from the NASA-WMO Workshop recommendations[18]. A temperature-dependent absorption cross-section[22] is used to calculate the N_2O photolysis rate. A uniform boundary value of 300 p.p.b.v. at the ground is assumed for the calculation. The data shown are reported by groups from NOAA[8,9] NASA–Ames[10–12], KFA[13] and NCAR[14].

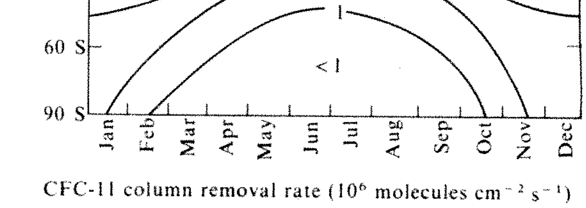

Fig. 2 Calculated N_2O column removal rate as a function of latitude and time of the year.

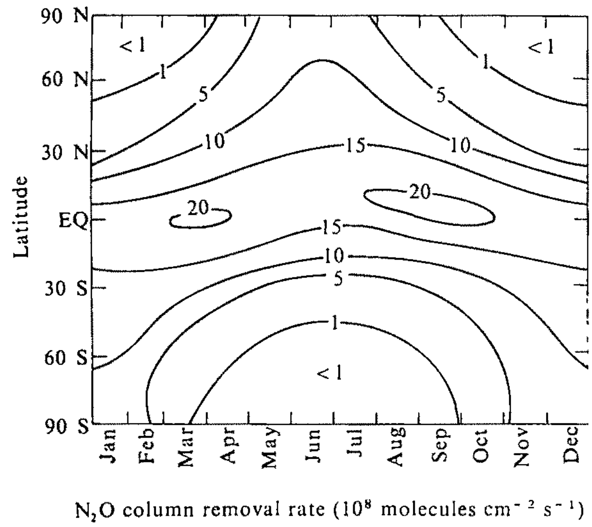

Fig. 3 Calculated CFC-11 column removal rate as a function of latitude and time of the year. The model simulation was performed using a boundary value of 1 p.p.b.v. at the ground.

We have also calculated the lifetimes for CFC-11 and CFC-12 using a steady-state simulation. Direct comparison of the calculated gas distributions of this model simulation with observations is not possible as the gases have not attained the steady-state concentrations in the present atmosphere. As an alternative, the computed CFC-11 and CFC-12 distributions corresponding to the year 1979 of a model simulation using known release rates[17] can be compared with the available observations[8-14]. Agreement is reasonably good for CFC-11 and CFC-12 at the Equator but poor at mid-latitudes[18]. The calculated mid-latitude CFC-11 and CFC-12 mixing ratios above 25 km are higher than the observations by about a factor of 2–4. The discrepancy could be due to either the error in the photolysis rates or error in the transport coefficients. The column removal rate of CFC-12 has features very similar to that of N_2O (Fig. 2). For CFC-11, the latitudinal gradient of the removal rate is stronger as shown in Fig. 3. The calculated lifetimes are 65 and 135 yr for CFC-11 and CFC-12 respectively.

The corresponding 2-D model calculated lifetimes reported by Hinds[19] are 81 and 182 yr and those from the Oxford University model[3] are 78 and 133 yr respectively. Direct comparison of these values with our calculated values is difficult because it is not clear whether the values reported correspond to steady-state lifetimes.

Note that the calculated lifetimes given here also depend on model structure, such as parameterization for transport and treatment of photochemistry. The question of whether these calculated values truly represent the actual atmospheric lifetimes can be answered only following further validation of the corresponding calculated distributions using more observational data and improvement in transport and chemical data. However, we believe that the latitudinal behaviour of the column removal rate simulated by the 2-D model is qualitatively correct and that the positive correlation between the latitudinal variation of f and L should not be ignored.

Although 1-D models are still the most widely used diagnostic and prognostic tools in stratospheric research, two limitations should be noted with regard to their lifetime predictions: first, their inability to incorporate the covariance effects discussed here; second, and more problematic, the inherent difficulty in validating their lifetime predictions using field data. Our discussion points to the fact that, even for a fully validated 1-D model in which the calculated profiles agree with global average observations, the model may still underestimate the global removal rate and, therefore, overestimate the lifetime because of its inability to account for the positive contribution from the covariance of f and L. With a modest increase in computer time, 2-D models, on the other hand, can simulate the latitudinal and seasonal variations of atmospheric species as well as the solar insolation and may therefore be useful in refining the lifetime estimates calculated by 1-D models. In light of the above discussion, a combination of selective field data and a validated 2-D model appears to be the best approach to obtaining more accurate lifetime estimates. Obviously, 2-D models are still in a developmental state, and more atmospheric data are needed for further validation and improvement.

We thank Bruce Lane and Ronald Prinn for useful discussion on the possible difference between present-day and steady-state lifetime, John Pyle for providing the dynamical framework of our zonal-mean model, and P. B. Ryan for analysis of the 2-D model calculations. Research supported by Chemical Manufacturers Association and the Air Force Geophysics Laboratory under contract F19628-81-C-0016.

Position of the Lhasa block, South Tibet, during the late Cretaceous

Jean-Pierre Pozzi*, Michel Westphal†, Yao Xiu Zhou‡, Li Sheng Xing‡ & Xian Yao Chen‡

‡ Chinese Academy of Geological Sciences, Bai Wan Zhuang Road, Beijing, People's Republic of China

The latitude of the Lhasa block (Xizang, South Tibet) during the late Cretaceous–early Tertiary is of prime importance for understanding the collision of India and Eurasia and the mechanism of the formation of the Qinghai–Xizang plateau. During the first field expedition of the French–Chinese collaboration, several geological formations have been sampled in southern Tibet between Lhasa (29.40° N; 91.09° E) and Dingri (28.35° N; 86.38° E). We present here the first results obtained for middle Cretaceous to Palaeocene red beds from the Lhasa block, north of the Yarlung–Zang Bo suture zone, recognized as the main suture between the Indian and the Eurasian plates. They indicate a palaeolatitude of the Lhasa block of 20° N during the late Cretaceous while India was situated 30° S.

0028–0836/82/210319—03$01.00

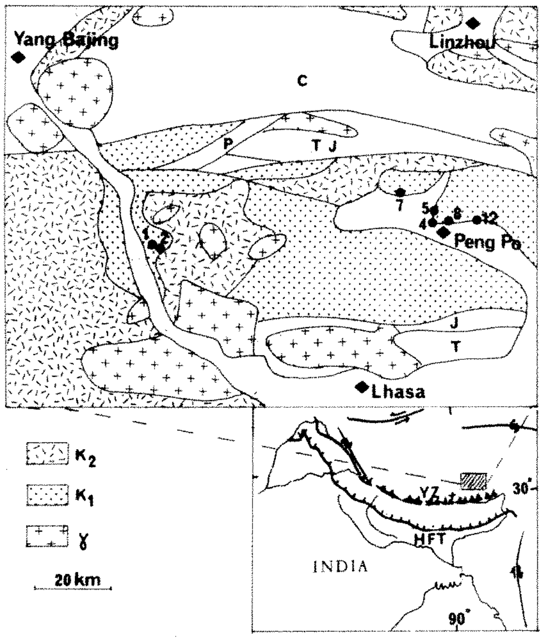

Fig. 1 Geological outlines of the Lhasa region: C, Carboniferous; P, Permian; T, Trias; J, Jurassic. K_1, Takena Formation and lower-middle Cretaceous; K_2, Lingzizong Formation; γ, granitic intrusives. Redrawn from geological map of Lhasa–Nyalam Area (Academia Sinica). YZ, Yarlung Zang Bo suture zone; HFT, Himalayan Frontal Thrust.

The geological formations that we sampled were red beds from Linzhou basin. Continental sediments are present all over the Tibetan plateau and particularly in the Linzhou basin north-east of Lhasa (Fig. 1) where they are represented by two formations separated by a major unconformity. The rock lying under the unconformity is Takena Formation of middle to late Cretaceous age, mainly consisting of sandstone, limestone and shale, strongly folded and with a total thickness of ~1 km. Volcanics (andesite and dacite) are interbedded at the base of this formation. Above the unconformity, Lingzizong Formation of late Cretaceous age mainly consists of black shale in its lower part and red sandstone often conglomerate upwards. A thick sequence of greyish-blue andesite overlays the Lingzizong Formation. Red sandstones of the Takena Formation were sampled (Fig. 1) at sites 1, 2, along the road Lhasa–Yangbajin and at sites 4, 5, 7, 8, 12 near Linzhou (Peng Po Farm).

Samples were taken with a portable drill or as block samples, and were oriented with magnetic and solar compass. Individual sites were sampled laterally over 50–100 m and vertically over 10–20 m.

The measurements were done in Paris and Strasbourg on standard 25-mm cores using either a Schönstedt or a Digico Spinner magnetometer. The two series of measures were cross checked. Samples were demagnetized by step heating and cooling in a zero field (better than 20 nT). The different magnetic components were analysed using the classical Zijderveld vector diagram method.

Thermal cleaning shows the presence of two magnetic components in approximately half of the samples. One is eliminated after heating at 400–500 °C and does not show a clear mean direction. The other is only broken down above 650 °C and is usually the last component. The directions of this component are well grouped. Other samples show only one direction eliminated above 650 °C. Before tectonic correction, the mean directions are generally different from the present field.

Table 1 shows the results before and after tectonic corrections. k increases from 7.3 to 35 by a factor of 4.8. Statistical tests have been used to estimate the validity of the fold test. McElhinny's test[1], which is very stringent, is positive at 95% significance level. McFadden and Jones[2] devised another test but this was difficult to use when each site had a different tectonic setting. We can confidently conclude that the fold test is positive and that the magnetization predates the late Cretaceous–Palaeocene folding phase.

In site 7, four specimens are of normal polarity while seven are inverse, the two directions being antiparallel. The presence of normal and reverse polarity in site 7 of red and green sandstone also argue for a primary origin of the hard component of magnetization.

Nevertheless, against the strong technical arguments for primary origin, one has to consider (Fig. 2) that before bedding correction, the virtual geomagnetic poles (VGP) for sites 1, 2, 4, 5, 8 and 12 are not significantly different (C. T. Klootwijk, personal communication) from the apparent polar wander path (APWP) for India. In the Linzhou basin, tectonic movements of comparatively little amplitude occurred after the main late Cretaceous–early Tertiary folding phase. VGP from site 7 with

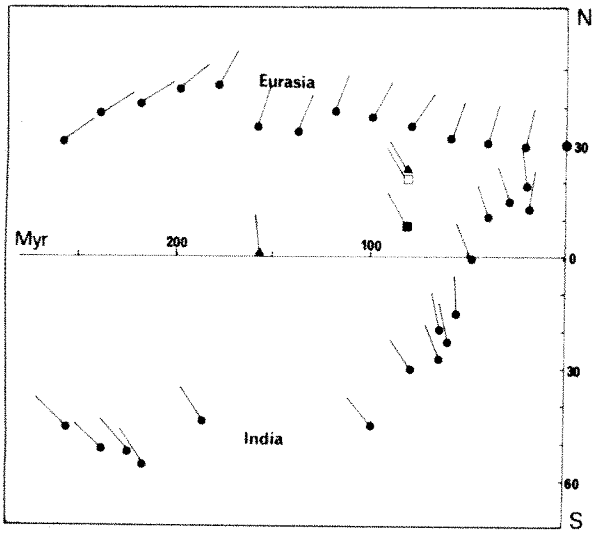

Fig. 3 Palaeolatitude and palaeoorientation of a point now in Lhasa as if it were bound to Eurasia (upper curve), or as if it were bound to India (lower curve). Recalculated from ref. 5 and from refs 6, 7. □, Results from this paper; ▲, results from ref. 4; ■, results from ref. 3.

both normal and reverse layers is different from the APWP of India. Although only a few sites are considered here, it seems that VGPs from site 12, from sites 1 and 2 and from sites 4 and 5 correspond respectively to periods of 65, 50 and 25 Myr on the APWP for India, the two last being critical periods for remagnetization. This could argue for a remagnetization of these formations, when the Lhasa block collided with India. If remagnetization occurred, other methods of investigations will be necessary to decipher the magnetization, or other types of formations should be used to assess the palaeolatitude of Lhasa block; useful conclusions can then be deduced from overprinted components concerning the latitude of the collisions, but it will be difficult to explain how three phases of remagnetization have affected, first site 12, then sites 1 and 2 and possibly sites 4, 5 at 65–50 Myr in a near equatorial latitude, and finally at higher latitude site 4, at 25 Myr.

Until now, the positive fold test has led us to conclude that a complete remagnetization probably did not occur and that the results give a good approximation of the position of the Lhasa block during the Cretaceous.

Chinese palaeomagneticists have done several studies in Xizang, only a few of which have been published. Zhu Xiang Yuan *et al.*[3] have sampled the Takena red beds probably not far from site 4 (the Yayong hill near Peng Po farm). A few samples were a.f. demagnetized up to 30 mT and do not show any directional change. The result given is based on natural remanent magnetism measurements and is dip corrected.

A more extensive study has been published by Zhu Zhi Wen *et al.*[4] over Xizang. Results concerning the Lhasa block are on red beds from Takena (Lhasa cement mill). All samples were a.f. demagnetized up to 50 mT and the results corrected for tilt are given in Table 1.

Compared with the Chinese results for the Linzhou red beds, new results have been obtained on more widely distributed sites using thermal demagnetization techniques which are generally more effective for resolving multi-component magnetizations of red beds than are a.f. techniques. Indeed, a.f. demagnetizations performed on red beds by Zhu Zhi Wen and others leave 90% of the initial magnetization undestroyed at the peak field used (50 mT).

Figure 3 gives the palaeolatitude of Eurasia recalculated from ref. 5 and India from refs 6, 7 as a function of time, with the results of Zhu Zhi Wen[4] for Jurassic limestone and Cretaceous red beds. Arrows indicate declinations with respect to the north and show an anticlockwise rotation of the Lhasa block since the Jurassic. During the middle Cretaceous, the palaeolatitude of the Lhasa block was about 20° N. The results of Zhu Zhi Wen[4] indicate a near equatorial latitude during the Jurassic. These results confirm that the Lhasa block, which is of Gondwanan origin and has preceded northwards drifting India, was widely separated from India during the late Cretaceous and possibly during the Jurassic according to Zhu Zhi Wen results (Fig. 3). During the Cretaceous the northern edge of India was situated near 30° S and the southern margin of Asia probably not far from 30° N. As the palaeolatitude of the Lhasa block was about 20° N it is likely that the Tertiary convergence between South Tibet and India was much larger due to subduction and crustal shortening[8] than between South Tibet and Asia. The anticlockwise rotation of the Lhasa block (Fig. 3) probably occurred under the constraint of the anticlockwise rotation of northward moving India block.

Palaeoclimates at Lake Turkana, Kenya, from oxygen isotope ratios of gastropod shells

Paul I. Abell

Chemistry Department, University of Rhode Island, Kingston, Rhode Island 02881, USA

Climatic changes in the Plio-Pleistocene of East Africa during the evolutionary development of early man have been identified only in their broadest outlines. A variety of palaeontological[1–3] and geochemical[4] techniques have already been applied to the study of palaeoclimates in this area, but the use of stable oxygen isotope ratios, so helpful in marine palaeoclimatology, has not been fully exploited[5,6]. The frequent occurrence of well-preserved mollusc shells in the sedimentary column at Lake Turkana provides a sensitive oxygen isotope record, varying over a range of 7‰, which can be interpreted in terms of evaporative concentration of the heavier oxygen isotope in waters of the closed lake, alternating with isotopically lighter freshwater when the lake has been open. I report here the results of a study of the $^{18}O/^{16}O$ ratios of three species of gastropods from the sediments of the Koobi Fora region of Lake Turkana, and evaluate how the technique might be applied to the study of the palaeoclimates of other tropical lakes.

The sedimentary deposits of palaeo-Lake Turkana in northern Kenya are well known for their yield of hominid fossils[7] and artefacts[8] of early man. They also include numerous and varied land and freshwater fossils, including the frequent occurrence of well-preserved mollusc shells. A well-documented collection of these shells[9] provided the impetus and raw materials for this study. Among the 95 shell-bearing horizons recognized by Williamson in his study of the palaeontology of the Lake Turkana molluscs, some 36 contain the gastropods *Mellanoides tuberculata*, *Cleopatra ferruginea* and *Bellamya unicolor*. These three were chosen from among the ~20 species identified by Williamson because: (1) they occur in shallow water habitats and would be expected to be in good equilibrium with the surrounding water; (2) they are capable of living over a wide range of *p*H and concentrations of dissolved salts

0028–0836/82/210321—03$01.00

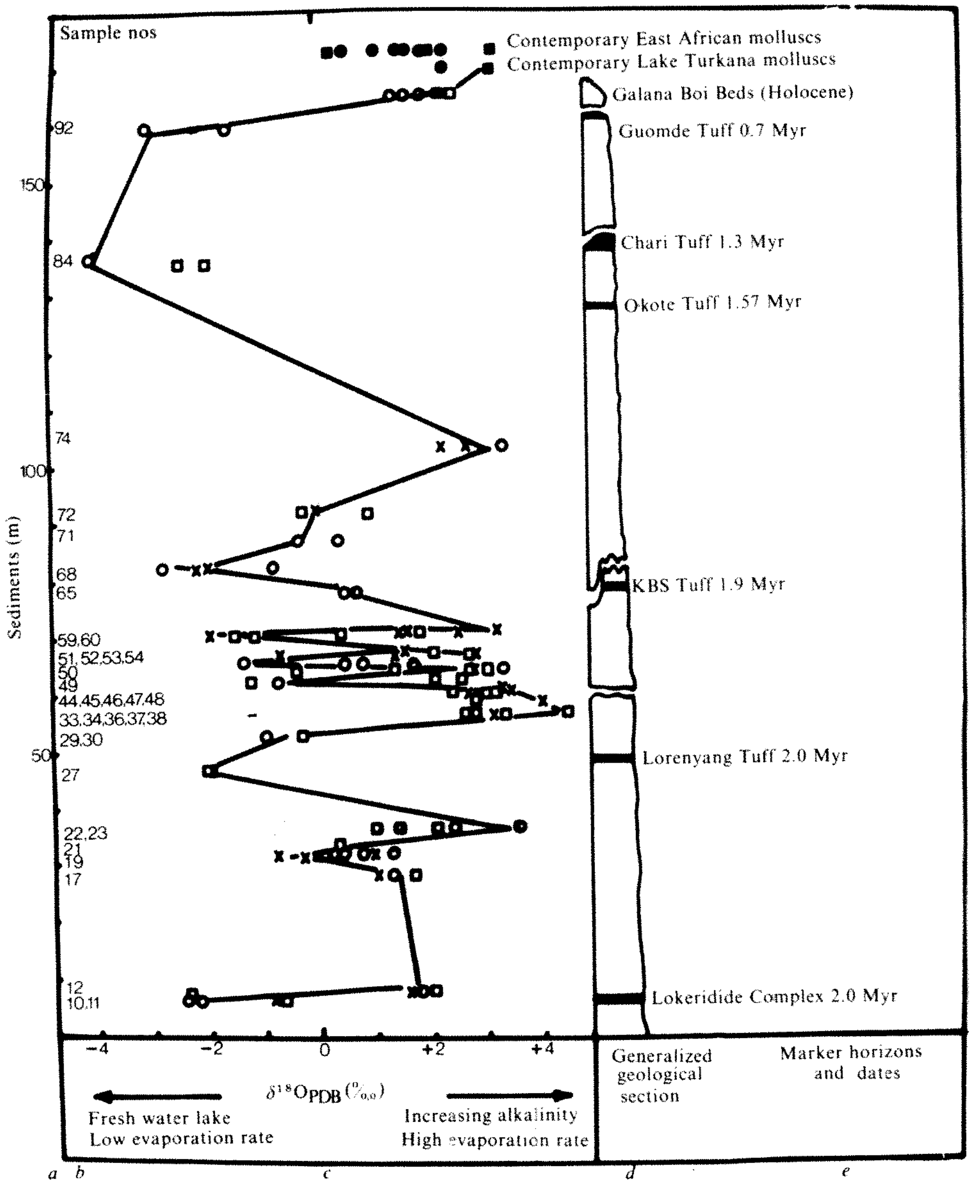

Fig. 1 Variation of $\delta^{18}O_{PDB}$ with stratigraphical level of the fossil molluscs in the Plio-Pleistocene sediments east of Lake Turkana, Kenya. *a*, Sediment depth. *b*, Molluscan stratigraphical levels. These levels were assigned by Williamson[3] and are numbered consecutively from the lowest and oldest horizon where shells are found, upwards. The stratigraphical levels cited include all those in which one or more of the three species of gastropods chosen for this study were found. *c*, $\delta^{18}O$ in ‰ versus the PDB standard. ×, Fossil *Cleopatra ferruginea*; □, fossil *Bellamya unicolor*; ○, fossil *Melanoides tuberculata*, all from the Lake Turkana sediments; ■, contemporary *Bellamya*; ●, contemporary *Melanoides*. In constructing the regression line, generally the most extreme values of $\delta^{18}O$ at each level were selected, representing the extremes of evaporative concentration of $H_2{}^{18}O$, or dilution by meteoric water. This emphasizes short-term extremes of climate over longer-term averages. *d*, Generalized geological section, with disconformities. *e*, Dated marker beds. The contemporary Lake Turkana gastropods came from delta areas near the Omo and Kerio Rivers. The stratigraphy and tuff marker bed correlations are described elsewhere[11,19,20]. Reproducibility for the isotope measurements was ±0.1‰ for multiple analyses of the same individual gastropod and generally better than ±0.5‰ for interspecies comparisons when more than one species was found at the same stratigraphical level.

(although *Bellamya* is more sensitive than the other two); (3) they frequently inhabit the same sedimentary horizon, and thus provide an intergeneric check on the isotope results; and (4) they are the most ubiquitous of the Lake Turkana molluscs, and are thus best suited to give a reasonably continuous climatic record.

Well-preserved specimens were selected and whole shells were ground to a powder and examined by X-ray diffraction for aragonite/calcite ratios. All results reported here are for shells of >90% aragonite. Oxygen isotope ratio measurements were made on a VG Micromass 602C spectrometer, the $\delta^{18}O$ values were calculated in the usual way and are reported here versus the PDB standard[10]. The results are shown in Fig. 1, together with various stratigraphical and sampling data. Details of collection sites, stratigraphy and palaeontology are given elsewhere[3,9,11], while locations and the sample numbers used in this study are recorded in Fig. 2. The results from the Williamson collection were supplemented by a few samples which I collected from the Galana Boi Beds (Holocene), and samples from the modern lake, obtained by dredging near the mouths of the Kerio and Omo Rivers. For comparison contemporary gastropod shells from Lakes Victoria, Edward, Albert and Kivu were analysed and their isotopic results included at the top of Fig. 1. Excursions of the oxygen isotope curve towards positive values represent evaporative regimes and indicate dry and/or hot climates. Excursions towards negative values represent non-evaporative conditions, and indicate cool and/or wet climates.

Note that a few of the climatic fluctuations in Fig. 1 are marked by a substantial range of isotopic values at the same stratigraphic horizon (for example, 59, 60), implying a substantial change in $\delta^{18}O$ with little change in lake level. A rapidly changing microenvironment is the obvious explanation, but no choice can be made among the many detailed scenarios that might produce such changes. These situations are, fortunately, few in number, and do not vitiate the principal trends.

The concentration of the heavier isotope of oxygen in evaporative regimes is well known[12,13] and has been studied over short time spans in both marine and lacustrine environments. The study by Fontes and Gonfiantini[14] on Saharan closed basins, Gara Diba Guelta and Melah Sebkha, is the most pertinent. However, the nearly idealized conditions of their study (limited to 1 yr on a basin with no further input of water or salts during that year) are difficult to extrapolate to Lake Turkana, which has existed for 10,000 yr as a closed basin since its last flushing[15], has had continuous but erratic input of water during that period, and been through a period of considerable volcanic activity by volcanoes actually in the lake, and has been subjected to widely different conditions of relative humidity during those years. Nevertheless, at Lake Turkana, the evaporative history can be deduced approximately because we have three known points defining the relationship between $\delta^{18}O$ and the increasing alkalinity of the lake. This relationship is shown graphically in Fig. 3. In temperate cool/wet climatic conditions, calcium carbonate precipitated from meteoric water has a range of $\delta^{18}O_{PDB}$ at about −5 to −4‰ (ref. 16), depending on the

prevailing temperature[17]. (A 5 °C temperature range, such as currently exists among East African lakes[18], is indicated by the crosshatched area of Fig. 3.) At Lake Turkana, the most positive $\delta^{18}O_{PDB}$ values for mollusc shells fall near +4‰, representing near extinction conditions (16 mequiv. l^{-1} of alkalinity). The present lake, with virtually all molluscs extinct except in areas immediately off the mouths of the Omo, Turkwell and Kerio Rivers, has an alkalinity of 22 mequiv. l^{-1} and a $\delta^{18}O_{SMOW}$ value of +6‰, would be expected to precipitate calcium carbonate with a $\delta^{18}O_{PDB}$ value of nearly 6‰ (ref. 16). Note that Fig. 3 is an approximation for palaeo Lake Turkana only, and a line of drastically different slope could result from similar constructions for other lakes, or even for Lake Turkana in different carbonate supply conditions. (Lake Baringo, $\delta^{18}O_{SMOW}$ = +8.43‰ and an alkalinity of 4.44 mequiv. l^{-1} (ref. 16) represents such a very different lake.)

A similar alkalinity–oxygen isotope curve can be constructed for other palaeolakes, provided, of course, that alkalinity has not accumulated so rapidly that it curtailed molluscan growth early in the history of the lake.

The climatic trends recorded in Fig. 1 for Lake Turkana have some contemporary analogies in Africa. The warm/dry periods which have characterized much of the past at Lake Turkana and which prevail today are also recorded by much the same oxygen isotope ratios in modern gastropods at Lakes Victoria, Edward, Albert and Kivu ($\delta^{18}O_{PDB}$ = 0 to +4‰), suggesting that temperature more than relative humidity controls the

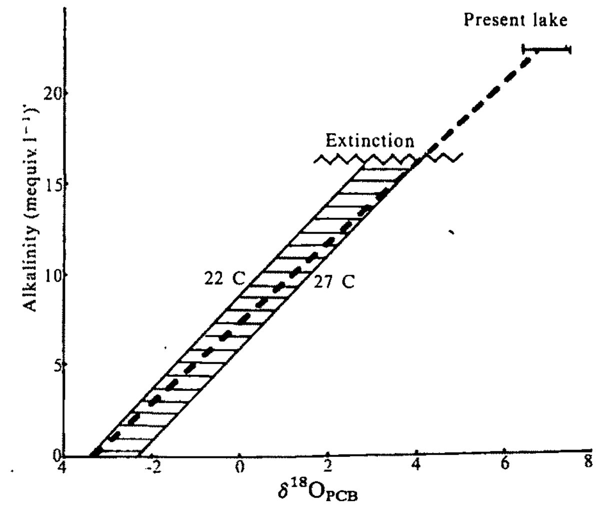

Fig. 3 Change in $\delta^{18}O_{PDB}$ of gastropods at Lake Turkana as a function of progressive increase in alkalinity. Meteoric waters, subjected to little evaporative loss, would yield molluscs of $\delta^{18}O_{PDB} \cong -4‰$ at near zero alkalinity. Progressive evaporation of the lake in a closed basin would increase the alkalinity and the $\delta^{18}O$ of the molluscs along the curve to the right. Extinction occurs at an alkalinity of about 16 mequiv. l^{-1}. The cross-hatched area represents temperature effects on $\delta^{18}O$ (ref. 17), assuming the normal temperature range of contemporary East African lakes of ~5 °C (ref. 18).

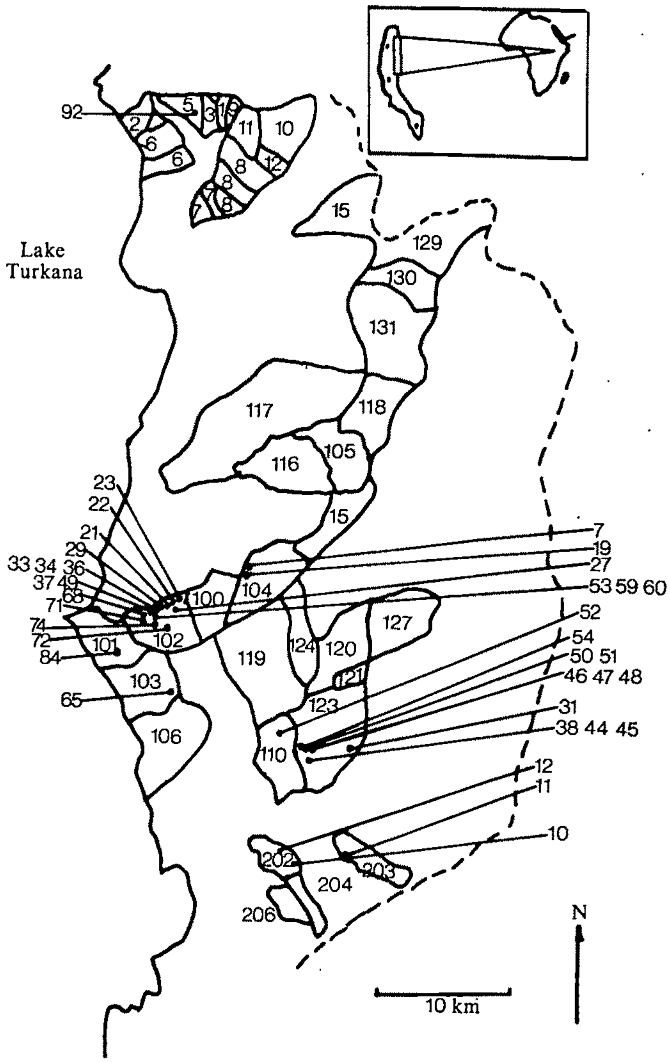

Fig. 2 Koobi Fora region of the Lake Turkana Basin, Kenya, showing the sample numbers (molluscan stratigraphic horizons) and collection sites of the gastropods used in this study in the topographically delineated fossil localities[3].

evaporative concentration of ^{18}O. On the other hand, the negative values of $\delta^{18}O$ which have been observed for gastropods of historical times are similar to the isotope ratios of contemporary gastropods of rivers in the Transvaal ($\delta^{18}O_{PDB}$ = −2 to −4‰) or in southern Zaire (−3.5‰). Lake Turkana thus had quite a temperate climate at times in the past.

It is unfortunate that the only dated sediments at Lake Turkana are the tuff horizons, so that correlations with the well-dated marine climatic fluctuations cannot be very precise. However, the more important use for this technique is to secure climatic information to be associated with particular fossil beds or archaeological sites, and thus define the climatic component of the evolutionary pressures on the animal population, including man.

I thank Peter Williamson for providing the molluscs for this study, Tom Rockett for assistance in the X-ray analyses, Cecile Vanech for assistance in preparation of the carbon dioxide samples, the Graduate School of Oceanography at this university for use of the mass spectrometer, Andrew Cohen for furnishing samples of contemporary molluscs from Lake Turkana, the Museum of Comparative Zoology of Harvard University for providing mollusc samples from many African lakes, and particularly Richard Leakey for field support at Lake Turkana.

Reconstruction of spatial information in the human visual system

Göte Nyman & Pentti Laurinen

Department of General Psychology, University of Helsiniki, Ritarikatu 5, 00170 Helsinki 17, Finland

The remarkable capacity of an observer to perceive and recognize objects and forms independent of the exact nature of their components can be described as a process of reconstruction. We have measured the ability of human observers to recognize square-wave or sinusoidal gratings when presented as a pattern of regularly taken spatial samples (see Fig. 1). To recognize the waveforms, the observer must visually reconstruct them from the samples—a process which can be described by the Shannon–Whittaker theorem[1,2] of sampling and which Barlow suggests may be carried out by the numerous stellate cells of the visual cortex[3]. We report here that at low spatial frequencies, relatively more sample lines per spatial cycle were needed for wave recognition than were needed at higher frequencies. However, a square-wave grating was still recognized easily even when it was sampled at a rate at which its third harmonic could not be recognized when presented alone. At high spatial frequencies the square wave was identified when the sampling rate was so low that it caused the third harmonic to be undersampled. This contradicts the idea that a complex wave is analysed by parallel spatial frequency channels[4,5] and emphasizes the capacity of the visual system to use signal features other than the harmonic frequency components of an image to recognize it.

From the Shannon–Whittaker sampling theorem[1,2] we know that a signal having a limited bandwidth B can be completely reconstructed from samples provided that the samples are taken densely enough, that is, above the minimum sampling frequency of $2B$ (the Nyquist frequency). The signal can be reconstructed by suitable interpolation between the samples or, conversely, by reconstruction filtering. In the psychophysical context described here, the term 'reconstruct' refers to the observer's ability to perceive certain predetermined spatial features, such as waveform or spatial frequency, in a stimulus consisting of spatial samples of a grating of particular waveform and spatial frequency. The sampling theorem cannot be applied to spatial vision in a straightforward manner, because the number of samples per cycle needed for signal reconstruction actually depends on the spatial frequency value of the grating (that is, the number of cycles $\deg^{-1}$ the grating subtends at the observer's eye). When viewed close to, the coarsely sampled gratings on the right and left in Fig. 1 cannot be recognized as sinusoid and square wave, respectively, but at far enough distance the 'grating Gestalts' become visible in the sampled images.

We have measured psychophysically how many samples per spatial cycle are needed to recognize sinusoidal and square-wave gratings. Two gratings were presented successively for 600 ms. The first was always a 'sampled' grating consisting of vertical sample lines of width 4 min. The samples were taken either from a sinusoid with contrast $c = 0.80$ or from a square wave with $c = 0.63$, where $c = (L_{max} - L_{min})/(L_{max} + L_{min})$ and L_{max} and L_{min} refer to the maximum and minimum luminances, respectively, in the grating. With these contrasts the fundamental frequency component of the square wave and the sinusoid of corresponding spatial frequency both have the same energy content. The samples were taken at regular intervals and presented against a background of constant mean luminance, 120 cd m^{-2}. The second stimulus was a continuous grating, also vertical, but with lower contrast (0.50 in sinusoids and 0.31 in square waves). This made the perceived contrast of the reference and the sampled grating approximately similar. The subject had to indicate whether or not the appearance of the first grating, the sampled one, matched the reference grating in certain required properties. The density of sampling was increased or decreased according to the response, to determine the subject's threshold. Dense sampling results in a clearly visible grating of continuous appearance, when the sampling rate is decreased, the sample lines become visible, but a total 'grating Gesalt' can still be seen.

Two different threshold criteria were used. First, the subject decided whether he could see the same spatial frequency and waveform in both of the gratings. If he could not, the sampling rate was increased, otherwise it was decreased. Then he indicated when he was sure that no features of the reference grating waveform remained in the sampled image. This was done in order to estimate how much the criterion level shifts affected the results. The thresholds were measured separately for the sinusoids and the square waves and four spatial frequency values were used. The threshold sampling rate was calculated as the mean of the 10 last minium and maximum values occurring during a threshold run.

The results are expressed in terms of sampling efficiency, which relates the measured threshold sampling rate to the Shannon–Whittaker or Nyquist limit of the grating frequency which was studied. The sampling efficiency $E(s) = N(s)/S(s)$, where s is the spatial frequency, $N(s)$ is the corresponding Nyquist rate and $S(s)$ is the measured value. Thus, $E(s)$ describes the functional sampling efficiency of the visual system in recognition tasks which require spatial interpolation or reconstruction. The results in Fig. 2 indicate that almost identical $E(s)$ values were obtained for the two different waveforms. For both waveforms, $E(s)$ increased as a function of spatial frequency. When the spatial phase of the grating at which the sampling started had the value 0, $\pi/4$, $\pi/2$, $3\pi/4$ or π, similar results were obtained, suggesting that the phase was not critical. This was not surprising because the sampling efficiency was rather low at the spatial frequencies used, at 8 $c \deg^{-1}$ being still

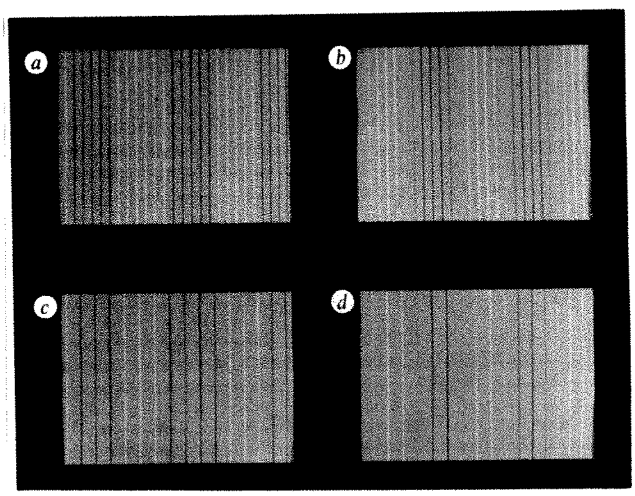

Fig. 1 Spatial sampling effects in grating perception. Square-wave (a, c) and sinusoidal (b, d) gratings of equal spatial frequency have been sampled at regular intervals. Only the sample values carry the grating information and the spaces between them have a constant background value. a, b, Sampling rate of 11 lines per cycle. Increasing the viewing distance (that is, the spatial frequency of the gratings and the angular sampling density) makes it easier to identify the two waveforms even though the physical sampling constraints remain the same. c, d, The same gratings as in a and b, but with sampling density of 7 lines per cycle. The waveforms can be recognized only by increasing the viewing distance sufficiently. The edges of the square wave (a, c) are seen first and it does not have the appearance of its fundamental frequency component. Furthermore, both waveforms are identified simultaneously when the viewing distance is increased. Quantitative results of the sampling and reconstruction effects ar presented in Fig, 2.

0028–0836/82/210324—02$01.00

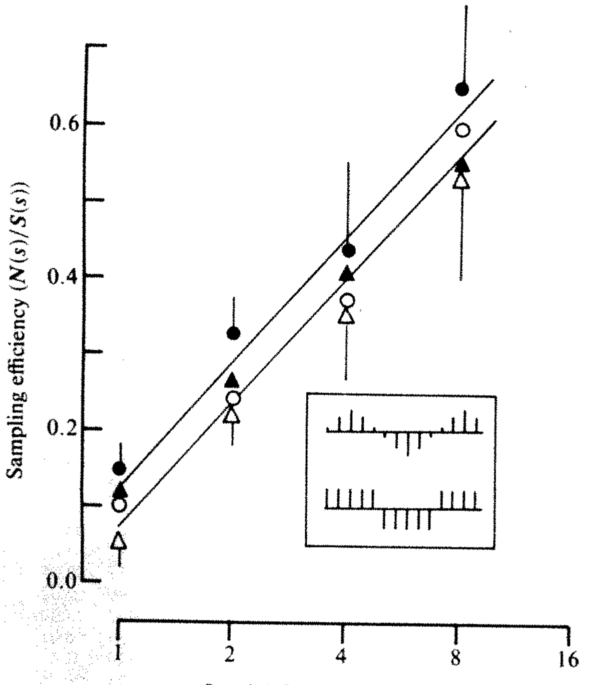

Fig. 2 Sampling efficiency of human spatial vision. We studied the number of sample liners per cycle needed for grating waveform recognition . Two different waveforms were used: ▲, △, sinusoid; ●, ○, square wave. The stimuli from which the samples were taken had contrasts of 0.80 and 0.63, respectively, which makes the energy content of the sinusoid equal to that of the fundamental component in the square wave having the same spatial frequency. The subject adjusted the density of sampling in the grating until he decided that it had the required appearance. Two criteria for the appearance were used: threshold for recognizing the waveform (open symbols) and threshold for the disappearance of the recognizable waveform (filled symbols). The threshold value was taken as the mean of the last 10 settings. The results are expressed in terms of sampling efficiency, $E(s) = N(s)/S(s)$, Where $N(s)$ is the Nyquist sampling frequency at spatial frequency s and $S(s)$ is the threshold value obtained. Viewing was monocular, with natural pupil. Mean luminance was 120 cd m^{-2}, the grating size 28 × 21 cm, and viewing distance 798 cm. Results for one subject (P. L.), an experienced and emmetropic observer, are shown. Experiments with three other subjects gave similar results. The bars represent 1 s.d. and for clarity, only some representative s.d. values are shown. The lines have been drawn by eye and indicate the results for the two different waveforms. The inset describes the waveforms sampled.

~0.6. Changing the threshold criteria caused an average change of 0.10 in efficiency.

If the sampled square wave is recognized when enough of its harmonics contribute to its appearance, then it follows that the sampling rate needed for its recognition should be high enough to make these harmonics recognizable when presented alone. In contrast, the results show that the square wave was recognized even if it was sampled at a rate at which the third harmonic could not be seen. Furthermore, for higher spatial frequencies, the threshold sampling rates for identifying the square wave grating were so low that an efficiency value better than 0.33 was achieved, indicating that the third harmonic of the image must have been undersampled.

Our results contradict the models which describe the visual system as a Fourier analyzer in which a complex waveform is recognized on the basis of the information obtained from its harmonics, each of which is channelled through its own spatial frequency selective channel[4,5]. The visual system can also use other features than the harmonic frequency components of an image to recognize it. In the case of a high frequency square-wave grating it performs better than expected on the basis of the sampling theorem. Such performance is known to be possible in some artificial signal processing systems[6,7] and has also been demonstrated for a model of cortical information processing[8,9].

Local cerebral glucose utilization in non-rapid eye movement sleep

Sleep is accompanied by alterations in neurophysiological activity in many discrete regions in the brain[1]. Such alterations could be expected to be accompanied by corresponding changes in local metabolic rate[2]. We have now looked for the specific regions involved in sleep, at least in the stages other than rapid eye movement (REM) sleep, by using the [2-^{14}C]deoxyglucose method for measuring local cerebral glucose utilization[3] in the rhesus monkey. Contrary to what many have predicted, animals during stages 2–4 of sleep exhibited a non-selective, generalized 30% decrease in cerebral metabolic rate. Of the 75 structures measured, none exhibited a higher rate in non-REM sleep than in wakefulness.

The study was carried out in four awake and four sleeping rhesus monkeys weighing 3.8–5.9 kg. They were surgically prepared several weeks before the experiment with electrodes implanted over the dura, in the orbital region and in neck muscles to permit electrical monitoring of cerebral, ocular and muscular activities. The animals spent daytime hours in cages in which they were free to move. To accustom them to the experimental conditions, we placed them in a restraining chair at a regular hour in the early evening. The chair was moved to a ventilated, darkened chamber in which white noise was continuously generated at an intensity of 70 dB to mask adventitious sounds outside the chamber. The animals readily accepted this environment and would sleep normally each night.

On the day of the experiment catheters were inserted in the femoral artery and vein of one leg to allow the intravenous administration of ^{14}C-deoxyglucose and arterial sampling. This was done under light halothane anaesthesia, from which they took 5–10 min to recover. Three hours later the animals were placed in the sleep chamber. The experimental procedure was initiated in the four sleeping animals ~5 min into the period of slow-wave sleep that immediately followed the first period of REM sleep. Three of the control (awake) animals were also allowed to fall asleep. Five minutes after their first period of REM sleep, however, they were aroused by a gentle jostling of the chamber after which the experiment was begun. The jostling was occasionally repeated when necessary to maintain

wakefulness. A fourth awake control was studied before the onset of sleep. In addition to polygraphic monitoring, a video camera in IR light was used to assess the animal's degree of consciousness during the experiment. In the four sleeping animals, on the average 23 min of the 30 min experimental period was occupied by sleep stages 3 and 4. There were occasional, randomly distributed lapses into stage 2 which lasted on the average 5 min. These lapses took place in only two monkeys during the crucial first 15 min and both lasted 1.5–2 min. Periods of REM sleep and wakefulness, averaging 1 min each, occurred during the last 10 min, when their effect on the results would be negligible due to the relatively low concentration of deoxyglucose in the blood at that time.

The experiments were initiated by an intravenous pulse of 2-deoxy-D-[1-^{14}C]glucose (specific activity 50–56 mCi mmol^{-1}) dissolved in physiological saline in a dose of 100 μCi per kg. The procedure was carried out as previously described[4]. For each animal, approximately 400 brain sections in the Horsley–Clarke frontal plane were prepared for quantitative autoradiography together with a smaller number for histological staining. The local rates of glucose utilization were calculated from 12 measurements of optical density for each of 75 structures in each animal, by means of a transmission densitometer. The aperture used was 0.5 or 0.25 mm, depending on the size of the structure. When the location of a small nucleus in the autoradiograph was uncertain, positive identification was made with the aid of an adjacent histological section stained with cresyl violet.

Midway through the procedure, arterial blood was sampled for the determination of *p*H and the partial pressure of the respiratory gases. The mean values ±s.e.m. of 7.47±0.01,

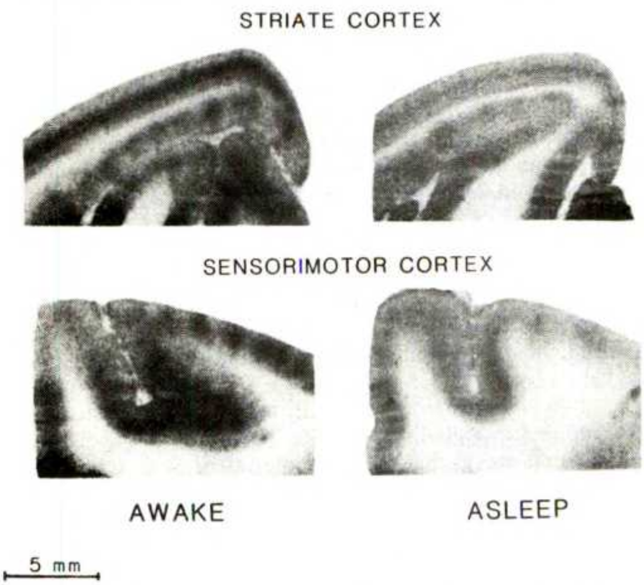

Fig. 1 ^{14}C-deoxyglucose autoradiographs of coronal sections of striate/prestriate cortex (above) and sensorimotor cortex (below) of monkey brain. The sections on the left are representative of the group of awake monkeys, those on the right, of the group asleep. In the striate/prestriate cortex of the awake monkey, the dark bifid line parallel to the cortical surface corresponds to Layer IV. Fine, regularly spaced markings perpendicular to the cortical surface traverse the entire cortical thickness. Directly beneath the cortex on the upper surface and parallel to it is part of the prestriate cortex. Here Layer IV is not seen but there are rather broad perpendicular markings which are irregularly spaced. In the corresponding section of striate/prestriate cortex of a sleeping animal (upper right), these markings are virtually indistinguishable. The narrow dark and light bands (lower right hand side of the section from the sleeping animal) are artefacts due to wrinkling of the section at the time of cutting. In the sensorimotor cortex of the awake animal (lower left), both perpendicular and horizontal markings are seen. In sleep (right), all these markings virtually disappear in both cortical regions, and the metabolic rate is nearly uniform in the various cortical layers.

Table 1 Glucose utilization in monkey brain during slow-wave sleep (μmol per 100 g per min)

Values are mean ±s.e.m.

40 ± 2, 88 ± 2 mm Hg for pH, P_{CO_2} and P_{O_2}, respectively, in awake animals were not significantly different from those of 7.43 ± 0.02, 46 ± 2 and 91 ± 3 in sleep.

The rates of local cerebral glucose utilization in the awake controls in this study were similar to those previously obtained by Kennedy *et al.*[4] in awake animals in the laboratory, except for the rates in a few structures of the auditory and visual pathways. The alterations in these structures could be accounted for by the differing environmental conditions.

In the present study, mean rates of glucose utilization were lower in sleeping monkeys than in awake controls in each of the 75 structures examined, and the difference was significant ($P < 0.05$) in 44 cases (Table 1). The reductions were largest and most consistent in cerebral cortex, cerebellum and thalamus, but no anatomic or functional system was selectively affected, and in no structure was the value in sleep above that during wakefulness. There is, therefore, no evidence to suggest that any cerebral centres were activated during slow-wave sleep. Rates of glucose utilization in the cerebral cortex of the awake animals were seen to be variable in the autoradiographs, which revealed dark markings perpendicular to, and in some areas also parallel to, the cortical surface. Such markings were found in nearly all the major subdivisions of the cortex and, in some cases, the pattern was characteristic for the given area, such as the striate cortex (Fig. 1). This variable pattern of metabolic rates, reflecting the columnar organization of cortical function, virtually disappeared from all regions of the cortex in sleeping animals (Fig. 1).

It has recently been reported that the rate of glucose utilization in the choroid plexus of the cat is elevated in slow-wave sleep[5]. Although the kinetics of deoxyglucose in this tissue has not been sufficiently analysed to ensure accurate quantification of its rate of glucose utilization, the calculation used in this study for brain tissue probably provide at least an index of its metabolic rate. We used a computerized image-processing system[6] to obtain values for choroid plexus in the monkeys. The brain sections containing this tissue were enlarged 15 times to display the irregular borders which then could be traced with an outline marker. Thus it was possible to obtain an integrated value for the structure in each section. Values did not vary significantly in the lateral, third and fourth ventricles, and no statistically significant differences were found between sleeping and waking animals.

It was possible to calculate a single weighted average rate of glucose utilization of the brain as a whole by scanning all sections with the computerized image-processing system previously described[6]. The mean ±s.e.m. was 35 ± 2 μmol per 100 g per min for the four awake control animals. This value was not statistically significantly different from the value of 36 ± 1 μmol per 100 g per min found by Kennedy *et al.* for the previously published results from seven conscious monkeys studied in the ambient environment of the laboratory[4]. Thus the awake control animals in the present study did not have a generalized activation of cerebral metabolic rate due to the experimental conditions, such as the confinement in a closed chamber and the acoustic stimulation. In the four sleeping monkeys, the average rate of cerebral glucose utilization was 25 ± 1 μmol per 100 g per min, a statistically significant reduction ($P < 0.02$) below either of the awake groups.

The results of this study might seem inconsistent with those of Mangold *et al.*[7], who used the Kety–Schmidt method and found no difference in cerebral metabolic rate between slow-wave sleep and wakefulness in human subjects. In five subjects, cerebral oxygen consumption declined during sleep, but in the remaining subject it increased by 34%. As a result, in the group as a whole, cerebral oxygen consumption was not statistically significantly different in sleep and wakefulness. The large difference in the one subject, however, indicates that this subject is a statistical outlier by the criteria of either Grubbs[8] or Dixon[9]. Thus there is a statistical rationale for his elimination from the series. Mangold *et al.*[7] had no reason to discard the findings on the basis of the subject's behaviour or any aspect of the procedure, but had they done so for the statistical reasons cited, the mean value for cerebral oxygen consumption in the remaining five subjects would have declined during sleep by a statistically significant ($P < 0.03$) 11%. The earlier study in man would then be qualitatively consistent with the findings reported in the present studies in the monkey. The discrepancy in the magnitude of the effects may be due to differences in the methods, species, or conditions in which the studies were conducted. In the present study, the measurements were made at the usually normal sleeping time of the monkeys; in the earlier studies in man, the measurements were made at 4:00–6:00 a.m. following deprivation of sleep at the normal scheduled time, and the individuals could have been fatigued.

Organelle movement in axons depends on ATP

Richard J. Adams

MRC Cell Biophysics Unit, 26–29 Drury Lane, London WC2B 5RL, UK

When living axons are examined in the light microscope many of the membrane-bounded organelles they contain can be seen to undergo rapid saltatory movements, predominantly in the retrograde direction[1]. This is thought to be an important component in the fast transport of materials in axons, the mechanism of which is unknown although cytoskeletal elements such as actin filaments and microtubules are probably involved (see ref. 2 for review and refs). I describe here experiments in which giant axons from the legs of the crab *Carcinus maenas* have been made permeable to ions and small molecules using a high voltage discharge to puncture holes in the plasma membrane[3]. This allows, in a suitable buffer, movement to be arrested due to the loss of metabolites and then reactivated by the addition of exogenous ATP, thus showing directly for the first time that rapid saltatory motion in axons is an ATP-requiring process.

Electrically active giant axons (~30 μm in diameter) from the walking legs of *C. maenas* were dissected in sea water or in a standard reactivation buffer (400 mM K glutamate, 150 mM glycine, 10 mM EGTA, 20 mM HEPES pH 7.2, 15 mM $MgCl_2$) at room temperature (about 20 °C). This was carried out in a 5-cm plastic Petri dish in the base of which a 1-cm hole had been drilled and a poly-L-lysine-coated[4] glass coverslip inserted. The polylysine allows the axons to adhere strongly to the glass coverslip so that high magnification phase contrast objectives may be used. A region of axon with particles exhibiting saltatory movement was selected for permeabilization, and the dielectric breakdown of the plasma membrane was then brought about by the discharge of a 1 μF capacitor across the axon between two fine stainless steel electrodes held in micromanipulators. A discharge voltage of 70–80 V with the electrodes set 160 μm apart (about 5 kV cm^{-1}) gave the best results and a series of holes were made in this way at intervals of 10–20 μm over a distance of 2 mm. The exact size of the holes produced is not known but can be inferred, from the results shown below, to allow molecules of molecular weight at least 900 to pass into and out of the axon; tracer studies

0028–0836/82/210327—03$01.00

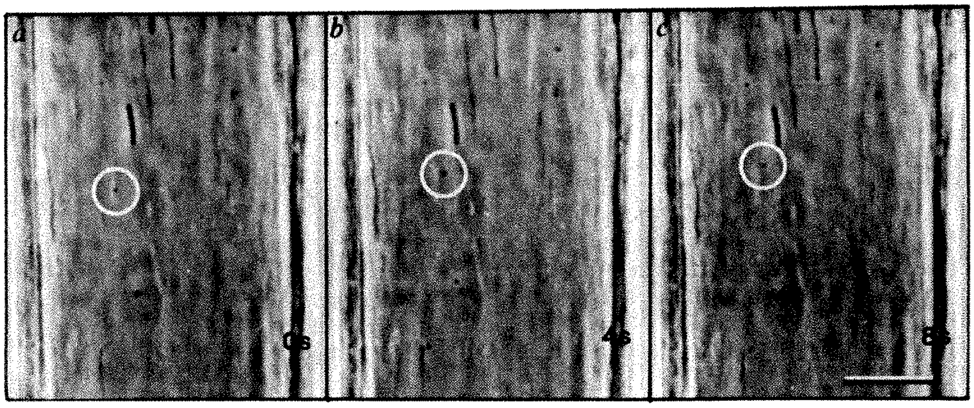

Fig. 1 A sequence of photographs of a particle (encircled) moving in an unlysed axon. The axon was mounted as described in the text and viewed with a Zeiss IM35 inverted microscope. Photographs were taken at the indicated times using Ilford FP4 film. Scale bar, 10 μm.

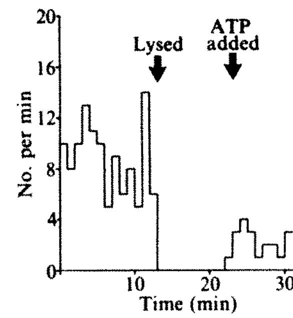
with adrenal medullary cells[3], have shown that this procedure produces holes of about 4 nm diameter. The stability of the holes made in the axon was shown by the observation that the axoplasm of permeabilized but not intact axons was rapidly liquified by the addition of millimolar concentrations of calcium (in the absence of protease inhibitors). It could thus be shown that the holes remain open for at least 2 h; experiments were not continued for longer than this as both permeabilized and intact axons seems to lose their ability to sustain movement after this time *in vitro*.

Movements in axons dissected from the crab leg and mounted in reactivation buffer were similar to those described in other systems[1,5]. Particles underwent transient movements at rates of up to 2 $\mu m\,s^{-1}$ with the majority (>80%) travelling in the direction of the cell body (Fig. 1). Many particles that did not undergo persistent movement underwent oscillations of small amplitude (<1 μm) along the axis of the axon. Mitochondria, which in these axons reach up to 50 μm in length, moved only occasionally, but at high rates when they did so. On permeabilization in reactivation buffer lacking ATP, movement progressively declined, with first the large and then the smaller particles coming to rest; the mitochondria often fragmented to give the appearance of beads on a string. The decline in movement depended on the loss of ATP, ADP and arginine phosphate by diffusion into the external medium. The method given above resulted in a complete cessation within about 5 min of making the holes. The decline could be accelerated, however, by the inclusion of 10 mM 2-deoxyglucose in the medium which greatly increased the rate of ATP (and thus arginine phosphate) turnover; 2-deoxyglucose was not routinely used.

Fig. 2 Number of particles passing a cross-section of axoplasm perpendicular to the long axis of the axon. The graph shows particles moving in a single axon before permeabilization ('lysis'), after permeabilization, and after reaction with 6 mM ATP.



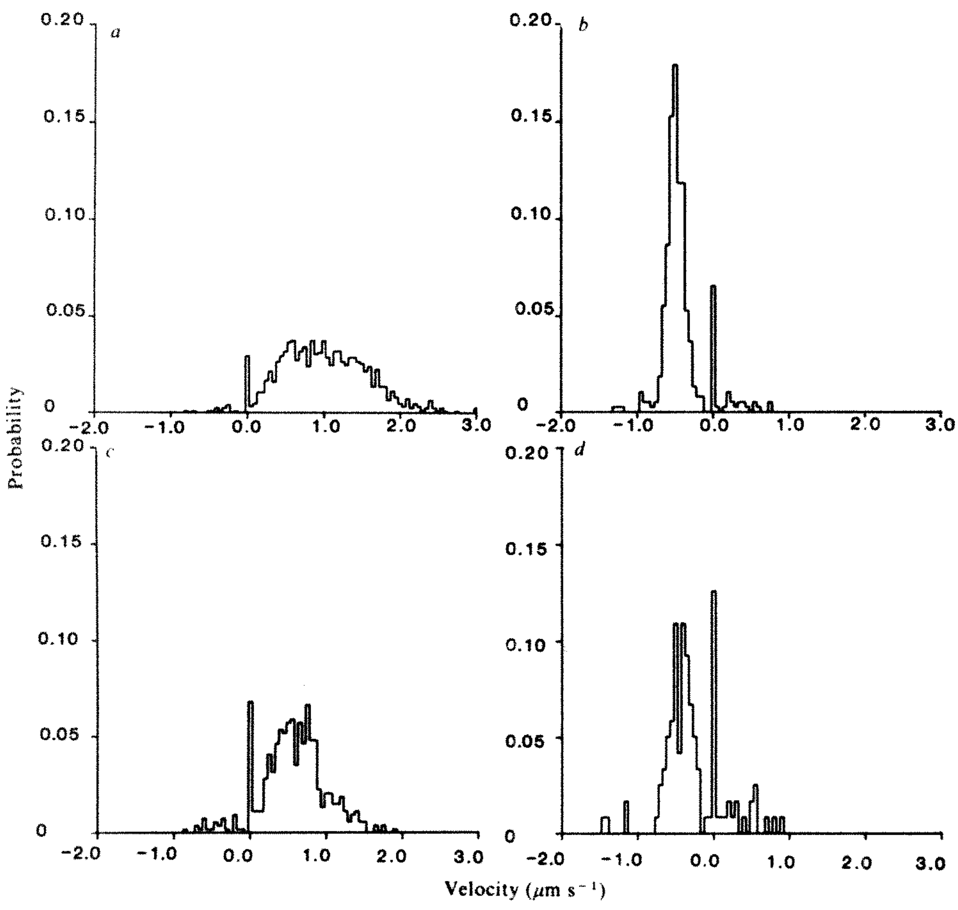


Fig. 3 Instantaneous velocities of particles moving in: *a*, *b*, intact axons; *c*, *d*, axons reactivated in 6 mM ATP. Particles are grouped according to their major direction of transport: *a*, *c*, towards the cell body (retrogradely); *b*, *d*, away, from the cell body (anterogradely). Instantaneous velocities were calculated from the time particles took to pass between gradations on an eyepiece graticule corresponding to 0.97 μm along the axon. Times were recorded initially on a cassette tape and then analysed by a computer program which calculates the velocity over each increment. The graphs represent the normalized distribution of velocities from several particles in each case: *a*, 1,251 velocity measurements from 18 particles; *b*, 380 from 5 particles; *c*, 542 from 15 particles; *d*, 119 from 5 particles.

Movement was rapidly restored by the addition of ATP; the usual concentration used was 6 mM but as little as 500 μM could restore some movement. Movement could be reactivated in axons within 90 min following permeabilization; and persisted for up to 2 h in exogenous ATP. The extent of reactivation, as measured by the number of particles passing a point per minute, varied between experiments, ranging over 25–70% (Fig. 2). This variation may be due to both the more erratic nature of movements after reactivation and a reduction in the average velocity at which particles moved. A study of instantaneous velocities (here defined as the velocity over a distance of 1 μm) of particles moving in unlysed and reactivated axons showed a reduction in the mean velocity of retrogradely moving particles (Fig. 3). The average velocity may have decreased because the conditions of reactivation were less than optimal, although ATP did not seem to have a limiting effect as further increases in its concentration did not increase the rate of movement.

Movement was not reactivated by either GTP (6 μM) or the non-hydrolysable ATP analogue adenylylimidodiphosphate (AMPPNP, 6 mM). However, the addition of 6 mM ADP did restore some movement. This may have been due to the action of adenylate kinase, a ubiquitous enzyme which can produce ATP from ADP (2 ADP$\rightleftarrows$ATP+AMP), as the restoration of movement was prevented by an inhibitor of adenylate kinase (500 μm P^1, P^5-di(adenosine-5′)pentaphosphate[6]). This inhibitor (diadenyl pentaphosphate) did not inhibit movement in the presence of exogenous ATP. It appears that the functional integrity of the axoplasm depends on the anion included in the reactivation mixture; movement continued if glutamate was replaced with aspartate but not with α-ketoglutarate, tartrate, methanesulphonate or chloride ions. However, L-glutamate could be replaced by D-glutamate without loss of activity, suggesting that a specific interaction is not involved but that merely stabilization of the structure occurs, as predicted from their relative positions in the lyotropic series. Movement in permeabilized (but not intact) axons was completely inhibited by vanadate ions at a concentration of 500 μM, although a reduction in the number of particles moving in reactivated axons was seen at concentrations as low as 5 μM. Vanadate ions in this range prevent mitosis[7] and ciliary beating[8] and inhibit the activity of a number of ATPases and kinases[9].

The buffer in which reactivation was achieved did not contain exogenously added Ca^{2+} and included 10 mM EGTA. An increase in the EGTA concentration to 50 mM had no apparent effect on reactivation. Although it remains possible that a local release of Ca^{+2} occurs from the organelles themselves and is required for them to move, this seems unlikely considering the long duration (up to 2 h) in which movement can continue in EGTA. Inclusion of the calmodulin inhibitor trifluoroperazine to a concentration of 50μM does not inhibit movement although at a concentration of 100 μM movement did appear to decline after ~15 min. It seems unlikely, due to the delay in the effect, that this is a specific inhibition but it may reflect the detergent-like activity of the drug as seen in other systems[10]. If Ca^{2+} was added to produce a concentration estimated to be ~1.5 μM (9 mM $CaCl_2$, 10 mM EGTA, 15 mM $MgCl_2$, pH 7.2) transport still continued for longer than 1 h. The addition of Ca^{2+} at concentrations higher than this is complicated by the presence of Ca^{+2}-activated proteases in the axon which cause its rapid dissolution. However, when the reactivation buffer was supplemented with protease inhibitors (1 mM TLCK, 0.4 μM acetyl-L-leucyl-L-leucyl-L-arginal, (leupeptin), 0.5 mM phenylmethyl sulphonyl fluoride) movement continued in 0.5 mM Ca^{2+}, in the absence of EGTA, for greater than 1 h. Thus this movement apparently neither requires Ca^{2+} nor is inhibited by high concentrations of Ca^{2+}.

A major aim in the study of cell motility is the establishment of cell-free systems in which movements of interest take place. Only in this way can the components required for movement be analysed and the mechanism of their action determined. The preparation described here is a first controlled step towards a cell-free system that exhibits fast axonal transport, allowing rapid saltatory movements to occur in axons that have been permeated by a defined mixture of ions and small molecules. The principal conclusion obtained from this system is that the rapid movement of organelles in axons has an absolute requirement for ATP. Furthermore, it seems likely that the hydrolysis of ATP is an essential step in the generation of movement, as it is in the contraction of muscle, the beating of cilia and cytoplasmic streaming in giant algal cells[11].

I thank Professor P. F. Baker and Dr D. Bray for much help and advice. This work was supported by an MRC studentship.

Slow reacting substances (SRS) are potent bronchoconstrictors that are thought to be important in the pathophysiology of asthma[1]. Human[2–5] and animal[6,7] lung fragments release SRS when sensitized by IgE antibody and challenged with specific antigen. SRS have been shown recently to be a family of peptidolipids called leukotrienes (LTC_4, LTD_4 and LTE_4) that are derived from arachidonic acid[8–11] and are potent bronchoconstrictors *in vivo* and *in vitro*[12–14]. It is not known which cell(s) is responsible for releasing SRS but two recent observations have directed our attention to alveolar macrophages. First, Capron and co-workers demonstrated that serum IgE antibody from rats immune to *Schistosoma mansoni* parasites could cause rat peritoneal macrophages to be cytotoxic for schistosomules *in vitro*[15]. This is a result of the interaction of IgE with macrophage IgE Fc receptors[16]. Similar receptors are also present on rat alveolar macrophages[17]. Second, Bach and Brashler[18–21] established that rat peritoneal macrophages could release a mixture of LTC_4 and LTD_4 when stimulated by the calcium ionophore A23187. We now show that rat alveolar macrophages can be activated by calcium ionophore to release SRS and, when challenged with IgE antibody and specific antigen, release LTC_4.

Male Sprague–Dawley rats were killed in a CO_2-filled chamber. Their lungs were lavaged with 150 ml of 0.9% NaCl and the recovered cell suspensions were centrifuged at 500g for 8 min. The cell pellet was washed with 0.9% NaCl, centrifuged and resuspended in Hank's balanced salt solution (HBSS); in mM: $CaCl_2$ 0.95, KCl 5.3, KH_2PO_4 0.4, $MgCl_2$ 149, $MgSO_4$ 0.04, NaCl 136.8, $NaHCO_3$ 4.1, Na_2HPO_4 0.33, glucose 55). The macrophages were identified by uptake of neutral red dye and total cells were counted in a haemocytometer. Viability was assessed by Trypan blue exclusion and the cell number was adjusted to 5×10^6 viable macrophages per ml in HBSS.

Cell differentials on Wright–Giemsa-stained cytocentrifuged preparations revealed the lung lavages to contain 93.2% macrophages, 3.3% lymphocytes, 3.3% neutrophils and 0.14% mast-basophiloid cells (data represent the mean of 15 experiments).

The ability of rat alveolar macrophages to release SRS was tested initially by incubating cell suspensions for 20 min with 1 μmol of the calcium ionophore A23187, in the presence of 5×10^{-4} M L-cysteine. In subsequent experiments, cell suspensions were stimulated with purified mouse monoclonal anti-DNP (dinitrophenyl) IgE antibody[22] (provided by Dr D. H. Katz) and DNP–human serum albumin ($DNP_{22}HSA$) in the following manner: cell suspensions were incubated with anti-DNP IgE antibody for 20 min at 37 °C, $DNP_{22}HSA$ was then added and incubation continued for a further 20 min.

Controls consisting of cells alone and cells with antibody alone were incubated simultaneously. Following incubation, the cell suspensions were centrifuged at 500*g* and the supernatants assayed for SRS on guinea pig ileum in the presence of atropine sulphate (3.4 $\mu g\ ml^{-1}$), methysergide maleate (0.1 $\mu g\ ml^{-1}$) and mepyramine maleate (0.34 $\mu g\ ml^{-1}$). Positive contractions were repeated in the presence of the selective SRS antagonist[23] FPL 55712 (0.1 $\mu g\ ml^{-1}$). As the chemical nature of the SRS released by alveolar macrophages was unknown initially, we compared quantitatively the magnitude of the contractions produced by our supernatants with those produced by synthetic (5*S*, 6*R*, 7E, 11*Z*, 14*Z*)-5-hydroxy-6-[(2*R*-amino-2-carboxyethyl)thio]7,9,11,14-eicosatetraenoic acid[24] (LTE_4; kindly made available by Dr M. Rosenberger, Hoffman-LaRoche). LTE_4 is a constituent of SRS that appears with biologically generated LTC_4 and LTD_4.[25] Thus, our data are expressed in $mol\times10^{-10}$ of LTE_4 equivalents per 5×10^6 alveolar macrophages.

Figure 1 shows that the non-immunological stimulus A23187 induced the release of SRS ($3\pm1.1\times10^{-10}$ mol of LTE_4 equivalents). Cells incubated in identical conditions without A23187 and L-cysteine showed no spontaneous release of SRS. Thus, rat alveolar macrophages can release SRS when stimulated by the calcium ionophore.

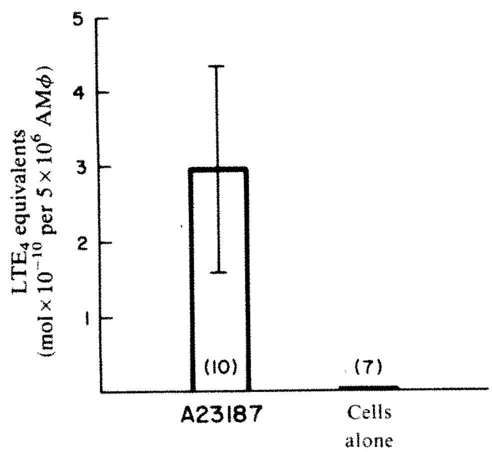

Fig. 1 A23187-induced release of SRS from alveolar macrophages. Rat lung lavages consisting of 93.2% alveolar macrophages and only 0.14% mast-basophiloid cells were adjusted to 5×10^6 viable alveolar macrophages per ml and were incubated at 37 °C with 5×10^{-4} M L-cysteine for 150 s and then for 18 min with 1 μM A23187. After centrifugation the supernatants were assayed for SRS on guinea pig ileum in the presence of atropine (3.4 $\mu g\ ml^{-1}$), mepyramine (0.34 $\mu g\ ml^{-1}$) and methysergide (0.1 $\mu g\ ml^{-1}$). Positive contractions were repeated in the presence of 0.1 $\mu g\ ml^{-1}$ FPL 55712 and were inhibited by 80–100%. Measured contractions were compared with a synthetic LTE_4 standard. LTE_4 equivalents are shown on the ordinate in $mol\times10^{-10}$ per 5×10^6 alveolar macrophages. The columns represent mean values for the experiments performed. The number of experiments is shown at the base of the columns; bars represent standard errors.

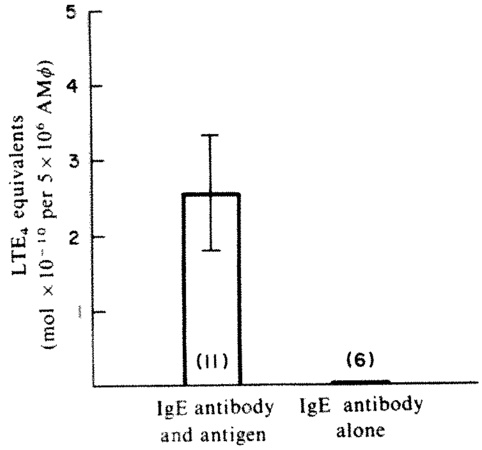

Fig. 2 SRS released from rat alveolar macrophages: induction by mouse monoclonal anti-DNP IgE and $DNP_{22}HSA$. Cells were prepared and SRS assayed as described in Fig. 1 legend. Positive contractions were inhibited by 100% in the presence of 0.1 $\mu g\ ml^{-1}$ FPL 55712. LTE_4 equivalents are shown on the ordinate in $mol\times10^{-10}$ per 5×10^6 alveolar macrophages. The columns represent the mean values for SRS released, and the bars the standard error. The number of experiments is shown at base of columns. Alveolar macrophages were incubated with hapten affinity-purified anti-DNP IgE antibody (10 μg) for 20 min at 37 °C and for an additional 20 min with $DNP_{22}HSA$ (100 ng). In control experiments, alveolar macrophages were incubated with IgE alone.

Figure 2 shows the pooled results of 11 experiments in which cell suspensions were incubated with anti-DNP IgE for 20 min, followed by a further 20 min incubation with $DNP_{22}HSA$. Alveolar macrophages also released SRS by this IgE-dependent reaction ($2.5\pm0.8\times10^{-10}$ mol of LTE_4 equivalents). When cells were incubated with antibody alone (Fig. 2), or with antigen alone, no SRS was released (data not shown). Thus, immunological release of SRS by alveolar macrophages probably depends on a combination of specific IgE antibody and antigen.

Supernatants generated in additional experiments using anti-DNP IgE and $DNP_{22}HSA$ were subjected to chemical analysis in order to characterize the nature of the SRS. Pooled supernatants were deproteinized by 1:4 dilution with methanol and centrifugation, stored at −70 °C, thawed, concentrated, hydrolysed in 0.1 M NaOH, desalted and then chromatographed on a Florisil column with elution in a methanol/water gradient[19]. All biological activity eluted in the same position as synthetic LTC_4 standard (prepared by Dr D. R. Morton, Upjohn) and LTC_4 derived from rat peritoneal macrophages[19,21]. The single peak was concentrated and applied with ^3H-labelled LTC_4 tracer (NEN) to a reverse-phase HPLC column (10 μm Nucleosil C-18), eluted isocratically with 65% methanol, 35% water and 0.01% acetic acid, *p*H 5.4. The absorption at 280 nm, the biological activity and the radioactivity all co-eluted from the column, while a synthetic LTD_4 standard was clearly resolved from the elution peak of the radiolabelled LTC_4 in a separate run on the same column. Thus, two different chromatographic procedures showed that supernatants from alveolar macrophages, activated by an IgE-dependent reaction, contained predominantly LTC_4.

We have thus demonstrated that (1) rat alveolar macrophages release SRS when stimulated non-specifically by the calcium ionophore A23187 in the presence of L-cysteine, and (2) IgE antibody and appropriate antigen cause alveolar macrophages to release SRS leukotriene, LTC_4. Calcium ionophore has been used previously to elicit SRS release from mouse and rat peritoneal mononuclear cells[18,26], human leukocytes[27], rat basophilic leukaemia cells[28,29], and mouse mastocytoma cells[30]. However, our results differ from previous studies in two ways. First, Orange *et al.*[26], using a different strain of rat and a different concentration of L-cysteine, elicited "very little" SRS from alveolar macrophages with A23187. We calculate that the total amount produced by IgE-stimulated alveolar macrophages is

of the same order of magnitude as produced by ionophore-stimulated rat peritoneal macrophages. Second, Bach *et al.*, in collaboration with Capron and Joseph, reported that activation of rat peritoneal macrophages by IgE–anti-IgE—conditions that cause release of lysosomal enzymes[31]—failed to elicit SRS release[32]. We have, in fact, confirmed this result: when rat peritoneal cells were incubated with anti-DNP IgE and $DNP_{22}HSA$ in conditions identical to those used for our alveolar macrophages, they did not release SRS (data not shown). Thus, alveolar macrophages may be specialized to perform this function. Furthermore, alveolar macrophages release predominantly LTC_4 in an IgE-dependent mechanism whereas rat peritoneal macrophages when stimulated with A23187, release both LTC_4 and LTD_4[20,21]. In our experiments, it is probable that alveolar macrophages are the source of SRS because alveolar macrophages comprised 93% of the cells in the lung lavage, and when lavage cells were first allowed to adhere to glass for 1 h they were also capable of IgE-dependent release of SRS (data not shown). However, we cannot exclude the possibility that the minority cells present in our cell suspensions (such as mast-basophiloid cells) contributed to the detected SRS either directly[33] or indirectly[1].

The exact mechanism by which IgE antibody and antigen effect SRS release remains to be determined. Capron and co-workers established that complexes of IgE and schistosome antigen were responsible for eliciting cytotoxicity for schistosome larvae in rat periotoneal macrophages[34] and Dessaint and co-workers showed that IgE binding to Fc receptors on these cells is of much lower affinity than IgE binding to mast cells[16]. Thus IgE antibody and antigen may effect SRS release from alveolar macrophages through formation of immune complexes that activate the cells via these lower-affinity Fc receptors. However, it is also possible that a cytophilic mechanism, analogous to that which sensitizes mast cells and basophils for IgE-dependent release of histamine, is responsible, as 'direct' cytophilic antibodies with high affinity for murine macrophage Fc receptors do exist—but they may be specific for IgG2a[35]. Our preliminary experiments indicate that both mechanisms may be involved because washing the cells after incubation with IgE and before addition of antigen reduces, but does not eliminate, SRS release. Further experiments are being conducted to investigate this issue further.

The relevance of our findings to allergic lung disease mechanisms remains to be determined. It is clear that many important mediators are released by mast cell-dependent pathways[1] and there is recent evidence that pulmonary mast cells may be an important source of SRS in humans[33]. However, it has also been demonstrated recently that human alveolar macrophages can release lysosomal enzymes and superoxide anion after incubation with IgE and anti-IgE antibody, or with serum from allergic patients and the appropriate allergen[36]. Merrill and co-workers have examined the immunoglobulins present in the lung lining fluid of the lower respiratory tracts of normal individuals, and found that although IgG and IgA were the predominant immunoglobulins present, IgE was present in detectable quantities in ~80% of the 43 people tested[37]. Similar studies on asthmatic individuals have not been reported, but IgE levels are increased in the nasal secretions of patients with allergic rhinitis[38–40] and probably result from local production[41]. As the mucosa of the nose and lower respiratory passages are in many ways similar, it is reasonable to hypothesize that IgE–antigen–macrophage interactions occur on the air–surface interface of the lung. Our demonstration that rat alveolar macrophages release SRS by an IgE-dependent mechanism raises the possibility that IgE-dependent release of mediators by alveolar macrophages may have a role in asthma or other immunologically mediated lung diseases.

Corticotropin releasing factor produces behavioural activation in rats

Richard E. Sutton, George F. Koob*, Michel Le Moal*, Jean Rivier & Wylie Vale

Peptide Biology Laboratory and * Arthur Vining Davis Center for Behavioral Neurobiology, The Salk Institute, PO Box 85800, San Diego, California 92138, USA

A 41-residue peptide with high potency and intrinsic activity to stimulate the secretion of corticotropin and β-endorphin by the adenohypophysis has been characterized and synthesized[1,2,19]. From experience with other hypophysiotropic and brain peptides[3–5], and studies suggesting that CRF could act centrally to activate the sympathetic nervous system (M. Brown *et al.*, in preparation), we considered it likely that this corticotropin/β-endorphin releasing factor (CRF) would have direct behavioural actions. We decided to investigate the effects of CRF on a simple measure of activation in the rat, locomotor activity in photocell cages. We report here that centrally injected synthetic CRF produces a dose-dependent locomotor activation in rats. This increase in activity was not produced by peripheral administration of CRF. In an open field test, rats receiving centrally injected CRF exhibited behaviour consistent with an increase in emotionality. These results suggest that CRF may have an activating action in the central nervous system independent of its effects on the anterior pituitary gland.

Table 1 Effects of CRF (i.c.v.) on behaviour of rats in open field

	Crossings* inner	Crossings outer	Rearing* free	Rearing wall	Rearing duration (s)	Grooming duration
Saline	7.9±3.0	96.4±7.6	4.9±1.4	33.3±3.7	44.0±4.7	29.4±6.6
CRF (0.0015 nmol)	14.6±4.6†	90.1±10.4	9.4±3.3	34.9±3.7	42.1±4.1	38.1±14.2
CRF (0.015 nmol)	5.1±1.3	92.3±13.4	2.3±0.6	24.4±3.6	37.8±8.1	30.6±8.9
CRF (0.15 nmol)	1.9±0.6	29.1±7.5‡	0.0±0.0‡	4.3±1.5‡	7.1±2.3‡	90.9±18.4‡

* F_{max} $P<0.05$: raw data square root transformed for ANOVA; *a posteriori* tests were only made after obtaining significant differences using ANOVA. † Significantly different from CRF 0.15 nmol group, Newman–Keuls test $P<0.05$. ‡Significantly different from saline group, Newman–Keuls test $P<0.05$.

In the initial experiments the subjects were male albino Wistar rats (200–230 g at the time of injection) which were group housed and maintained in a temperature- and light-controlled environment. For the intracerebroventricular (i.c.v.) injections, rats were equipped with a cannula aimed above the lateral ventricle. For this surgery, the animals were anaesthetized with Chloropent (Fort Dodge Laboratories) and secured in a Kopf stereotaxic instrument with guinea pig ear bars. A 7-mm long, 23-gauge stainless steel guide cannula was lowered within 1 mm of the ventricle and anchored in place with two stainless steel screws and dental cement. With the tooth bar 5 mm above interaural zero, coordinates were −0.6 mm posterior to bregma, ±2.0 mm lateral and −3.2 mm below the skull surface at the point of entry. For an injection, the dummy stylet was removed and an 8-mm 30-gauge stainless steel cannula with 1 m of Tygon microbore tubing (Norton Plastics and Synthetics) was inserted through the guide.

CRF, synthesized by the solid phase method on a paramethylbenzylhydryl amine resin using previously described techniques[6], was purified by HPLC after cleavage and deprotection by HF. The isolated material was shown to be highly purified (>98%) when tested by homogeneity in several reverse phase HPLC systems including analysis of a tryptic object. As reported earlier, such closely related analogues of CRF as des-Ala^{41}-CRF, [$Met(O)^{21}$]-CRF, des-$Ileu^{40}$, Ala^{41}-CRF and CRF-OH could be separated in the chromatographic conditions developed in our laboratory (ref.1 and J.R. *et al.*, in preparation). One hour before injections, the peptide was dissolved in 0.9% saline and kept on ice; 2 µl of peptide were injected by gravity over a 30-s period simply by raising the tubing above the head of the rat until flow began. Volume was measured by marks on the PEID tubing previously calibrated with a 10-µl Hamilton syringe. Only those rats whose cannulae flowed easily with this technique were used in the experiment. The lateral ventricle cannula placements were verified by injecting 2 µl of toludine blue dye into the ventricle and immediately killing the rat by decapitation. Of 35 rats tested in this way, all showed spread of the dye throughout the ventricular system. For subcutaneous CRF injections, each rat received the peptide dissolved in 1 ml per kg body weight saline in the neck.

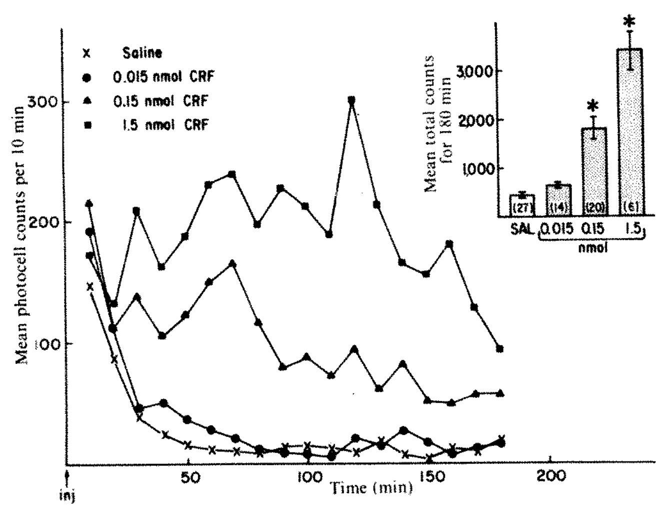

Fig. 1 Locomotor response after i.c.v. infusions of 0.1, 1 and 10 µg corresponding to 0.015, 0.15 and 1.5 nmol of CRF, respectively. Ordinate refers to total photocell counts for each 10-min period of a 3-h test.* Significantly different from saline, and from each other. $P<0.05$, Neuman-Keuls test following analysis of variance. Mean total counts for 180 min represent average ±s.e.m.

Locomotor activity was measured in a 4×4 bank of 16 wire cages 20×25×36 cm each with two horizontal IR photocell beams across the long axis 2 cm above the floor. Noncumulative photocell beam interruptions were recorded every 10 min from electromechanical counters located in an adjacent room. Each rat was habituated first overnight and then for 2 h 1 day before peptide injections. On a test day, rats were habituated for 90 min just before peptide injections, which were given at 10 a.m. Results were analysed with a two-factor analysis of variance (ANOVA), with peptide or saline groups being the independent factor and time the repeated measure. If ANOVA revealed a significant ($P<0.05$) group effect, comparisons of individual means were made using the Newman–Keuls *a posteriori* test.

Open field testing took place in a large open field[7] measuring 115×115×46 cm tall and divided by thin white lines into 23×23 cm squares. In the open field, the light intensity was ~150 ft-candles and the white noise level was 70 dB. The open field was enclosed by sheets of one-way viewing sunscreen. Naive rats were tested in a 5-min session by placing the rat in the centre of the open field. The following behavioural measures were taken by two blind observers: rearing—inner and outer squares; locomotion—inner and outer squares, time rearing, time grooming and number of grooming bouts. Here, the rats were injected with 0.0015, 0.015 and 0.15 nmol of CRF 1 h before testing.

CRF injected i.c.v. produced a dose-dependent increase in activity as measured by photocell interruptions (Fig. 1). This increase in activity was significant at the 0.15 and 1.5 nmol doses. Rats injected with saline habituated rapidly, showing low photocell counts after 1 h, but rats given 1.5 nmol CRF had high counts for over 5 h post-injection (data not shown). Repeated i.c.v injections of CRF over several days did not modify this increase in behavioural activity. Following injections, rats in the photocell cages were observed through a one-way mirror. In addition to normal locomotion and sniffing, the rats injected with 0.15 and 1.5 nmol CRF exhibited a unique set of behaviours which seemed to reflect a general behavioural activation. These included elevated walking, grooming and rearing. The elevated walking was characterized by rhythmically walking forwards and backwards such that only the toes of the rat touched the cage. The rats frequently climbed up and down the two mesh sides of the photocell cages, and they also engaged in other repetitive locomotion such as moving forwards and backwards in a straight line with their head along the ground and sniffing vigorously. While rearing, rats pawed rapidly against the sides of the cages. When returned to their home cages, the rats exhibited an increase in mounting behaviour and aggressivity.

Although other peptides, such as endorphins and ACTH, have been shown to produce increases in behavioural activity[8–11], the time course and nature of the response observed with CRF differed dramatically from the responses observed with endorphins. Opioid peptide activation following i.c.v. injection consists of an initial depressant phase which varies in duration with the dose and of a staring behaviour that

approaches a catatonic-like state at higher doses. CRF did not produce these responses, nor the bursts of locomotor activity interrupted by scratching and grooming behaviour observed with opioid peptides[8], nor the well-documented 'stretching–yawning syndrome' (SYS) observed after i.c.v. injection of ACTH and ACTH-like peptides[9–12]. In contrast, the activation produced by CRF at the lower doses appeared to be an exaggeration of normal activation produced by introduction into a familiar environment. At the highest dose, the behaviour was characterized by the more bizarre elevated walking and rhythmic walking forwards and backwards.

Results in the open field test indicate that rats receiving CRF i.c.v. in a novel environment respond in such a way as to be consistent with an increased emotionality or increased sensitivity to the stressful aspects of the situation. Here, the rats at the 0.15 nmol dose of CRF showed decreases in locomotion and rearing, but increases in freezing behaviour. These behavioural responses are characteristic of an increase in emotional reactivity (Table 1). Typically, a rat injected with 0.15 nmol CRF and placed 1 h later in the open field moved hesitantly to the outer squares of the open field. The animal then either slowly circled the open field, remaining close to the floor and wall with virtually no rearing, or remained in one of the corners grooming or moving forwards and backwards. In contrast, control animals injected with saline rapidly circled the open field initially with a substantial amount of rearing and later in the 5-min period made forays into the inner squares with some free rearing. Interestingly, at the lowest dose of CRF, 0.0015 nmol, there were some increases in rearing and locomotion (Table 1) that would be considered more consistent with the activation observed in the photocell cages described above.

Subcutaneous injections of identical doses of CRF failed to produce significant effects in the open field test, although the highest dose produced some trends in the same direction. These trends were not statistically significant by ANOVA, nor are these results of similar magnitude to those observed by central injections. For example, the largest effect of the peripheral injection was a 46% decrease in wall rearings in the open field at the 0.15 nmol per rat dose compared with an 87% decrease following central injection (ANOVA $P > 0.10$). Also, there was a complete blockade of the free rearing with the 0.15 nmol dose injected i.c.v. but only a 37%, not statistically significant, change following the same dose injected subcutaneously. Thus, these preliminary results suggest a relatively minor contribution of the systemic actions of the peptide for the open field effects. In addition, subcutaneous injections of 0.015, 0.15, 1.5 and 7.5 nmol of CRF failed to increase locomotor activity significantly in the photocell cages (data not shown). These results together suggest that CRF is acting centrally to produce its behavioural activation, as these systemic doses are capable of producing significant elevations of plasma ACTH and β-endorphin.

Although these results suggest that CRF can act centrally to produce a dose-dependent behavioural activation, physiologically CRF might act in concert with ACTH, β-endorphin or glucocorticoids to bring about some behavioural responses to circumstances such as stress. CRF, however, is structurally specific in its behavioural effects, as the C-terminal free carboxyl analogue, which is inactive *in vitro*[1], did not augment locomotor activity to the extent observed with CRF itself. Based on maximal response, this analogue was $\frac{1}{1,000}$th as potent as CRF in increasing locomotor activity. Sauvagine, a non-mammalian polypeptide with striking homology with CRF[13] and similar *in vitro* activity[20], was equipotent in increasing locomotor activity.

Thus, in a familiar environment (photocell cages) CRF produces a behavioural activation as reflected by a prolonged increase in locomotor activity where similarly treated, saline-injected animals rapidly habituate and go to sleep. However, in a novel stressful environment (open field test), similar doses produce decreases in behaviour such as rearing and inner square crossings that are consistent with an increase in the stress of the situation. How these effects described above extend to other less stressful situations involving such theoretical constructs as learning and attention remains to be determined.

The present results thus provide evidence that CRF may have neurotropic action independent of the hypophyseal system. These observations, in conjunction with the well documented involvement of β-endorphin and corticotropin in stress[14–18], suggest a possible role of central CRF in similar adaptive mechanisms.

The research was supported in part by NIH grants AM26741 and AA03504, and conducted in part by the Clayton Foundation for Research, California Division. W.V. is a Clayton Foundation Investigator. We thank Drs F. Bloom and M. Brown for helpful discussions, Sylvia Quijada, Ron Kaiser, Rick McClintock, R. Galyean, Eva Alwerud and Jonathan Schleimer for technical assistance, Bob Peterfreund for coding the blind procedure, and Susan McCall for manuscript preparation.

Dimeric tetrapeptide enkephalins display extraordinary selectivity for the δ opiate receptor

Yasuyuki Shimohigashi, Tommaso Costa, Hao-Chia Chen & David Rodbard

Bethesda, Maryland 20205, USA

The μ and δ opiate receptors, postulated on the basis of pharmacological observations, have been well characterized in ligand-binding studies[1–6]. The several classes of opiate receptor appear to subserve different functions[7–9]. Although highly specific μ ligands are available, there has been a paucity of high-affinity ligands with δ specificity that could be used to investigate the functions, properties and spatial distribution of the δ receptor. Previous structure–activity studies of the enkephalins have suggested that a free carboxyl group at the C-terminus is an important determinant of δ selectivity[9,10]: amidation of Leu⁵ or Met⁵ results in a non-selective ligand. Recently, however, we have demonstrated that cross-linking enkephalin amides by a methylene bridge of suitable length produces a dimeric pentapeptide, with greater affinity and selectivity for the δ receptor than is found in the original δ ligand[11,12]. Evidence that this dimer may interact simultaneously with two δ, but not two μ receptors[12] is consistent with independent demonstrations that the δ receptors are clustered in the membrane[7,13]. When the C-terminal amino acid of enkephalin is removed, the resulting tetrapeptide enkephalin amide H-Tyr-D-Ala-Gly-Phe-NH_2 and its analogues are potent and selective

ligands for μ opiate sites[14,15]. If the δ receptors were closely clustered, as suggested by our findings with dimeric enkephalin pentapeptides[11,12] and by others[7,13], then it might be possible to form a dimeric analogue of the tetrapeptide enkephalin which could interact with two δ receptors but not with two μ receptors. Theoretically, this would confer δ selectivity on the dimer of a μ-selective ligand. We have thus synthesized a series of dimeric analogues of the μ-selective tetrapeptide [D-Ala^2, des-Leu^5]enkephalin amide by cross-linking at the C-terminus with NH_2-$(CH_2)_n$-NH_2, with $n = 2$–12. We report here that the dimer with $n = 12$ has a nearly 1,000-fold increase in δ/μ selectivity ratio, and is thus a δ-selective ligand.

A series of dimeric tetrapeptide enkephalins have been synthesized by a two-step coupling procedure: cross-linking of Boc-Phe-OH with NH_2-$(CH_2)_n$-NH_2 (where $n = 2$–12), followed by elongation with Boc-Tyr-D-Ala-Gly-OH. Purity was confirmed by mass spectrometry, amino acid analysis and TLC. [D-Ala^2, D-Leu^5]enkephalin (DADLE), [D-Ser^2, Leu^5]enkephalyl-Thr (DSLET) and monomeric tetrapeptide [D-Ala^2, des-Leu^5]enkephalin amide (DAPEA) were purchased from Peninsula Laboratories (San Carlos, California). All peptides were evaluated for their activity in two different radioligand assay systems, using either ^{3}H-DADLE (40 Ci mmol^{-1}; 0.10 nM) and membranes from neuroblastoma–glioma hybrid (NG108-15) cells[5,16], or ^{3}H-naloxone (^{3}H-NAL, 50.2 Ci mmol^{-1}; 0.15 nM) in rat brain membrane preparations[17].

In the 'δ receptor' assay, the removal of the C-terminal amino acid residue from the pentapeptides [D-Ala^2, Leu^5]enkephalin amide (DALEA) and DADLE, giving the tetrapeptide [D-Ala^2, des-Leu^5]enkephalin amide (DAPEA), caused a substantial loss of δ activity (Table 1). When ^{3}H-DADLE was used as the labelled ligand in the assay, DAPEA was approximately 30-fold less potent than DALEA and DADLE. In contrast, the dimeric tetrapeptide enkephalins (DTE$_n$) were very active for the δ receptors with IC_{50} values of 1–4 nM. In particular, DTE$_{10}$ and DTE$_{12}$ (with cross-linking methylene chains of $n = 10$ and 12 respectively) were 30-fold more potent than the DAPEA monomer, and were as active as DADLE and DALEA, and more active than [D-Ser^2, Leu^5]enkephalyl-Thr (DSLET).

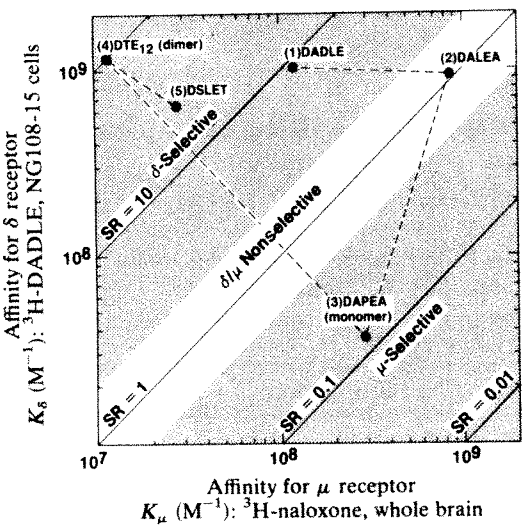

Fig. 1 Two-dimensional display of affinities of enkephalin peptides in a μ-specific radioligand assay (K_μ, abscissa), and in the δ-specific radioligand assay (K_δ, ordinate). Non-selective ligands would fall in the region along the main diagonal, μ-selective ligands below and to the right, and δ-selective ligands above and to the left. Compare (1) DADLE, the δ prototype; (2) DALEA, the amidated pentapeptide enkephalin; (3) DAPEA, the amide of the tetrapeptide [D-Ala^2, des-Leu^5]enkephalin; (4) DTE$_{12}$, the dimer of DAPEA, connected by a methylene bridge with $n = 12$; and (5) DSLET, the best δ-selective ligand previously reported. Fine diagonal lines correspond to 10-fold changes in the δ/μ SR. All affinities were calculated using the formula: $K_1/K_2 = (IC_{50})_2/(IC_{50})_1$, which is valid in the present experimental conditions with low per cent binding of labelled ligand[19]. The calculations used the following data, obtained in similar conditions: in the δ activity assay, DADLE shows $K = 1.03 \times 10^9$ M^{-1} (N = 4 expts) and an $IC_{50} = 1.15 \pm 0.07$ nM ($N = 4$); in the μ assay, naloxone displays $K = 6.6 \pm 1.8 \times 10^8$ M^{-1} ($N = 6$) and $IC_{50} = 1.56 \pm 0.15$ nM ($N = 3$).

In the 'μ receptor' assay, when ^{3}H-NAL was used as labelled ligand, DAPEA monomer retained high affinity, was only three-fold less potent than DALEA, and was twice as potent as DADLE and 10-fold more potent than DSLET. Dimers with $n = 2$–8 (DTE$_2$–DTE$_8$) showed higher potencies than the monomer DAPEA, and had IC_{50} values of 1.8–2.7 nM. DTE$_{10}$ was slightly less active than DAPEA. Surprisingly, the dimer of tetrapeptide enkephalins with $n = 12$ (DTE$_{12}$) showed an extremely low affinity for μ receptors: approximately 28-, 12- and 80-fold lower affinity than DAPEA, DADLE and DALEA respectively.

We may define the δ/μ selectivity ratio (SR) as the ratio of the IC_{50} using ^{3}H-NAL and whole brain divided by the IC_{50} obtained using ^{3}H-DADLE and NG108-15 cells (Table 1). A completely non-selective compound with the same potency in both assays should have a ratio of unity[9]. For example, DALEA shows a SR of 0.97, and thus serves as a non-selective ligand. The tetrapeptide DAPEA shows a SR of 0.1, corresponding to its 10-fold preference for μ receptors, while DADLE (SR = 7.2) and DSLET (SR = 20) are δ-selective peptides. Dimers DTE$_2$ and DTE$_4$ are non-selective (SR ~ 1), while DTE$_6$ and DTE$_8$ slightly favour the μ and δ receptor sites respectively. The dimer DTE$_{10}$, with a longer cross-linking methylene chain, favours δ receptors (SR = 4.7). The dimeric tetrapeptide enkephalin DTE$_{12}$ shows an extraordinary selectivity for δ receptors: its SR of 91 is approximately 13 times that of DADLE and 4.5 times that of DSLET, which has been regarded as the most δ-selective ligand available to date. The DTE$_{12}$ dimer shows a 30-fold greater affinity for the δ receptor and a 30-fold weaker affinity for the μ receptor, relative to the monomer DAPEA.

The inter-relationships among the various ligands are illustrated in Fig. 1. The abscissa indicates the equilibrium constant of association (affinity constant K_μ) estimated using the μ-specific radioligand assay. The ordinate shows the affinity (K_δ) in the δ-specific radioligand assay. The line of identity corresponds to a δ/μ non-selective ligand. The region below the line of identity corresponds to a μ-selective ligand, that above the line to δ-selectivity. Lines corresponding to 10-fold changes in SR are shown. DADLE (point number 1) is the progenitor of the δ-specific ligand, with a K_δ of $\sim 10^9$ but a K_μ of 10^8. Amidation of [D-Ala^2, Leu^5]enkephalin, forming DALEA (point 2), results in loss of selectivity. The amide of the tetrapeptide (DAPEA, point 3) shows ~10-fold selectivity for the μ receptor, consistent with previous reports[14,15]. However, the dimer of this tetrapeptide with a methylene bridge of $n = 12$ (DTE$_{12}$, point 4) shows a dramatic increase in δ selectivity ($K_\delta = 10^9$, $K_\mu = 10^7$). Its affinity and selectivity surpass those of DSLET (point 5).

The present results for DADLE and DSLET are consistent with those derived from *in vitro* muscle bioassays. Gacel *et al.*[18] reported that DSLET was seven times more selective than DADLE when evaluated in terms of its inhibitory potencies on the electrically stimulated mouse vas deferens and guinea pig ileum (corresponding to δ and μ bioassays respectively).

The present findings (Table 1, Fig. 1) are consistent with the hypothesis that the dimers of the tetrapeptide can serve as bivalent ligands, binding simultaneously to two distinct but closely clustered δ receptors, but failing to bridge two μ receptors, and complement those for the dimers of the pentapeptide leucine enkephalins, (H-Tyr-D-Ala-Gly-Phe-Leu-NH-)$_2$ (-CH_2-)$_n$. If the C-terminal leucine residue were approximately as long as a methylene chain with $n = 3$, then chain lengths of $n = 2$–6 for the dimeric pentapeptides would correspond to $n = 8$–12 for the dimeric tetrapeptides. Thus it is not surprising that the most selective and potent tetrapeptide has the longest methylene bridge, whereas the most potent pentapeptide has

Table 1 Receptor binding activities of enkephalin analogues

Enkephalins	IC_{50} (nM) δ Activity (^{3}H-DADLE)	μ Activity (^{3}H-NAL)	δ/μ Selectivity ratio $(IC_{50})_\mu/(IC_{50})_\delta$
Monomer			
DAPEA: H-Tyr-D-Ala-Gly-Phe-NH_2	33.2	3.48	0.10
DALEA: H-Tyr-D-Ala-Gly-Phe-Leu-NH_2	1.24	1.20	0.97
DADLE: H-Tyr-D-Ala-Gly-Phe-D-Leu-OH	1.15	8.22	7.2
DSLET: H-Tyr-D-Ser-Gly-Phe-Leu-Thr-OH	1.85	37.9	20
Dimers; DTE_n (H-Tyr-D-Ala-Gly-Phe-NH–$(CH_2)_n$–NH-Phe-Gly-Ala-D-Tyr-H)			
DTE_2	1.68	1.81	1.1
DTE_4	2.87	2.79	0.97
DTE_6	3.67	2.28	0.62
DTE_8	1.46	2.66	1.8
DTE_{10}	1.04	4.84	4.7
DTE_{12}	1.06	96.3	91

Results are expressed as the IC_{50} for each compound in an assay for δ activity using ^{3}H-DADLE (0.10 nM) and NG108-15 cell membranes according to Chang *et al.*[5,16], and in an assay for μ activity using ^{3}H-naloxone (0.15 nM) and membranes prepared from whole brain[17]. Specific binding was measured as the difference between total binding and that in the presence of 10^{-5} M DADLE or 10^{-5} M naloxone. Competition curves were analysed by computerized non-linear least-squares estimation of the logistic curves, to obtain an estimate of the IC_{50} with its standard error[20]. IC_{50} values showed a within-experiment coefficient of variation (c.v.) of 6%, and a between-experiment c.v. of 14% for the δ activity assay, with values of 14 and 16% respectively in the μ activity assay. The δ/μ selectivity ratio is defined as the IC_{50} in the μ assay divided by the IC_{50} in the δ assay.

the shortest methylene bridge ($n = 2$): the observations for both series of dimers are consistent with very close spacing of δ receptors.

To establish that the special properties of the dimer is due to its bivalency, we are currently synthesizing alkylamidated derivatives of the enkephalin monomers and 'handicapped dimers' with mono-*N*-acetylation of one of the tyrosines in both the tetra- and pentapeptide series. Studies of these new compounds should help to exclude alternative hypotheses to the cross-linking mechanism. Presumably, the lack of increased affinity of DTE_n or DPE_n for the μ receptor is due to a different spatial pattern of μ receptors in the membrane. This rationale has provided a basis for the design and synthesis of what appear to be superior probes of the δ receptor. A similar strategy should be useful in designing ligands with improved affinity and selectivity for a wide variety of other receptor systems for drugs, hormones and neurotransmitters.

We thank Drs H. Fales and R. D. Macfarlane for mass spectrometry of peptides, and Dr S. Matsuura and P. J. Munson for many helpful discussions. Drs K. J. Catt and S. Krumins provided constructive reviews of the manuscript, and G. M. Thornton provided secretarial assistance.

Characterization of the structural gene and putative 5′-regulatory sequences for human proopiomelanocortin

Madeleine Cochet*, Annie C. Y. Chang & Stanley N. Cohen

Departments of Genetics and Medicine, Stanford University School of Medicine, Stanford, California 94305, USA

It is now well established that the hormones corticotropin (ACTH) and β-lipotropin (β-LPH) are contained within a common precursor peptide called proopiomelanocortin (POMC), which is synthesized in the anterior and/or intermediate lobes of the pituitary[1–3] and in the hypothalamus[4]. The recent cloning of a 'full-size' cDNA copy of bovine POMC mRNA has revealed the presence of additional peptides in the previously 'cryptic' segment of the precursor protein[5]. This cDNA has been used as a hybridization probe for the isolation and characterization of a bovine genomic DNA segment encoding the complete POMC mRNA[6], and for isolation of part of the corresponding human genomic DNA sequence[7]. DNA sequence analysis of these isolates and of part of the rat POMC gene[8] has shown that, in the species studied, certain segments of the POMC structural gene have been conserved during evolution, whereas the nucleotide sequences of other segments have diverged sharply. We have now isolated and characterized a 11.6-kilobase (kb) human genomic DNA fragment that encodes the complete POMC mRNA and putative regulatory sequences proximate to the gene (which is repressed by glucocorticoids *in vivo*[9]). We have also analysed the 800-base pair (bp) segment preceding the mRNA coding sequence, within which—at a position nearly 480 bp upstream from the mRNA start site—is a 21-bp segment that shares homology with a DNA sequence beginning 370 bp upstream from two other glucocorticoid-controlled genes. We speculate that these sequences may be involved in the regulation of POMC gene expression by glucocorticoids.

0028-0836/82/210335-05$01.00

Using probes made by nick-translation of segments of a previously characterized human POMC genomic DNA fragment (Fig. 1, probes *a* and *b*)[7,10], we screened a human fetal DNA library (a gift of T. Maniatis) by *in situ* hybridization in standard conditions (Fig. 1 legend). Two bacteriophage λ plaques that reacted with probe *a* also hybridized with probe *b*, which only contains sequences corresponding to the 5′ end

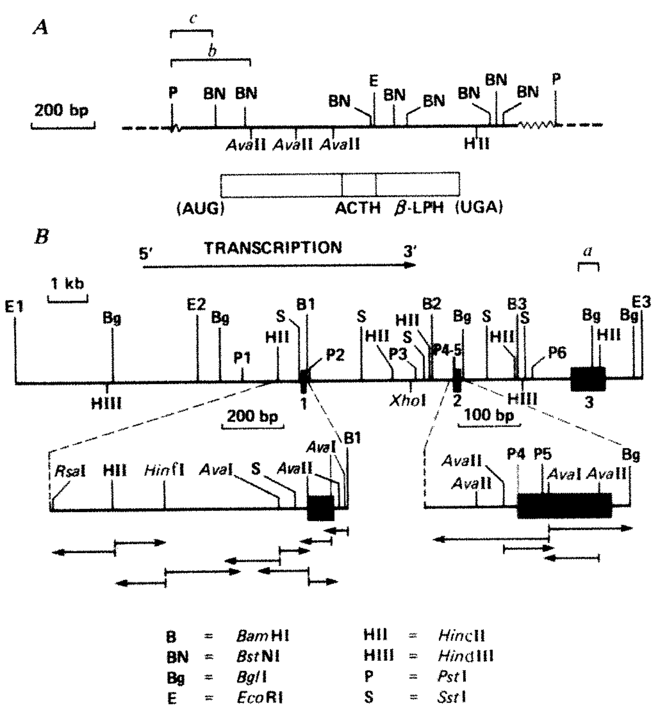

Fig. 1 *A*, partial restriction endonuclease map of the bovine POMC cDNA insert of pSNAC20 (ref. 5). The broken lines represent pBR322 DNA sequences. The serrated lines represent the 27- and 112-nucleotide poly(dG)·poly(dC) tracts lying at junctions between the plasmid vector and the cloned cDNA. The 5′ and 3′ termini of double-stranded cDNA are designated according to the corresponding ends of bovine POMC mRNA. *b* and *c* indicate the probes used for the hybridization studies described in the text and were prepared as follows. An *Ava*II endonuclease-generated fragment of the pSNAC20 plasmid, containing 248 bp of the 5′ end from the bovine cDNA insert plus 119 bp of pBR322 sequences, was inserted into the *Hinc*II cleavage site of pACYC177 by blunt end ligation after filling-in of the ends by DNA polymerase. The resulting plasmid (pACYC654) was digested by the *Pst*I restriction endonuclease, generating two fragments, one of which contains the 5′ end of the bovine cDNA. This fragment (530 bp) was then purified by sucrose gradient centrifugation, and used as probe *b*. Probe *b* was also digested by *Bst*NI endonuclease, giving three fragments, and the resulting 134-bp fragment (which contained most of the sequences corresponding to the 5′-untranslated region of bovine POMC mRNA) was purified by electrophoresis, yielding the *c* probe. The open bar below the POMC cDNA corresponds to the POMC peptide; the initiation and termination codons are in brackets. *B*, partial mapping of the structural gene encoding human POMC mRNA and strategy of sequencing. The human fetal DNA library used was constructed by inserting DNA fragments from a partial *Eco*RI endonuclease digest into a bacteriophage λ charon 4A vector[30]. It was screened by *in situ* hybridization[31] using the nick-translated[7,10] *a* probe. This probe corresponds to an *Ava*I–*Hinc*II fragment of a human genomic DNA segment previously cloned in the pACYC401 plasmid[7] and contains sequences encoding the ACTH–βLPH region of POMC. The partial restriction enzyme cleavage map corresponding to the genomic DNA contained in H-POMC λ5A (one of the two identical clones we obtained) was deduced by analysis of DNA samples singly or doubly digested with restriction endonucleases. The black thick bars and the numbers below them designate DNA sequences corresponding to POMC mRNA (exons). Their positions were determined by hybridization, with the nick-translated probes *a*, *b* or *c*, of endonuclease-treated DNA digests transferred onto nitrocellulose filters[32] or aminothiophenol paper (see Fig. 3 legend). Hybridization conditions with probes *a* and *b* have been described previously[7]; conditions used with probe *c* are described in Fig. 3 legend. For convenience, DNA fragments were identified by the abbreviated names of the endonuclease cleavage sites that bracket them, followed by a number designation according to the direction of transcription (for example, E2–E3 is the DNA fragment terminated at the 5′ end by *Eco*RI cleavage site number 2 and at the 3′ end by *Eco*RI site number 3). The DNA fragments carrying exons 1 and 2 are enlarged in the diagram and the strategy of sequencing is shown. The arrows designate the segments sequenced; the tails indicate the sites of ^{32}P end-labelling of the fragments.

of bovine POMC mRNA. Analysis of the DNA from these clones by restriction endonuclease digestion and electrophoresis on agarose gels indicated that both included *Eco*RI fragments 11.6 and 4.7 kb long.

DNA from one of these clones (H-POMC λ5A) was analysed further by electrophoresis of products resulting from single or double digestion with restriction endonucleases (Fig. 1*B*). Only the E2–E3 segment of the 11.6-kb fragment hybridized to both probes; DNA fragments B3–E3 and P6–E3 hybridized only to probe *a*, which includes all of the protein-coding sequences for ACTH and β-LPH, whereas DNA fragments B2–B3 and P5–P6 hybridized only to probe *b*. These findings suggested that at least a proportion of the sequences encoding the amino-terminal end of the precursor peptide[5] is contained in fragment B2–B3, and permitted the endonuclease cleavage sites of the genomic DNA fragment to be oriented with respect to transcription (see Fig. 1).

Finer mapping of the B2–B3 fragment following subcloning using the vector pBR322 indicated that sequences homologous to probe *b* are localized to the region surrounding the P5 site (data not shown). The DNA sequence for this region (Fig. 2) was determined according to the strategy shown in Fig. 1*B*. A high degree of homology was observed for 152 bp (nucleotides +88 to +239) in the region designated as exon 2 in Fig. 2, which is contiguous with a previously identified region of interspecies conservation that begins near the 5′ end of exon 3. The conserved region is delineated by intron–exon junction consensus sequences[11], which include G-T at the 5′ end and A-G at the 3′ end of the intron. Exon 2 contains the AUG translational start codon for the POMC peptide, the conserved downstream codons specifying the hydrophobic leader sequences of human and bovine POMC, and only a short (20 bp) segment of the untranslated region of POMC mRNA. Thus, the remainder of the untranslated region was either not present on the 11.6-kb fragment, or alternatively, the lack of detectable hybridization of probe *b* with any other segment of this fragment might be explained by evolutionary divergence in the sequences of the two mammalian genes.

As human POMC mRNA was not readily available, we re-probed the 11.6-kb fragment with the 5′ end of bovine DNA, using less stringent hybridization conditions that might allow identification of regions of incomplete homology. Fragments of H-POMC λ5A DNA generated by *Eco*RI and *Bam*HI endonucleases were subcloned, transferred to aminothiophenol paper (B. Seed, personal communication) after electrophoresis in gels, and hybridized at various temperatures between 45 and 65 °C with probe *c*, which contains 107 bp of the extreme 5′ end of bovine POMC cDNA (15 bp of which are included in exon 2). At 56 °C, the temperature that gave the best signal over background, a positive signal was obtained only with the genomic DNA fragment containing exon 2 (Fig. 3, lane 3) and with the E2–B1 fragment (lane 2). More detailed analysis of fragment E2–B1 (Fig. 3*b*) localized the homologous sequence to a 160-bp *Ava*I endonuclease-generated fragment near the *Bam*HI terminus of the E2–B1 fragment (Fig. 3*b*, lanes 3, 4). The DNA sequence of this fragment and the surrounding regions between the *Rsa*I and *Bam*HI sites was determined according to the strategy shown in Fig. 1*B*.

Alignment of the nucleotide sequence (Fig. 2) with the published sequence for bovine POMC genomic DNA[6] (starting at position −181) allows assignment of a putative start site for the human mRNA (+1). The dinucleotide G-T is found 87 bp downstream from this start site at the end of a region that contains three segments showing >80% homology with the corresponding bovine sequences (positions +9 to +28, +43 to +63 and +71 to +87). We conclude therefore that this region may contain the first mRNA-coding segment (that is, exon 1) of the human gene, despite its different length from the corresponding bovine segment (87 instead of 108 bp). A 'TATA' box characteristic of an RNA polymerase II (or B) promoter site[12] and a 'CAAT' box[13] are found 28 and 63 bp respectively upstream from the putative start site of the POMC mRNA at

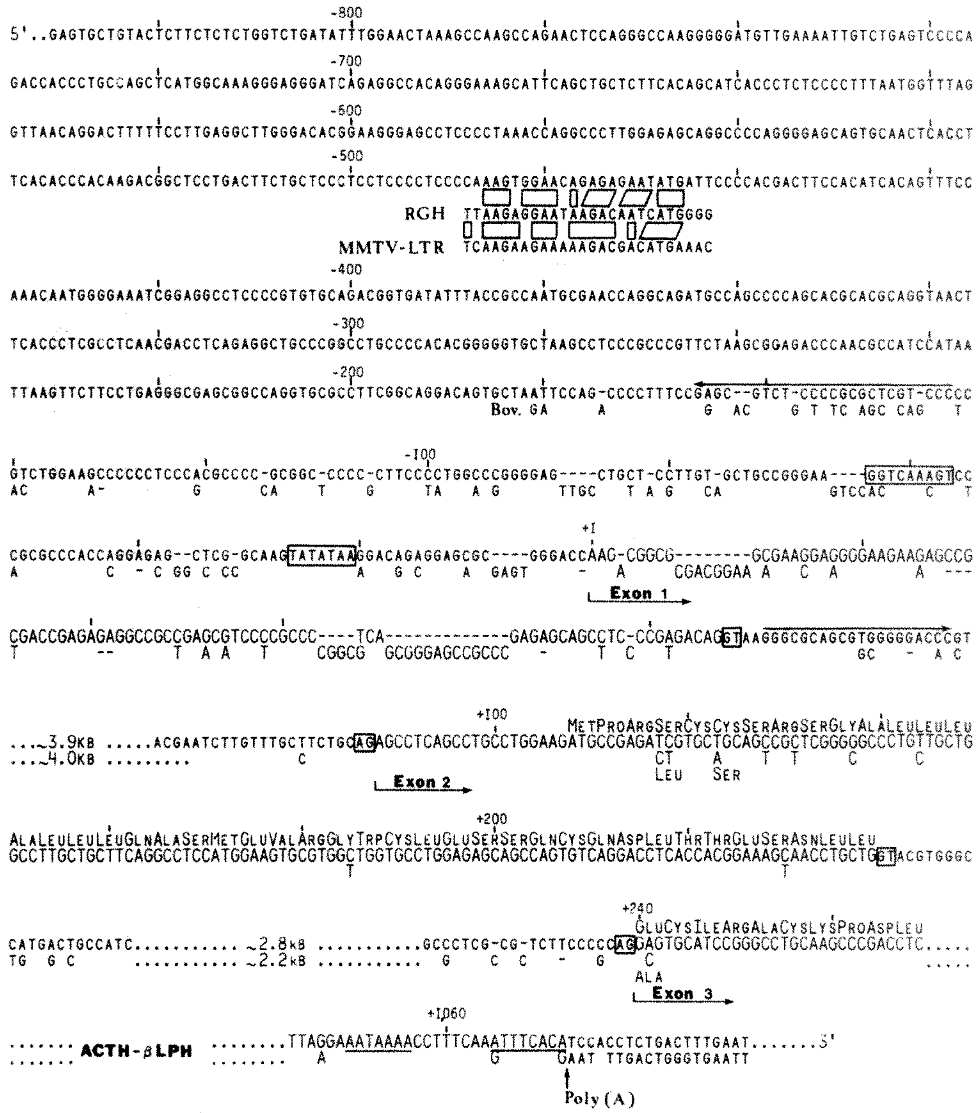

Fig. 2 Nucleotide sequence of the human POMC genomic DNA strand corresponding to POMC mRNA. Digests of DNA fragments E2–B1 and B2–B3, which had been subcloned using the pBR322 plasmid vector, were digested with *Ava*I, *Ava*II, *Bam*HI or *Hin*fI endonucleases and treated with polynucleotide kinase[33]. The nucleotide sequence was then determined[33] by following the strategy of Fig. 1*B*. The sequence of the strand that corresponds to mRNA is shown. Differences in nucleotides and amino acids in the bovine versus human sequences are indicated below the human DNA sequence. Broken lines represent nucleotides absent from the genomic DNA sequence. Position +1 indicates the putative start site of human POMC mRNA based on known bovine sequences[6]. Nucleotides are numbered plus for exonic sequences downstream from the mRNA start site and minus for sequences upstream from the mRNA start site. The TATA and CAAT sequences, and the A-G, G-T dinucleotides at the intron–exon junctions are boxed. The proposed consensus sequence[13] for the poly(A) addition site is underlined. The region of dyad symmetry is overlined by arrows. The region of homology between human DNA sequences and RGH[22] or MMTV-LTR[23] are shown by boxes; in both RGH and MMTV-LTR, the homologous sequence begins 392 nucleotides upstream from the mRNA start site. Errors in the partial sequence of exon 3 published previously[7] have been corrected as a result of additional analysis, and the sequence determined agrees with the DNA sequence of Takahashi *et al.*[27] and the protein sequence of Seidah and Chrétien[28,29]. Despite careful sequencing and reading we were unable to decide whether nucleotides −164 and 165 are G-A or A-G.

positions similar to those described for other mammalian genes[14]. Upstream from the CAAT box of the human POMC gene are runs of nucleotides (positions −64 to −75, −101 to −145, −165 to −179) that are significantly homologous with sequences found in the corresponding positions of the bovine gene; at other locations the bovine and human sequences are highly divergent. Interestingly, a region of very stable dyad symmetry ($\Delta G = -47$ kcal) is located 100 bp upstream from the CAAT box and at the 3′ end of intron A, therefore enclosing the CAAT and TATA boxes and all of exon 1.

If the identifications made above on the basis of DNA sequence analysis are correct, the E2–B1 segment of the 11.6-kb DNA fragment cloned in H-POMC λ5A should contain a promoter for RNA polymerase II. We demonstrated the presence of such a promoter in this region by *in vitro* transcription experiments[15–17] using endonuclease-generated digests of cloned POMC human genomic DNA (plasmids pλP2 and pλEB7) as templates for RNA polymerase II. The plasmids used for these studies contained respectively the human genomic DNA fragments P1–P2 and E2–B1; if the regions identified as TATA and CAAT boxes in these clones are in fact signals allowing initiation of trancription of the POMC gene, digests of pλP2 DNA by *Bam*HI, *Pst*I, or *Pvu*I endonuclease should yield *in vitro* RNA 'run off'[15] transcripts of 130, 300, and 427 nucleotides respectively, and a digest of pλEB7 DNA by the *Sal*I endonuclease should give a 405-nucleotide RNA transcript. The RNA transcripts synthesized *in vitro* on cloned POMC genomic DNA have the lengths predicted (Fig. 4). Thus, the sequences we have identified as the putative transcriptional regulatory region for the POMC gene seem capable of directing RNA polymerase II-dependent initiation of transcription *in vitro*.

Much work has focused on the role in gene regulation of sequences immediately upstream from the mRNA-coding regions of prokaryotic[18] and eukaryotic[14] genes, but little attention has been given to the possible influence of more distant upstream sequences. Recently, however, a putative binding sequence for the progesterone–receptor complex involved in the control of egg-white protein synthesis in the chicken oviduct has been identified 250–300 bp upstream from the mRNA start site of the ovalbumin gene[19]. In the case of the POMC gene, sequences at an equal or greater distance from the mRNA start site might be important in the glucocorticoid regulation of gene expression, or in the abnormal production of the POMC-derived peptides by certain non-pituitary tumours[20,21]. To explore the role of more-distant upstream regions in normal and abnormal POMC gene expression, we have determined the primary sequence of the 800-nucleotide segment preceding the POMC mRNA start site.

Comparison of the DNA sequence obtained by such analysis with published sequences of other glucocorticoid-controlled genes showed that between position −486 and −466 upstream

from the POMC mRNA start site is a 21-bp DNA segment (see Fig. 2) that shows 80% homology with a 21-bp stretch beginning 370 bp upstream from the mRNA start site of the rat growth hormone (RGH) gene[22]. A similar sequence (75% homology) starts at the same location relative to the mRNA start site of the long terminal repeat (LTR) of the mouse mammary tumour virus (MMTV) DNA[23]. The expression of both the RGH gene and the MMTV genetic sequence are positively regulated by glucocorticoids[24,25], whereas the expression of the POMC gene is negatively regulated by this hormone[9].

The existence of specific DNA sequences that may be involved in the binding of the hormone-receptor complexes has been suggested recently by *in vitro* studies for the MMTV LTR gene[26] and the egg-white protein genes in the chicken oviduct[19]. The presence of largely homologous sequences in two gene segments positively controlled by glucocorticoids, and also in

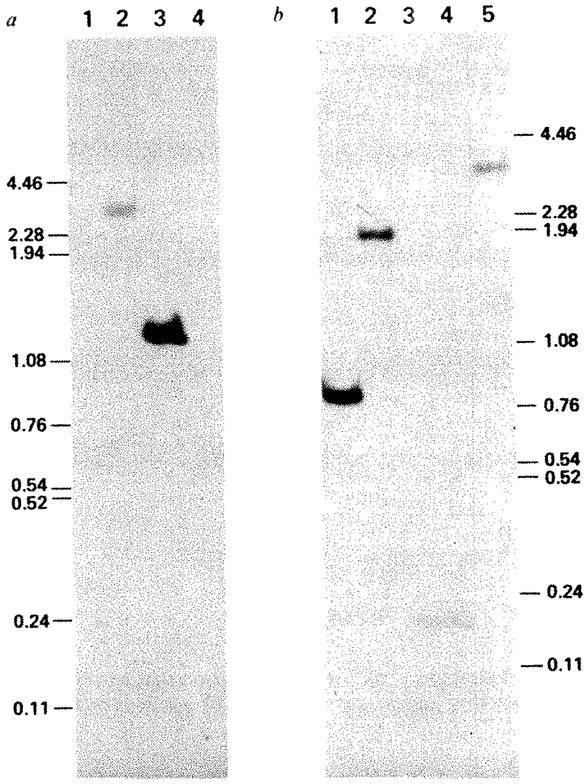

Fig. 3 Detection of the 5'-untranslated region of human POMC mRNA. Genomic DNA fragments E1–E2, E2–B1, B1–B2 and B2–B3 generated by *Eco*RI and *Bam*HI restriction endonuclease digestion of H-POMC λ5A DNA were subcloned using the pBR322 vector. The DNA of plasmids containing the various fragments was digested by restriction endonucleases, subjected to electrophoresis on 2% agarose gels, transferred on aminothiophenol paper (B. Seed, personal communication) and hybridized to 20 ng of the nick-translated probe *c* (10^8 c.p.m. μg^{-1}) for 48 h at 56 °C in 5×SSC, 0.1 M $NaPO_4$ *p*H 6.8, 10× Denhardt's solution[34]. After hybridization, the filters were washed at room temperature for 10 min in 2×SSC, 0.1% SDS twice, then 10 min in 0.5×SSC, 0.1% SDS once, and subjected to autoradiography for 12 h at −70 °C with XR-5 film and Dupont Cronex lightening plus intensifying screen. *a*: Lane 1, 0.4 μg of E1–E2 fragment digested with *Hin*dIII endonuclease; lane 2, 0.4 μg of E2–B1 fragment; lane 3, 0.5 μg of B2–B3 fragment digested by *Sst*I; lane 4, 0.5 μg of B1–B2 fragment. *b*, Digests of 0.5 μg E2–B1 fragment with *Hin*cII endonuclease (lane 1), *Pst*I (lane 2), *Ava*I (lane 3), *Ava*I plus *Pst*I (lane 4). Lane 5 contains undigested DNA. The numbers at the side of the figure indicate the molecular size (in kb) of marker DNA derived from λ wild-type DNA digested by *Hin*dIII, and SV40 DNA digested by *Hin*fI endonuclease. The hybridization signal seen with probe *c* (*a*, lane 3) is more intense than expected. We attribute this effect to slight contamination of probe *c* with probe *b* sequences, despite electrophoretic purification of the *c* probe fragment before use.

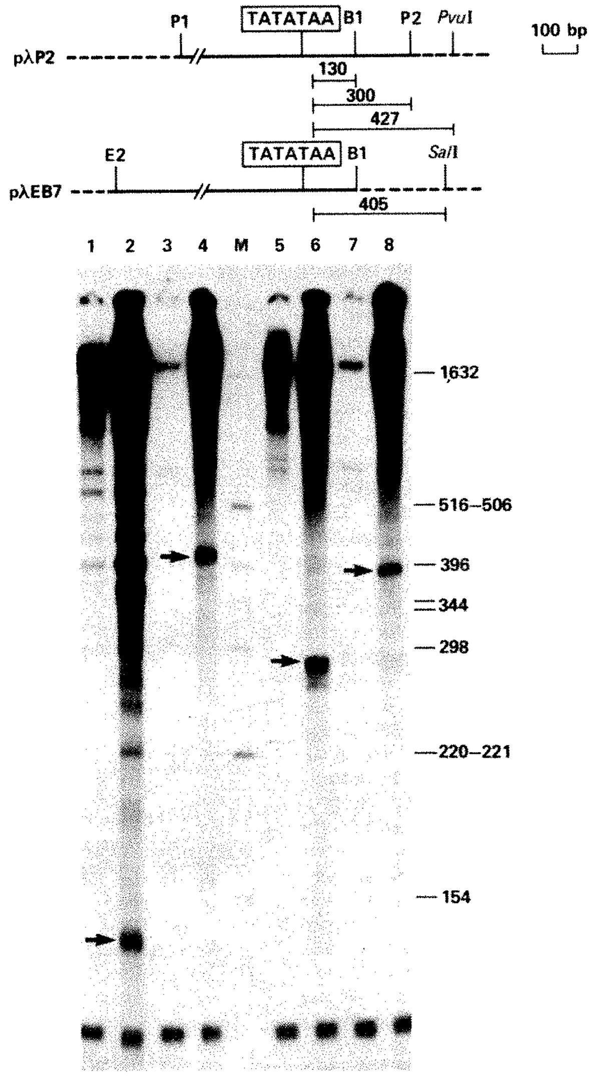

Fig. 4 Run-off analysis of RNA synthesized *in vitro* on human genomic DNA by RNA polymerase II (or B). The DNA fragments E2–B1 and P1–P2 of clone H-POMC λ5A were inserted into the pBR322 vector, yielding the chimaeric plasmids pλEB7 and pλP2. The resulting DNAs were used as templates for *in vitro* transcription by cell-free extracts of HeLa cells (BRL) as described[17]. The DNA fragments were either excised and purified by sucrose gradient centrifugation (fragment P1–P2, lanes 5, 6) or treated with restriction endonuclease and phenol-extracted (lanes 1–4, 7, 8). To differentiate transcripts made by RNA polymerase II (or B) from those resulting from RNA polymerase III (or C), 1 $\mu g\ ml^{-1}$ of α-amanitine was added to appropriate reaction mixtures (lanes 1, 3, 5, 7). RNA transcripts of the human genomic DNA were purified as described previously[16] and analysed on a 4.5% acrylamide/7 M urea gel. After drying, the gel was exposed to film for 6 h as described in Fig. 3 legend. The length of the RNA transcripts was determined relative to molecular length markers (lane M) consisting of fragments of pBR322 DNA produced by digestion with *Hin*fI and ^{32}P end-labelled. The lengths (in numbers of nucleotides, nt) are labelled on the right side of the panel. The region of initiation of transcription was inferred from the length of the RNA chains which are terminated prematurely by endonuclease digestion of the template DNA at specific sites, and which therefore 'run-off' the template[15]. The arrows point to the RNA transcripts described. Lanes 1–4, run-off transcripts of 4.5 μg of $p\lambda P_2$ double-digested with *Pst*I and *Bam*HI (lanes 1, 2) or *Pvu*I alone (lanes 3, 4). The α-amanitine-sensitive transcript has an apparent length of 135 (lane 2) and 415 (lane 4) nt. Lanes 5, 6, run-off transcripts of 2.8 μg of the excised P1–P2 fragment. The α-amanitine transcript has an apparent length of 292 nt (lane 6). The molecular weight was calculated for the upper transcript. The smear below is probably due to degradation because it does not appear each time. Lanes 7, 8, run-off transcript of 4 μg of pλEB7 digested by *Sal*I. The DNA transcript has an apparent length of 390 nt (lane 8).

the region upstream from the negatively controlled human POMC gene, could be accounted for if such sequences are involved in the binding to DNA of the glucocorticoid–receptor complexes. Although the homology in the DNA segments we have identified is incomplete, the occurrence of similar sequences at the same distance upstream from the mRNA start site in RGH and the MMTV LTR is of interest, although their functional significance remains unknown. In any case, the specific DNA sequence we have identified does not seem to be necessary for dexamethasone stimulation of MMTV LTR-regulated gene expression in transfected cells: stimulation still occurs after removal of all MMTV LTR sequences beyond the 170–200 nucleotides immediately upstream from the mRNA cap site (J. Majors and H. Varmus, and G. Ringold, personal communications).

Our data indicate that the 11.6-kb *Eco*RI endonuclease-generated gene fragment E2–E3 includes the entire structural gene for human POMC. The gene's mRNA coding sequences are contained in three exons of 87, 152 and 833 bp, separated by two introns of about 3.9 and 2.8 kb. While segments of both interspecies conservation and divergence exist in the mRNA-coding and non-coding regions of the human, bovine and rat POMC genes, the mRNA of all three species is spliced at identical sites. The longest segments of interspecies conservation occur in the protein-coding region of the gene, especially in the segment that includes the hormones ACTH and β-LPH. However, significant sequence conservation occurs also in the 3′-non-coding region and in a segment upstream from the TATA and CAAT boxes (−64 to −178), suggesting that these regions may be important in the expression of POMC *in vivo*.

After completing this work, we received a manuscript reporting a similar overall structure and DNA sequence of the mRNA-encoding region of the POMC gene and the immediately proximate upstream region[27]. The protein sequence recently reported in refs 28 and 29 corresponds to the DNA sequence that both we and Takahashi *et al.* have obtained.

These studies were supported by the US NIH. M.C. was a postdoctoral research fellow of the CNRS.

G inversion in bacteriophage Mu: a novel way of gene splicing

Micheline Giphart-Gassler, Ronald H. A. Plasterk & Pieter van de Putte

Laboratory of Molecular Genetics, Leiden State University, Wassenaarseweg 64, 2333 AL Leiden, The Netherlands

The G region of bacteriophage Mu is a 3,000-base pair (bp) invertible DNA segment that determines the host specificity of the phage[1,2]. Only phage with the G segment in the orientation designated (+) can adsorb to *Escherichia coli* K-12 (refs 3–5), whereas phage with the G segment in the (−) orientation infects other hosts such as *Citrobacter freundii* and *E. coli* C (ref. 1). It has been proposed that four genes are involved in host specificity—*S, U, S′* and *U′*—of which *S* and *U* are expressed in the orientation (+) and *S′* and *U′* in the inverted orientation (−) of the G segment. We have presented two alternatives for the organization of these genes (Fig. 1). In model A the four genes involved are entirely contained within the G segment, whereas in the alternative model (B) it is assumed that the proximal part of the *S* gene is located in the α part of the Mu genome. We report here that the *S* and *S′* genes are partially located outside the G segment and share a common part located in α (Sc). This common S region will be joined by G inversion to one of the two variable parts (Sv or Sv′) which results in the synthesis of either tail fibre protein S or S′.

In both models A and B two predictions were made concerning the *S′* gene: (1) that the structural polypeptide with a molecular weight (Mr) of 48,000 (48K) (see Fig. 2*a*,) which is a component of G(−) phage is indeed the product of a gene located at least partially in G and (2) that this *S′* gene is located in the region of G which is non-essential for G(+) phage[6]. Three Mu amber mutants were isolated which were amber phage on G(−) hosts but wild type on the G(+) host *E. coli* K-12. These amber mutations mapped in the G segment in that part which

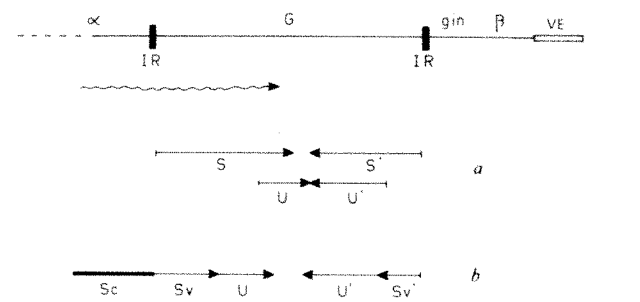

Fig. 1 Two proposed models for the organization of the G region of bacteriophage Mu. The G segment (3 kb) is situated between the α part (~30 kb) and the β part (1.5 kb). The G segment (drawn in orientation +) can invert by recombination between inverted repeats (IR). Amber mutations in genes *S* and *U* have been mapped in G with *U* mutations mapping distal to the *S* mutations[12] and these genes should be located in the leftmost 1,700 bp of G DNA[6]. *S* and *U* are essential for G(+) but not for G(−) phage[1]. The S protein (56K) and a 21K protein (U?) are structural components of G(+) phage particles but not of G(−) phage particles[1,13]. G(−) phage particles contain two structural proteins of 48K and 26K, tentatively designated S′ and U′, respectively, which do not occur in G(+) phage particles. It is assumed that S′ and U′ are involved in adsorption of G(−) phages and that their genes are located in the rightmost 1,300 bp of G DNA non-essential for G(+) phages. To obtain expression of S′ and U′ in the G(−) orientation, transcription of G genes starts in the α part of the Mu genome. The four proteins S, U, S′ and U′ require a coding capacity over 4 kb of DNA, a length exceeding the 3 kb G segment. If the four genes are located entirely in the G segment they should overlap (model A). In model B the *S* and *S′* genes span the α–G boundary with a common region in the α segment (Sc) and two variable regions at the ends of the G segment (Sv and Sv′).

0028–0836/82/210339—04$01.00

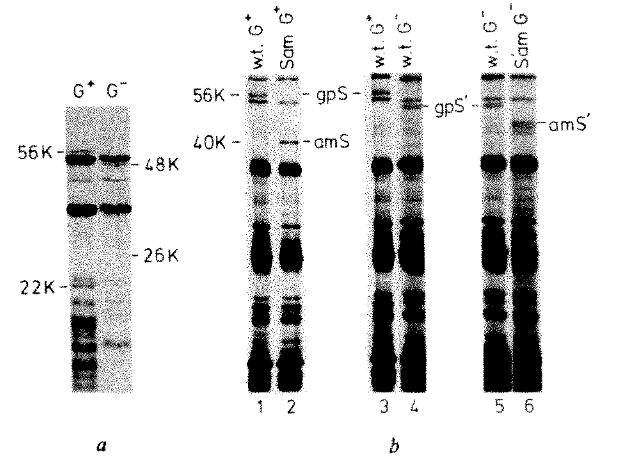

Fig. 2 *a*, Electrophoretic separation of the polypeptides of Mu G(+) and Mu G(−) phage particles[1]. The various structural polypeptides indicated are presumed to represent the following gene products (gp): 56K = gp *S*; 22K = gp *U*; 48K = gp *S'*; 26K = gp *U'*. *b*, Identification of *S* and *S'* gene products in *E. coli* minicells. Minicells were infected with Mu and Mu amber mutants. One hour after infection the minicells were labelled with ^{35}S-L-methionine and the proteins analysed on a 11.5–20% polyacrylamide gradient gel[13]. A Mu polypeptide of M_r 56,000 (56K, lane 1) is not synthesized in the minicells infected with Mu *Sam* 1004 (lane 2). The minicell producing strain PC2251, which resulted from a cross between an *E. coli* C donor and the minicell-producing Adler strain (P678–54), was found to be sensitive for G(−) phages. Lane 4 shows the polypeptide pattern of minicells of this strain infected with G(−) phages, compared with a pattern obtained from minicells of DS410 infected with Mu G(+) (lane 3). A 50K polypeptide is synthesized only after G(−) infection. This polypeptide is absent in minicells infected with Mu G(−) amber mutant 2101 (lane 6) or infected with G(−) amber mutant 2102 and 2103 (results not shown).

is non-essential for G(+) phage, as marker rescue of these mutations was observed with recombinant plasmids containing the right part of the G region (pGP202 and 203, Fig. 3*b*). Therefore, we conclude that there is indeed a region in the G segment which is only essential for G(−) phage. The gene product encoded by this region could be identified in minicells. As can be seen in Fig. 2*b*, minicells infected with Mu G(+) phage synthesize a 56K polypeptide identified as the *S* gene product (lane 2). This polypeptide is absent when G(−)-sensitive minicells are infected with G(−) phage, but another polypeptide of M_r 50,000 (50K, lane 4), comparable with that of the structural *S'* polypeptide, is synthesized instead. This polypeptide is not synthesized in minicells infected with any of the three Mu G(−) amber mutants (lanes 5, 6). These results show that the *S'* gene located in G is essential for G(−) phage only and encodes the structural protein unique for G(−) phage.

To analyse the genetic organization of the G region further, we cloned a Mu DNA fragment containing this region in pBR322. In isolates of this plasmid, pGP56 (Fig. 3*a*), the G region is found for 50% in the (+) and for 50% in the (−) orientation. Cells containing pGP56 express the genes *R*, *S* and *S'* as measured by complementation of Mu amber mutants.

To distinguish between models A and B (Fig. 1), we have isolated various Tn*5* insertions in pGP56, constructed various subclones of this plasmid and tested them for complementation and marker rescue of 'G' amber mutants. Fourteen independent Tn*5* insertions were mapped by restriction enzyme analysis in the G region and in regions flanking G (Fig. 3*a*). Figure 3*a* also shows the level of complementation of Mu *S* and Mu *S'* amber mutants in strains (either *E. coli* K-12 or *E. coli* C) harbouring pGP56 with the various Tn*5* insertions. The results allow the following conclusions. (1) Both *S* and *S'* are expressed from a promoter which is located in α between 900 bp (position 22, S and S'(+)) and 350 bp (position 44, S and S'(−)) to the left of the G segment. (2) The entire *S'* gene or Sv' is, as postulated, located in the right part of the G segment (in the (+) orientation; see positions 69 and 43). (3) Two Tn*5* insertions (44 and 48), located outside the G segment in α, give loss of expression of both *S* and *S'*. Therefore, these insertions are either in the common part of *S* and *S'* or are located between the promoter and the translation start of *S* and *S'*. (4) The promoter distal end of the *S* gene seems to be located in the vicinity of the *KpnI* site (975 bp removed from the left inverted repeat), as Tn*5* insertions 66 and 42 allow complementation of Mu *S* amber mutants.

To localize both the proximal and distal ends of *S* and *S'*, marker rescue and complementation experiments were performed with subclones of pGP56 (see Fig. 3*b*). pGP202, which is deleted for the Mu DNA between the two *HpaI* sites in the G region of pGP56, did not complement Mu *S* or *S'* amber mutants. This result indicates that the C-terminal end of both genes *S* and *S'* stretches beyond the two *HpaI* sites, located respectively 600 and 900 bp away from the left and right inverted repeats. Marker rescue of the *Sam*1004 mutation was observed with pGP202 and pGP204, whereas both pGP202 and pGP203 rescued the *S'am*2101 mutation. Thus, the *Sam*1004 mutation was mapped in the leftmost 600 bp and the *S'am*2101 mutation in the rightmost 900 bp of the G region. We identified in minicells the amber fragments of *Sam*1004 and *S'am*2101 which represent the translation products of the *S* and *S'* genes up to the amber mutations (Fig. 2). The amber fragment of *Sam*1004 has a molecular weight of 40,000, which requires a coding capacity of 1,100 bp of DNA. Thus, the site of the *Sam*1004 mutation is 1,100 bp removed from the translation initiation point of the *S* gene. The N-terminal end of the *S* gene should therefore be located at least 500 bp to the left of the G region. As 1,500 bp are needed to code for the *S* gene product (56K) this result agrees with the conclusion that the C-terminal end of *S* is located in the vicinity of the *KpnI* site in the G region. Taking into account the size of the *S'am*2101 amber fragment (45K, Fig. 2), we calculated in a similar way that the *S'* gene should start at least 330 bp to the left of the G region. From the results obtained so far, we conclude that the *S* and *S'* genes share a common part of DNA located outside G in the α region.

To map the promoter proximal end of *S* and *S'* more precisely we identified gene products and truncated proteins synthesized in minicells containing pGP56 and its derivatives containing Tn*5* in *S* or *S'* (Fig. 4). If truncated proteins are found, these will represent mainly truncated *S* or *S'* encoded amino acids, for it seems from the DNA sequence of Tn*5* (ref. 7) that in all three possible reading frames, translation stop codons occur within the first 30 bp from the ends of the transposon. As is shown in Fig. 4, lane 8, minicells containing pGP56 synthesize the 56K S polypeptide and the 50K S' polypeptide. Unfortunately, Tn*5* encodes polypeptides of reported[8] M_rs 54,000 and 49,000 which co-migrate with S and S' (Fig. 4, lanes 1, 2). Therefore, it was not possible to show the disappearance of S

Table 1 Mapping of the promoter proximal end of the *S* and *S'* genes

Plasmid	Position Tn*5* insertion (bp)*	M_r ($\times 10^3$) of truncated proteins†	Distance (bp) from the translation start point to inverted repeat‡ *S*	*S'*
pGP56::Tn*5* no. 33	400 from left IR	37	600	
pGP56::Tn*5* no. 3	575 from left IR	43	600	
pGP56::Tn*5* no. 63	875 from left IR	54	600	
pGP56::Tn*5* no. 69	825 from right IR	48		475
pGP56::Tn*5* no. 43	150 from right IR	25		525

* See Fig. 4*a* legend. IR, inverted repeat.
† Truncated proteins are indicated → in Fig. 4.
‡ Assuming an average molecular weight of 110 for an amino acid. The calculated distance is a maximal value as a contribution of translation into Tn*5* has not been taken into account.

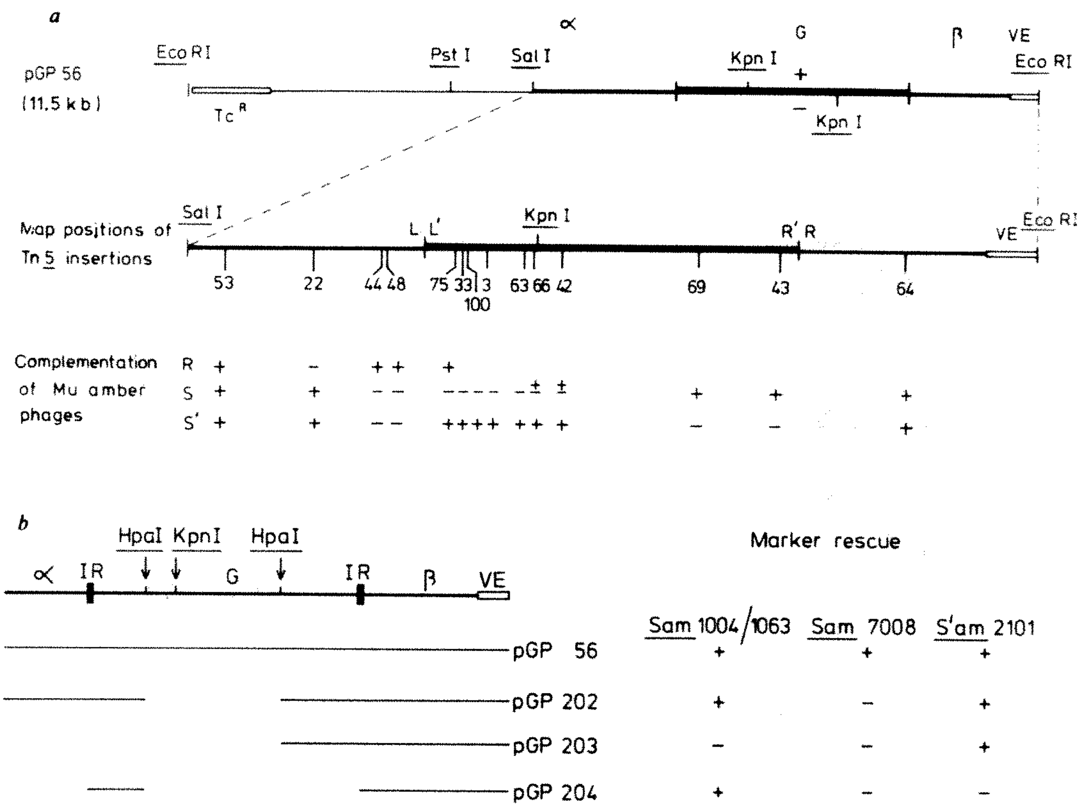

Fig. 3 *a*, Linear map of plasmid pGP56 (11.5 kb) which consists of Mu DNA (—) cloned in a *Pst*I–*Eco*RI fragment of pBR322(—). The Mu DNA comprises a part of α (3 kb), the G segment (3 kb), the β part (1.5 kb) and 0.4 kb of DNA from the variable ends (VE) of Mu DNA. A comparable plasmid has been described elsewhere[14]. The two possible orientations of the G segment in pGP56 preparations can be visualized by analysis of *Eco*RI/*Kpn*I fragments of pGP56 DNA. The map position of various insertions of transposon Tn*5* isolated in the *Sal*I/*Eco*RI fragment of pGP56 are indicated in the second line. The solid bar represents the G region and LL′ and RR′ the left and right inverted repeats. As restriction sites on Tn*5* have been presented[15], the integration sites of Tn*5* could be determined by digestion with restriction enzymes *Sal*I, *Eco*RI/*Xho*I, *Kpn*I and *Kpn*I/*Xho*I and length measurements of the obtained fragments on 1 and 1.4% agarose gels. As G inversion was observed within all plasmid preparations *Sal*I (which cuts once in Tn*5*), digestion shows whether Tn*5* is integrated in the G region. With *Kpn*I/*Eco*RI digestion, Tn*5* could be mapped to the left or to the right of the *Kpn*I site in G. The distance from the site of integration to the inverted repeats could be calculated by *Eco*RI/*Xho*I and *Kpn*I/*Xho*I digestion, as *Xho* sites in Tn*5* are known precisely[7] and the *Kpn*I site was mapped 975 bp from LL′. To measure complementation, *E. coli* K-12, *recA* or *E. coli* C, *recA* with and without pGP56 or pGP56::Tn*5*, were infected with Mu G(+) amber mutants (*Ram*1059 and *Sam*1004) or Mu G(−) amber mutants (*S′am*2101), respectively, with a MOI of 5. After an adsorption period of 15 min at 37 °C, the cells were incubated in the presence of Mu antiserum for 10 min at 37 °C, washed twice and diluted 1,000-fold in L broth. Phage titres were determined after 1 h growth at 37 °C by titration of phage on lawns of *E. coli* K-12, su$^+$ (for G(+) phage), or *E. coli* C, su$^+$ (for G(−) phage). The level of complementation is indicated + when the phage titres obtained are as high as that of pGP56 (5×10^8–1×10^9) and indicated (−) when they are as low as that of bacteria containing no plasmid (5×10^4–2×10^5). An aberrant level of Mu *Sam* complementation was obtained with Tn*5* at positions 66 and 42 (1×10^7 and 3×10^7, respectively). The reason for this low level of complementation is not known. *b*, Subclones of pGP56. The Mu DNA present on the different plasmids is indicated by a line. As pGP204 is derived from a G(−) molecule of pGP56 the β end is in fact directly linked to the left end of the G region (which is drawn here in the (+) orientation). The construction of the plasmids will be presented elsewhere (R.H.A.P. and P.P., in preparation). To measure marker rescue, *E. coli* K-12, su$^-$, or *E. coli* C, su$^-$, with or without a plasmid, were infected with Mu amber mutants with a MOI of 5. Titres of wild-type phage were determined by titration on lawns of *E. coli* K-12, su$^-$, or *E. coli* C, su$^-$. The *S* amber mutants used fall in different deletion groups[16].

or S′ when Tn*5* was inserted in the respective genes. However, truncated proteins are synthesized in minicells containing pGP56 with Tn*5* inserted at five different positions (Fig. 4, lanes 3, 4, 5, 7, 8). The C-terminal end of the *S* and *S′* genes could be mapped, respectively, less than 100 bp removed from Tn*5* no. 63 and Tn*5* no. 69, as their respective truncated proteins are only slightly smaller than the *S* and *S′* gene products (Fig. 4, lanes 5, 8). The N-terminal end, or translation startpoint, of *S* and *S′* could be calculated from the M_r of the various truncated proteins and the map positions of the Tn*5* insertions (Table 1). The position of the N-terminus of the *S* gene, ~600 bp removed from the G region, was also determined with pGP202 (Fig. 3*b*). Minicells containing pGP202 do not synthesize S or S′, confirming complementation data, but a 43,000 M_r polypeptide (Fig. 4, lane 10). Assuming that this polypeptide represents a truncated S protein, the *S* gene should start within 575 bp to the left of the inverted repeat. The results confirm that the start of both *S* and *S′* genes is located in the α region 500–600 bp away from the G region. Therefore, *S* and *S′* arise by a splicing of a common and an invertible part of DNA, as suggested in model B (Fig. 1).

With regard to *U* and *U′* in model B, we have previously been unable to prove genetically the existence of *U′* and to elucidate the expression of *U* and *U′* and their role in host specificity. However, in addition to S and S′, pGP56 encodes at least two polypeptides of M_r 22,000 and 18,000, which are not encoded by pGP202 (Fig. 4, lanes 9, 10). These polypeptides are good candidates for the gene products of *U* and *U′*. The 18K polypeptide may be the *U* gene product as it is not synthesized in minicells containing pGP56, Tn*5* no. 42 (Fig. 4, lane 6). Genetic experiments failed to prove that Tn*5* no. 42 is indeed integrated in the *U* gene, due to the leakiness of *Uam* mutants, although its physical position suggests this.

We have postulated that the *gin* gene is expressed, at least in part, from a promoter located in α (ref. 1). However, G inversion is observed with all derivatives of pGP56 described above. Assuming that the observed inversion is caused by *gin*[5,6], this result suggests that the *gin* gene is predominantly or entirely expressed from a promoter located to the right of Tn*5* no. 43, confirming the data of Kwoh *et al.*[9].

We believe the system described here to be the first example of gene splicing by an inversion event and the first example of

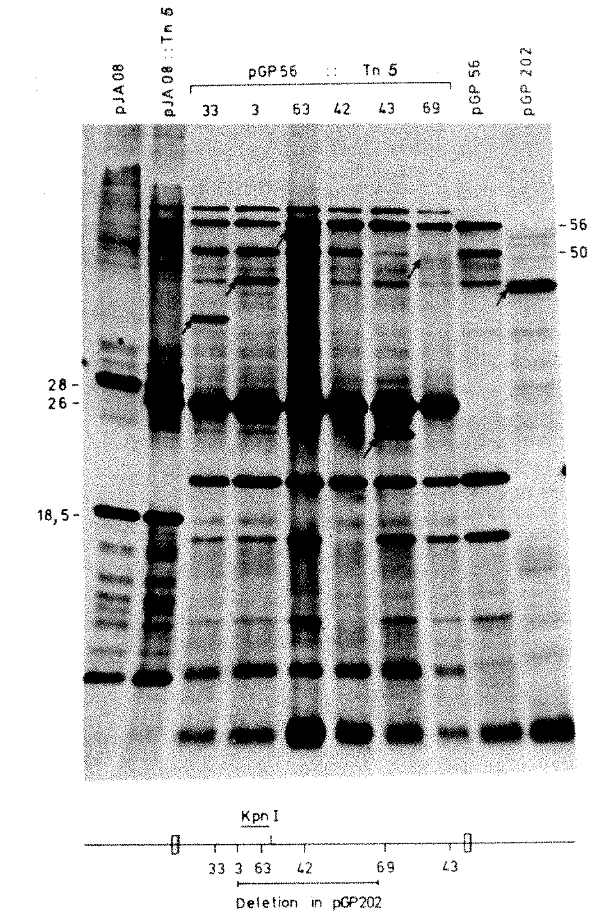

Fig. 4 Autoradiograph showing polypeptides synthesized in minicells isolated from cells containing pGP56, derivatives of pGP56 and plasmids with Tn*5* insertions. Minicells were labelled with ^{35}S-L-methionine and the polypeptides separated on a 12.5% polyacrylamide gel[13]. The autoradiograph shows the polypeptide pattern of minicells containing the following plasmids: control plasmid pJA08 (provided by R. Brandsma) (lane 1), pJA08::Tn*5* (lane 2), pGP56::Tn*5* no. 33 (lane 3), pGP56::Tn*5* no. 3 (lane 4), pGP56::Tn*5* no. 63 (lane 5), pGP56::Tn*5* no. 42 (lane 6), pGP56::Tn*5* no. 43 (lane 7), pGP56::Tn*5* no. 69 (lane 8), pGP56 (lane 9), pGP202 (lane 10). The *S* gene product (56K), *S'* gene product (50K), β-lactamase (28K)[13], neomycin phosphotransferase II (26K)[8] and the product of SSB (18.5K)[17] are indicated. Truncated proteins are indicated by →.

splicing within the prokaryotic cell. The recombination of a common region to different regions to form variable functional genes is a well known phenomenon in eukaryotes in the assembly of immunoglobulin genes[10,11]. In the case of G inversion, the variability is in the Sv or the Sv' region. The common region of the S and S' proteins is probably the part which becomes attached to the phage tail, whereas the variable part recognizes the receptor sites of the different hosts. This is now being tested by isolating and mapping mutants of Mu with other host ranges. Although we have shown that *S* and *S'* share a common region of DNA in α, this does not directly imply that their respective products are identical at the N-terminus. The calculated N-terminus of genes *S* and *S'* differed by ~75–100 bp. This may be due to errors in restriction mapping and/or molecular weight estimation. Moreover, we do not know exactly at which position translation has stopped in the various Tn*5* insertions. However, the observed difference may reflect a real difference in length of the Sc part of the two proteins. Therefore, definite proof for the presence of a common part in *S* and *S'* at the protein level must await determination of their amino acid sequences.

These results were first presented at the EMBO workshop 'Bacteriophage Mu' (May 1981) and were supported by the nucleotide sequence of the G region as presented by R. Kahmann (Max-Planck-Institute, München) at this workshop. We thank Ms J. Borst, W. Buys, S. Cramer, Ms A. Kuyper and H. Vrieling for their contribution to this work, Dr M. Howe for phage strains and Mrs N. van Hoek for typing the manuscript.

Erratum

In the letter by P. M. Conn *et al., Nature* **296,** 653–655 (1982), the title should read 'Conversion of a gonadotropin-releasing hormone antagonist to an agonist: implication for a receptor microaggregate as the functional unit for signal transduction'. In Fig. 2 the lines labelled *a*, *b* and *c* should be termed (1), (2) and (3) to correspond to the text. In ref. 4 the page numbers should read 264–265, and the journal in ref. 6 is *Endocrinology* **109,** 2040–2045 (1981). In addition the following 'Note added in proof' should have appeared: Additional evidence for the significance of microaggregation comes from the observation of potency enhancement of a GnRH agonist in conditions which favour receptor microaggregation[20]. In addition, a hormone antagonist has been converted to an agonist by antibody cross-linking[21].

21. Hopkins, C. R., Semhoff, S. & Gregory, H. *Phil. Trans. R. Soc.* B**296,** 73–81 (1981).

Corrigendum

In the letter 'Conversion of the chemical energy of methylmalonyl-CoA decarboxylation into a Na^+ gradient' by W. Hilpert and P. Dimroth, *Nature* **296,** 584–585 (1982), in Fig. 1 the total incubation volume should be 0.67 ml, not 10.67 ml as shown.

BOOK REVIEWS

Sociobiological sins

Michael Ruse

THESE two volumes, which should be read as one, are reports from a conference held in 1980 in Bresanone, Italy. As always with such reports, the quality of contributions is somewhat uneven and not everyone keeps quite so closely to the main themes as they should, in addition they are marked — and marred — by the leaden seriousness of the left. Nonetheless no one is left in any doubt as to the main motivating force behind the books, for, like King Charles's head, in virtually every contribution one topic keeps cropping up, namely the sins of sociobiology In response to this dreadful phenomenon, what the Dialectics of Biology Group offer us is one volume (*Against Biological Determinism*) directed to criticism of the suppositions behind sociobiology Then, the second volume (*Towards a Liberatory Biology*) turns to possibilities of something better

The critical volume wastes no time in setting the general theme, with an attack on human sociobiology as socially dangerous What worries Martin Barker is that sociobiology contains a "potential invitation to a unity of theory and practice in the latest forms of capitalist political economy" (p 26) This is a theme which we have heard sung many times before, most particularly by the Boston-based "Science for the People Sociobiology Study Group" I shall return to it later

Following more of the same, as well as a brief taxonomy by Hilary and Steven Rose of conventional attitudes to science, we arrive at what I find to be two of the more worthwhile papers, Lynda Birke's and Lesley Rogers's. These two feminists focus on attempts to explain gender identity and sexual orientation in terms of underlying biochemical causes (which in turn are supposedly linked to the genes) The well-known sex researcher, John Money, who must be rueing the day when E O Wilson spoke of his work favourably, is singled out for heavy criticism It is argued that Money bases his claims (specifically, that homosexuality has hormonal causes) on conceptual confusions, as well as inadequate evidence

The second charge cannot be denied Most sex researchers put me in mind of philosophers, as they generalize to the whole world from about two cases (which is one more case than Freud, who generalized exclusively from himself). But what of the more interesting claim of conceptual confusion? I am not sure that it holds. Is it really a mistake in logic to suggest that lesbians have "male" type emotions, or conversely that male homosexuals have female urges? What really counts in such a situation is the desire and the sex object towards which the desire is directed The actual mechanics involved seem to be irrelevant more an incidental by-product of physiology

Against Biological Determinism. Pp.184 Hbk ISBN 0-85031-423-2; pbk ISBN 0-85031-424-0 *Towards A Liberatory Biology* Pp 161 Hbk ISBN 0-85031-425-9; pbk ISBN 0-85031-426-7 The Dialetics of Biology Group, general editor Steven Rose (Allison and Busby/Schocken 1982) Each volume hbk £8 95, $14 95, pbk £4 50, $8 95

Moving along through slight variants on the anti-determinism (chiefly anti-sociobiology) theme in the first volume, we can turn to the more positive *Towards a Liberatory Biology.* Here we find what is perhaps the most sensible essay of the whole set "Synthesizing Views about the Origin of Behaviour" by Patrick Bateson The author perceptively points to some of the problems facing the student of behaviour, particularly those arising from the need to sort out innate from environmental factors. I suspect that Bateson must have felt somewhat uncomfortable at the Bresanone conference, for he calmly assumes that orthodox biologists have indeed made important advances in our understanding of behaviour. For instance, he praises Maynard Smith's use of game theory as a tool for understanding aggression, although elsewhere this is criticized as yet one more excursion into the realm of the unfalsifiable

Since sociobiology, with its emphasis on natural selection, is so very much part of the whole Darwinian paradigm, the most radical attack is obviously one which goes right to the heart of Darwinism itself, hoping to put forward a new theory of evolution This is the theme of several of the contributors to the second volume, as they urge upon us various neo-Lamarckian and neo-vitalist alternatives But I doubt that the Ernst Mayrs of this world need worry too much yet The critics base their case on some fairly worn arguments against natural selection, together with some incredible rewritings of history. I simply do not know how Gerry Webster and Brian Goodwin ("History and Structure in Biology") can accuse Darwin of being hostile to Cuvier's ideas or to the rational morphologists' "plan of creation" In fact, I would say that, in his thorough-going teleology, Darwin owes more to the non-evolutionist Cuvier than he does to the evolutionist Lamarck. Moreover, the very crux of Darwin's work was his incredible sensitivity to the morphologists' ideas, which he learnt from people like Richard Owen. Darwin's genius was to combine both form and function into one synthetic theory — form through common descent and function through natural selection Furthermore, to say that Darwin was "firmly in the empiricist/positivist tradition" (p 104) is to ignore entirely the influence on Darwin of such rationalist thinkers as William Whewell, and the difficulties that full-blown empiricists such as Huxley had with Darwin's selection mechanisms

All in all, I am afraid that I find these volumes unprepossessing; but let me make three concluding points First, I agree entirely with the DBG that a blind reductionism, aiming to explain everything in terms of the Hardy-Weinberg law — or even worse, some simplistic law of physics — is the last thing that biologists should aim for Anyone who says that life and its problems is just a set of molecules is either a fool or a liar But, second, there is no evidence that sociobiology is committed to such a gormless programme of reductionism, despite the outlandish statements of some of its more enthusiastic proponents Sociobiologists continue to deal with *biological* questions, moreover, the last thing that sociobiology does is to exclude methods and findings from other disciplines, such as psychology and sociology Rather, the social sciences are given a crucial role in the overall picture Thus, for instance, suppose that there is something in the sociobiological claim that incest barriers have a genetic foundation This says nothing about the role which genotypes have in causing such barriers Instead, all sorts of questions are asked (and answers demanded) about the ways in which close contact with siblings in early childhood lead to anti-sexual imprinting And who is to answer these questions but social scientists?

This conclusion is precisely what one would expect, given that sociobiology lies so firmly within the Darwinian tradition Darwinism has always claimed that evolution is a function of heredity in interaction with the environment. A purely biological (meaning especially a purely genetic) determinism is meaningless to the Darwinian

Third and finally, let me speak to the concern articulated by Martin Barker, but I think behind nearly all of the opposition to sociobiology and like enterprises When all is said and done, is it not really the case that sociobiology is merely right-wing ideology dressed up to look like genuine science? One would have to be insensitive not to recognize this as a genuine concern, or to deny that genetic theories of human behaviour have been (and still are) used to "support" some pretty horrible social doctrines But it is simply not true to claim unequivocally that all genetic theories are apologia for the worst excesses of Western capitalism, any more than it would be true to claim that all environmentalist theories are as ideologically pure as the driven snow Indeed, some thoroughly dreadful practices have been pushed by people who claim that all we need is a little of the right social conditioning

In short, I remain unconvinced that sociobiology is the inherently evil thing supposed by the DBG No doubt the members of the DBG will remain equally unconvinced of what I say But could I make one request? Do not let us degenerate into accusations that the other side is responsible for the rise and success of Creationism — as the cover of one of these books suggests There is simply no causal connexion between sociobiology and Creationism, and to pretend otherwise is gratuitously insulting For all our differences, do not forget that we are all striving, painfully, to see the light □

Michael Ruse is a Professor in the Departments of History and Philosophy at the University of Guelph His most recent book is Darwinism Defended *(Addison-Wesley, 1982)*

Journals' review issue 1982

On October 7th *Nature* will publish a second review supplement devoted to science journals Last year's supplement, covering journals first published between January 1978 and May 1980, appeared in *Nature* 293, 341-369, see p 343 of that issue for details

Criteria for inclusion of a journal in the 1982 issue are that

- the first number appeared, or the journal was re-titled, between June 1980 and May 1981,
- it is published at least three times a year,
- the main language used is English

Broadly, periodicals of professional interest to scientists will be considered for review, with the exception of abstracts' journals

In addition it is hoped to cover publicly available newsletters, first published between January 1978 and May 1981, in that issue

Publishers and societies are invited to submit four sample issues of periodicals satisfying the above criteria, *including the first and most recent numbers*, to the Review Editor, *Nature*, 4 Little Essex St, London WC2R 3LF, England (London 836 6633 ext 2570) as soon as possible

The biological roots of personality

Anthony Gale

A Model for Personality. Edited by H. J Eysenck Pp 287 ISBN 3-540-10318-X/ 0-387-10318-X (Springer-Verlag 1981) DM78, $37 20

AT THE dinner last summer to celebrate the publication of his *Festschrift*, Hans Eysenck declared himself to be confused This unusual state of mind resulted from a paradox The same scientific thinking which had led him to reject fascism in his youth had created enemies in his old age His analysis of IQ differences between ethnic groups, and his insistence that biological factors account for differences between individuals, have led to accusations of racism Eysenck-bashing has become a popular sport, not only on the campus, but in scientific journals He only needed to look to his own writings for an answer to the paradox, frequently he talks of the *zeitgeist*, the prevailing scientific fashion which favours some approaches and castigates others And he has never been afraid to profess unpopular views, whether it be to attack psychoanalysis or to accuse his fellow psychologists of sloppy thinking

In *A Model for Personality* Eysenck invites his critics to do their worst His theory of the biological basis of extraversion, and the data which support it, are laid out before us, warts and all He sees himself in a long line of biological theorists, stretching back to the Greek physician, Galen The argument is straightforward systematic studies of personality reveal two common factors, extraversion–introversion and neuroticism–stability, and their ubiquitous appearance implies that they are *given* by nature If they have biological roots, we expect them to be normally distributed across the population, to be transmitted by genetic mechanisms, expressed in brain function, and adaptive in governing the interaction of the individual with his physical and social environment Each of the contributors to the book (all are internationally established authorities) deals with one of these aspects of the theory

The reader should recognize that, for many psychologists, the establishment of links between genetics, biology, learning, and the way people think and interact socially involves a tremendous imaginative leap into the unknown, for it presupposes that all the philosophical problems raised by the Mind–Body relationship will ultimately be resolved Some of the tricks, which involve a shift between diverse domains of description, are truly remarkable For example, a 24-item *paper and pencil* test about how you feel in different situations ("Would you rather stay at home, or go to a dull party?") enables successful prediction of *electrical* properties of the brain Eysenck believes, as did Pavlov, that nervous systems *qua* nervous systems, have properties which determine the ways in which the organism acts upon and responds to the environment *The Dynamics of Anxiety and Hysteria* (Routledge & Kegan Paul, 1957) and *The Biological Basis of Personality* (Thomas, 1967) showed how Eysenck's theory could find operational expression in the form of systematic laboratory experiments This *rapprochement* between traditional experimental psychology and personality theory is illustrated by his son Michael's chapter, reviewing studies of personality, learning and memory

The penultimate chapter, by Jeffrey Gray, offers a savage critique of the theory He claims that Eysenck's selection of a particular mathematical solution to factor data does not fit the facts, that every data set supporting the theory is matched by a contradictory set, that the 1957 and 1967 versions generate different and even conflicting predictions, and that the key instrument of measurement (the Eysenck Personality Inventory) has undergone surreptitious changes over the years Only Eysenck could invite a colleague (possibly his successor at the Institute of Psychiatry?) to write such a provocative and thoroughgoing critique of his own theory

This is a very useful, balanced and sensibly compiled record of Eysenck's progress in this his retirement year It is ironic that in the 1980s there is a move towards a more biological perspective the pendulum is swinging back in Eysenck's direction □

Anthony Gale is Professor of Psychology at the University of Southampton He is co-editor of The Biological Bases of Personality and Behaviour *(Hemisphere Press, 1982) and* Psychology and People A Tutorial Text *(BPS–Macmillan, 1982)*

Chariots of water

M. Ian Phillips

Thirst By Barbara J Rolls and Edmund T Rolls Pp 194 Hbk ISBN 0-521-22918-9, pbk ISBN 0-521-29718-4 (Cambridge University Press 1982) Hbk £15, $29 50, pbk £5 50, $10 95

EVERY year in London on the neutral waters of the Thames there is a race between a row-boat from Cambridge University and one from Oxford I was reminded of this when asked to review *Thirst* by Barbara Rolls and Edmund Rolls from Oxford University, since a year ago I

reviewed *The Physiology of Thirst and Sodium Appetite* by James Fitzsimons from Cambridge University (*Science* **208**, 711, 1980)

This latest response from Oxford in the race for dominance of the water intake field is a fast-moving, sometimes too brief but nonetheless highly readable account of our present knowledge of thirst. It is not as erudite as the volume by Fitzsimons — it is less than half the size for one thing — but it is a book that one could recommend to students of physiological psychology and researchers newly attracted to the field It covers a comprehensive list of topics and as an introductory text it is excellent What it lacks for the researcher actively involved in these studies is the depth of sources and an accounting of all available information For example, the authors avoid covering the brain angiotensin system in detail by dismissing it as being controversial Perhaps that attitude is the better part of valour, but in consequence much recent data are overlooked

Since most of the interest in the subject can be attributed to the discovery that injections of angiotensin II stimulate thirst, it is appropriate that Barbara Rolls is the senior author of this text It was she, with Fitzsimons, who first showed that effect of angiotensin II intravenously and shortly afterwards intracranially Edmund Rolls adds his unique expertise in the understanding of central mechanisms of thirst in primates It is a winning combination for a work that will appeal to those interested in the physiology of motivation

The book is profusely illustrated with clear pictures, almost one to a page. The material presented is a readable summary of the progress that has been made in the study of thirst and particularly since the discovery of the effects of angiotensin II in 1969 It is apparent, however, that the race is not over because the control of drinking under normal physiological conditions has not yet been established, the authors say that involvement of angiotensin in thirst may only be in emergencies As a review of the field, the book enables one to see that advances have been made with relatively simple techniques The flow of experiments presently is towards more precise localization of receptors and more accurate descriptions of the brain pathways involved. In that respect, thirst research is not yet far from the starting line

The book does show that there is sufficient data for a course in thirst and for an active field of research There is certainly room for the two volumes on water intake without causing hypervolumia and, as far as competition between the two books goes, the winner seems to be Cambridge since its University Press is the publisher of both. □

M Ian Phillips is Chairman of the Department of Physiology at the University of Florida, Gainesville

Genes through the looking glass

P.H. Williams

Gene Function E coli *and Its Heritable Elements*. By Robert E. Glass Pp 487 Hbk ISBN 0-7099-0081-3; pbk ISBN 0-7099-0082-1 (Croom Helm/University of California Press 1982) Hbk £19 95, $45 60, pbk £9 95, $22 80

WHEN, several years ago, I embarked upon post-graduate research in microbial genetics, the pre-eminent textbook of the field was *The Genetics of Bacteria and their Viruses* by William Hayes To a newcomer like myself, Hayes was indispensable, offering all there was to know about molecular genetics in an authoritative, well-referenced, easily readable package It was with great regret that I watched that book drift slowly, but inevitably, out of date

Gene Function by Robert Glass is, to use Hayes's description of his own work, "a rather advanced text book" It covers much the same ground as Hayes, and is aimed at the same type of audience, namely at advanced undergraduates, and at researchers in the field at every level. Only a few authors since Hayes have successfully abridged the monumental mass of *Escherichia coli* research into a single informative but highly readable volume In my opinion Robert Glass has made a creditable attempt

Gene Function, however, is not merely Hayes updated Over and above the incorporation of the wealth of knowledge accumulated over a decade and a half, Glass's book has an entirely different viewpoint which reflects the backgrounds and attitudes of those who have more recently entered and contributed to the field Hayes began his book with an introduction to genetic principles, and then developed the theme of bacteria and bacteriophage as genetic systems Glass, on the other hand, writes as a biochemist, beginning with an overview of the structure and biological role of nucleic acids at the molecular level (or rather a preview, since these are covered in detail later), before outlining elements of microbial physiology and metabolism essential to a full comprehension of experimental methods

In the preface to his book the author thanks a colleague for "a 'sensible' title" It is a little surprising that a volume devoted exclusively to one organism should presume to claim for itself the title *Gene Function* However, this book is about genes and the way they function in that particularly convenient little bag known as *E. coli* — simple genes, perhaps, organized and regulated differently from those of eukaryotes, certainly, but the strong implication is that knowledge of the molecular wonderland of *E coli* genes will form a firm basis for the study of genes in any other organism Nonetheless, the title still worries me a little.

Gene Function is well researched, adequately referenced and nicely balanced in terms of breadth of material and depth of detail. In general it is clearly written, although extensive cross-referencing tends to destroy the reader's train of thought at times The frequent use of footnotes and parentheses in the text irritated me somewhat, and I confess that I found the index almost impossible to use However, these are quite minor quibbles, and, except for the last point, did not seriously detract from my enjoyment of the book. *Gene Function* may not, perhaps, be as fondly remembered 15 years hence as Hayes's book is now, but there is no doubt that it is an important and useful addition to the book-shelves of today's molecular geneticists I hope it can be regularly updated without losing any of the evident enthusiasm of its author. □

P H Williams is a Lecturer in the Department of Genetics at the University of Leicester

Space-time through time

Paul Davies

The Science of Space-Time By Derek J Raine and Michael Heller Pp 255 ISBN 0-912918-12-8 (Pachart Publishing, Tucson, Arizona. 1981.) $24.

IT IS curious the way that certain ideas and concepts in science exercise a wide and seemingly disproportionate fascination. These include the measurement paradoxes of quantum theory, and the origin of time's mysterious "arrow" Another is Mach's principle Scientists return to it again and again Now, for the first time, a comprehensive treatment of Mach's principle is available in a book that can be profitably read by those with only a basic knowledge of space-time physics

The basic idea of Mach's principle is that the property of inertia in a material body has its origin in cosmology A rotating planet, for example, feels centrifugal stresses and bulges at the equator But visually the Earth's rotation is deduced by "watching the stars go round" So, are these two radically different phenomena — the experience of centrifugal bulging and the whirling of the stars — in some way connected? Are rotations (and other types of accelerated motions) purely relative to the background framework of far-flung galaxies?

Einstein at first thought so, and Mach's work deeply influenced his development of the theory of relativity In 1916, on Mach's

death, Einstein wrote a tribute to him But in spite of this Machian input, a clear-cut manifestation of Mach's principle failed to emerge in any very obvious way from relativity theory Over the decades, many theoretical physicists have struggled to find formulations of Mach's principle that would mesh easily with either the theory of relativity, or some close variant It is a task as yet unfinished, but it remains as compelling as ever At issue is one of the fundamental properties of space-time structure, and the nature of motion

This timely and most welcome book contains a discussion of the evolution of the space-time concept from Aristotle to Einstein (and beyond), and presents a detailed and up-to-date analysis of Mach's principle in a modern setting The authors conclude that "At best, Mach's principle has been expressed in general relativity as a selection rule To go beyond this one may have to give up general relativity"

However, this book is far from a catalogue of failures It is a comprehensive and accurate survey of the physics of space and time and of the philosophical overtones which accompany it. The theory of relativity, both the special and general versions, obviously plays a central role in these ideas, and the reader will find discussions of black holes and details of gravitation experiments as well as a careful introduction to the more elementary aspects of space-time structure

Mach's principle is an intriguing context in which to learn relativity and space-time physics, as well as an end in itself I can thoroughly recommend this book to undergraduates learning general relativity, as well as to researchers who share the authors' fascination with one of science's age-old mysteries □

Paul Davies is Professor of Theoretical Physics at the University of Newcastle upon Tyne His most recent book (with N D Birrell) is Quantum Fields in Curved Space *(Cambridge University Press, 1982)*

The mixed blessing: oxygen in biology

Barry Halliwell

Oxygen and Living Processes An Interdisciplinary Approach Edited by Daniel L Gilbert Pp 401 ISBN 3-540-90554-5/0-387-90554-5 (Springer-Verlag.1981) DM135, $61 40

THIS colourless, odourless gas is an extreme fire hazard and is very toxic to some organisms at minute concentrations Its toxicity to human beings is much slower-acting, but nevertheless over a period of many years it produces a progressive oxidative deterioration that results inevitably in death Only the swim-bladders of certain fishes can tolerate it at high concentrations, although turtles and crocodiles are fairly resistant to its toxic effects unless they are placed in warm water

The above description, using information taken from this book, applies of course, to oxygen Oxygen is essential for efficient energy production by oxidation of foodstuffs in aerobic animals, but only its peculiar chemistry protects us from instant "spontaneous" combustion The same chemistry dictates that the oxygen reduction accompanying substrate oxidation must proceed via partially reduced oxygen intermediates on the pathway to water Such intermediates as superoxide and hydroxyl radical are particularly noxious and so aerobic cells are equipped with many defences against them, including superoxide dismutase, catalase, glutathione and/or ascorbate peroxidases and vitamin E The cytochrome oxidase complex of mitochondria is carefully designed not to allow the escape of such intermediates from its active site

As its title declares, this book is indeed an interdisciplinary approach to oxygen All of the items I have mentioned are covered in detail, and in addition there are chapters on photosynthetic oxygen production, the geological history of the oxygen in the Earth's atmosphere, oxygen-carrying pigments, kinetics of oxygen diffusion, the history of the discovery of oxygen, and the medical uses (and abuses) of the gas, covering blindness in babies, pulmonary oxygen toxicity and hyperoxygenation in the treatment of gas gangrene and cancer of the head and neck The contributions are well-written, all of them by experts in specific fields, and the book has been produced in an attractive style with the minimum of errors

I do have some minor niggles, however Much of Chapter 1, a history of the discovery of oxygen, is merely an over-condensed — and rather boring — list of names and dates, for example, it is impossible to do justice to the complex physiology expounded by Galen in a few lines In Chapter 6, on photosynthesis, I doubt whether non-biologists will really understand what exactly are photosystem I, photosystem II and Q In addition, the order of the chapters is sometimes a bit illogical

These comments are not meant to detract from what is an excellent book It is truly "everything you wanted to know about oxygen, but didn't know whom to ask" □

Barry Halliwell is a Lecturer in Biochemistry at King's College, University of London, and author of Chloroplast Metabolism *(Clarendon/Oxford University Press, 1981)*

ANNOUNCEMENTS

Awards

The French National Order of the Legion of Honor has been awarded to University of California, San Francisco clinical professor **Piero Mustacchi** for 25 years of prominence in professional activity, in particular for developing academic and medical links between the University of California and universities in France and French-speaking Africa

Professor William H. Thorpe (University of Cambridge) has been presented with the annual prize of the Fyssen Foundation for his research in animal behaviour

Dr Prescott L. Deininger (Louisiana State University Medical Center in New Orleans) and **Dr Jeffrey W. Williams** (Ohio State University) have been selected to receive the Boehringer Mannheim Biochemicals travel awards in molecular biology and in enzymology

The British Society of Rheology has awarded its annual award to **Professor Joachim Meissner, Dr Hans Martin Laun, Dr Helmut Munstedt** and **Dr Manfred Wagner** for work in the development of elongational rheometry

Five prizes have been awarded to young Wiezmann Institute scientists the Somach Sachs Memorial Award to **Dr Itamar Procaccia** for studies on rates of chemical reaction near phase transition points, the Sarah Zinder Leedy Memorial Award to **Dr Gideon Schechtman** for work on geometric structure of Banach spaces, the Samuel Yaroslavsky Memorial Award to **Dr Abraham Shanzer** for work on synthesis of large, ring-shaped organic materials, the E D Bergmann Award to **Dr Michael Levitt** for studies of conformation and structure of macro-molelcules, the M Levinson Prize to **Dr Mordechai Milgrom** for work on emission of spectral lines with changing wavelengths by the astronomical object SS 433

Twenty Harkness Fellowships tenable for between 12 and 21 months are offered each year The award includes return fares to the United States, living and family allowances, travel in America, tuition and research expenses, equipment allowance and health insurance Candidacy is open to men and women in any profession or field of study, who are citizens of the UK and have received both secondary schooling and further education (or equivalent professional experience in lieu of further education) wholly or mainly in the UK Candidates must be between 21 and 30 years of age on 1 September 1983, unless qualified in medicine or employed in the Civil Service or the media, in which cases the upper age limit is 33 For application forms (available only to candidates) send a self-addressed envelope carrying 29p postage, and measuring not less than 10 by 7 inches, to The Harkness Fellowships (UK), Harkness House, 38 Upper Brook Street, London W1Y 1PE Forms will not be posted from the office after 7 October, 1982

In recognition of his contributions to the understanding of the meaning of evolution, the history of life, animal taxonomy and mammalian systematics, The Peabody Museum of Natural History, Yale University has established the George Gaylord Simpson Prize in celebration of his 80th birthday, 16 June 1982 The prize will be presented annually by the Peabody Museum to a young author (under 35) of an outstanding paper in the above areas of science Applications to the Director, Peabody Museum of Natural History c/o Yale University, PO Box 6666, 170 Whitney Ave, New Haven, Connecticutt 06511, USA by 31 December 1982

Appointments

The National Academy of Sciences has announced the election of the following foreign associates **Nicola Cabibbo** (theoretical physics, University of Rome), **Shmuel Eisenstadt** (sociology, Hebrew University of Jerusalem), **Paul Fraisse** (experimental psychology, University of Paris V), **Marianne Grunberg-Manago** (CNRS, Paris, and biochemistry, University of Paris VII), **Hua Luogeng** (mathematics, Chinese Academy of Sciences), **Il'ya Mikhailovich Lifshitz** (theoretical department, Institute for Physical Problems, Moscow), **Jacques F.A.P. Miller** (experimental pathology, The Walter and Eliza Hall Institute of Medical Research, Melbourne); **Martin J. Rees,** (theoretical astronomy, University of Cambridge), **Ralph Riley,** (Agricultural Research Council of the UK); **John Maynard Smith** (biology, University of Sussex), **Takashi Sugimura** (molecular biology, Tokyo University); **Tsuneo Tomita** medicine, Keio University, Tokyo)

Professor Emanuel Mazor, has been named as the first incumbent of the Frank W Considine Chair in Hydrological Research at the Weizmann Institute of Science, Rehovot

Paul C. Martin will occupy the newly established chair at Harvard University the John Hasbrouck Van Vleck Professorship of Pure and Applied Physics

Dr William Taylor present director of the University of London Institute of Education has been appointed principal of the University of London from 1 September 1983 in succession to Mr J R Stewart who will be retiring

Meetings

21-24 June, **Environment 82,** Stockholm (Environment 82, Ministry of Agriculture, S-103 33 Stockholm, Sweden)
28 June-2 July, **Meeting on The Monsoon Climate Programme,** Geneva (WMO Secretariat, Geneva, Switzerland)
28-30 June, **Nordic Congress of Pathological Anatomy and Cytology,** Copenhagen (NOPAC '82 Secretariat, Institutterne, Frederik den V's vej 11, DK-2100 Copenhagen O, Denmark)
29 June, **Design and Safety of the Sizewell Reactor,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK)
29-30 June, **Food and People,** London (The Secretary BNF, 15 Belgrave Square, London SW1, UK)
30 June, **Energy Conservation, Economic Growth, and Employment,** London (Centre for Energy Studies, Polytechnic of the South Bank, Borough Rd, SE1, UK)
30 June-1 July, **Trace Elements in Animal Production and Vetinary Practice,** York (BVA, 7 Mansfield St, London W1, UK)
28 June-2 July, **Biomedical Writing,** Harvard (Office of Continuing Education, Harvard School of Public Health, 677 Huntington Ave, Boston, Massachusetts 02115, USA)
5-7 July, **Distributed Computing Systems,** Strathclyde (Mr F Chambers, Logica, 64 Newman St, London W1, UK)
5-9 July, **Concrete Mix Design,** London (Cement and Concrete Association, Fulmer Grange, Fulmer, Slough, UK)
6-9 July, **North Atlantic Ocean Stations,** Geneva (World Weather Watch Dept, WMO, Geneva, Switzerland)
8-9 July, **Physical Techniques in Cardiological Imaging,** Southampton (Dr M D Short, Dept of Medical Physics, University College Hospital, London WC1, UK)
9-10 July, **Genetics Cancer–Environment,** Monaco (Institut Pasteur de Lyon, 77 rue Pasteur, 69365 Lyon Cedex 2, France)
12-16 July, **Environment and Safety Risk Management,** Massachusetts (Director of the Summer Session, Room E19-356, MIT, Cambridge, Massachusetts 02139, USA)
13-16 July, **Proteins and Nucleic Acids in Plant Systematics,** Bayreuth (Prof Dr U Jensen, Dept of Plant Ecology and Systematics, University of Bayreuth, PO Box 3008-D-8580 Bayreuth, FRG)
14-15 July, **Quantatitive Structure Activity Relationships in Taste and Olfaction,** Reading (Dr M G Lindley, Tate & Lyle Group R & D, PO Box 68, Whiteknights, Reading, UK)
14-16 July, **Ions, Cell Proliferation and Cancer,** Lake Placid (Dr W L McKeehan, W A Jones Cell Science Center, Old Barn Rd, Lake Placid, New York 12946, USA)

15-16 July, **Climatic Effects of Increasing Atmospheric Carbon Dioxide,** East Anglia (Dr T M L. Wigley, Climatic Research Unit, University of East Anglia, Norwich, Norfolk, UK)

19-23 July, **Basic Cell and Organ Culture Course,** Boston (Course Administrator, Cell Culture Research Unit, Dept of Anatomy and Cellular Biology, Tufts University School of Medicine, Boston, Massachusetts 02111, UK)

19-22 July, **Computer Aided Design and Manufacture,** Manchester (S Mayhew, Scientific and Technical Studies, Norwich House, 11/13 Norwich St, London EC4, UK)

20-22 July, **Fetal Antigens and Cancer,** London (The Ciba Foundation, 41 Portland Place, London W1, UK)

23-24 July, **Immune Complexes: Formation, Biological Properties and Clinical Aspects,** Nottingham (Dr W G. Reeves, Dept of Immunology, University Hospital, Nottingham, UK)

10 August, **Milestones and Trends in Polymer Science,** Michigan (Dr J K Rieke, Chemical Company, Midland, Michigan 48640, USA)

23-28 August, **Stress Effects on Photosynthesis,** Diepenbeck (Dr R Marcelle, Laboratory of Plant Physiology, Research Station of Gorsem, B-3800 Sint Truiden, Belgium)

23-27 August, **9th Annual European Geophysical Society Meeting,** Leeds (Royal Meteorological Society, James Glaisher House, Grenville Place, Bracknell, Berks, UK)

23-26 August, **Powder Mixing Technology,** Central New Jersey (The Center for Professional Advancement, PO Box H, East Brunswick, New Jersey 08816-0257, USA)

29 August-4 September, **21st International Horticultural Congress,** Hamburg (Hamburg Messe und Congress Gmbh Abt. Offentlichkeitsarbeit, Postfach 30 23 60, 2000 Hamburg 36, FRG)

20-24 September, **Molecular Crystal Symposium,** Quebec (D Chartrand, National Research Council Canada, Ottawa, Canada K1A 0R6)

21-23 September, **Radiation Curing,** Illinois (S Buhr, Technical Activities Dept, Society of Manufacturing Engineers, 1 SME Drive, PO Box 930, Dearborn, Michigan 48128, USA)

21-24 September, **Ceramic-Metal Joining,** Amsterdam (The Center for Professional Advancement, Postbus 19865, 1000 GW Amsterdam, The Netherlands)

21-24 September, **Pteridines and Folic Acid Derivatives,** St Andrews (Prof H C S Wood, Dept of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral St, Glasgow, UK)

21-24 September, **Wind Energy Systems,** Stockholm (BHRA Fluid Engineering, Cranfield, Bedford, UK)

21-25 September, **British Veterinary Association, Centenary Congress,** Reading (BVA, 7 Mansfield St, London W1, UK)

22-24 September, **601st Meeting of The Biochemical Society,** Aberdeen (The Meetings Officer, The Biochemical Society, 7 Warwick Court, London WC, UK)

22-26 September, **Biophysical Aspects of Receptor Structure and Function,** Portorose (Prof. D. Hadzi, Bopis Kidric Institute of Chemistry, POB 380, 61001 Ljubljana, Yugoslavia)

23 September, **Fluids in Metamorphism,** Glasgow (Dr M. Brown, Dept of Geology and Physical Sciences, Oxford Polytechnic, Oxon, UK)

23-24 September, **Choice of Material for Condenser Tubes and Plates and Tube and Tightness Testing,** Avignon (Societe Francaise D'Energie Nucleaire, 48 rue de la Procession, F-75724 Paris, Cedex 15, France)

27 September-1 October, **1st International Congress of Neuroimmunology,** Lake Maggiore (Dr P O Behan, Institute of Neurological Sciences, Southern General Hospital, 1345 Govan Rd, Glasgow, UK)

28-30 September, **The Geological Evolution of the Eastern Mediterranean,** Edinburgh (Dr A,H F Robertson, University of Edinburgh, Grant Institute of Geology, West Mains Rd, Edinburgh, UK)

27 September-1 October, **Physical Chemistry of Transmembrane Ion Motions,** Paris (Dr C Troyanowsky, Societe de Chimie Physique, 10, rue Vauquelin, F75321 Paris, Cedex 05, France)

28-29 September, **Particle-Fluid Separation in Offshore Engineering,** Middlesborough (Dr G S Bainbridge, Dept of Chemical Engineering, Teesside Polytechnic, Borough Rd, Middlesborough, Cleveland, UK)

29 September-1 October, **Biotechnology in Clinical Chemistry,** Cambridge (Dr C P. Price, Dept of Clinical Biochemistry, Addenbrooke's Hospital, Hills Rd, Cambridge, UK)

30 September-2 October, **Deburring and Surface Conditioning,** New Orleans (J Slaughter, SME, 1 SME Drive, PO Box 930, Dearborn, Michigan 48128, USA)

4-6 October, **Technology for Space Astrophysics — The Next 30 years,** Danbury (N Geril, Perkin-Elmer Corp, 100 Wooster Heights Rd, Danbury, Connecticut 06810, USA)

4-7 October, **Hormones and Cell Regulation,** Alsace (Dr R Denton, Dept of Biochemistry, University of Bristol, Medical School, Bristol, UK)

5-8 October, **Leaf Protein Research,** Aurangabad, (Dr N Singh, Central Food Technological Research Institute, Mysore 570 013, India)

3 June 1982

Squabbles over East–West pipeline

The Soviet plan to build a huge pipeline for natural gas for customers in Western Europe has irked the United States Administration. But Washington's fears are exaggerated.

The Western economic summit that opens tomorrow (4 June) at Versailles is likely to be more than usually contentious. President Ronald Reagan, one of the several first-time participants at these occasions, is unlikely to find the meeting congenial, if only because the United States will find itself hemmed firmly into a corner about its distinctive (some say eccentric) economic policy, a curious blend of Keynes and Friedman whose chief external effect is to keep international interest rates so high that economic recovery will be impeded. (The Prime Minister of Japan, Mr Zenko Suzuki, will, on the other hand, be pilloried for what he may fairly claim is a paradoxical reason — interest rates notwithstanding, Japan has been too successful.) But when the going gets rough, the United States will reply with its now long-standing complaint that Western Europe should not be preparing to buy natural gas from the Soviet Union. This issue, about which Washington has been sucking its teeth off and on for the best part of a year, is without doubt important. But not in the sense in which the United States appears to believe.

The issue exists because of the discovery of substantial reserves of natural gas in the Soviet Urengoi field, in the southern Urals. The plan is to ship large quantities of this gas westwards towards Europe (East and West) by means of a huge pipeline on which construction is about to start. West Germany, France and Switzerland have already signed contracts to purchase natural gas over the next thirty years or so. American objections to European involvement in this scheme take three forms. First, the argument goes, Western European dependence on natural gas from the Soviet Union will undermine its strategic independence. Second, the method by which the pipeline will be financed, with the eventual customers providing credits for the construction, being repaid with gas at a later stage, makes it possible for the Soviet Union to avoid what would otherwise be a nasty brush with the international capital markets. And, third, some of the heavy pipe-laying machinery to be used in the construction of the pipeline will provide the Soviet Union with access to Western technology in a fashion that will ultimately rebound to its strategic and military advantage.

On all three counts, the fears, while not groundless, are exaggerated. The most obvious danger is that Western European states which come to depend on Soviet gas supplies will then be uncomfortably in Soviet hands if, at some point in the future, the Soviet Union should decide arbitrarily to turn off the taps. The Soviet Union has, however, an enviable record for acting meticulously in the performance of commercial contracts, so that fears of strategic vulnerability presumably attach to the hypothesis that there might one day be a European war in which the Soviet Union was at loggerheads with its customers. Then, no doubt, the gas would be cut off but that would not bring any of the intending customers to its knees (although the war might). In no case is the amount of gas being purchased more than five per cent of the customer's use of energy, while the arrangements that prudent gas consumers will make to insure against a mechanical failure of the pipeline would no doubt also allow them to get by if hostilities should break out. Thus the chief strategic significance of the pipeline is that it would shorten the period of time during which Western Europe could fight a conventional war in Europe, and thus quicken the trigger of nuclear escalation. But this is entirely in conformity with the military strategy of Western Europe, not entirely welcome to the Soviet Union.

What the United States objections to the pipeline project overlook is the value to Western Europe of a supply of fuel which, although not dominant in the energy strategy of any potential customer, is at once relatively cheap and also secure. Not often, these days, can people hope to get their hands on a supply of energy over a period of three decades. And even the method by which the project is being financed, requiring that the customers should somehow help with the cost of construction, is not the simple gift it is made out to be. For who among the West German steelmakers and their workers, who are supplying pipes, or in the French companies from whom turbines have been ordered, will complain at the extra work that is falling in their laps? But is it not against the interest of the West that European states should make deals with the Soviet Union whose effects are to make the Soviet Union economically stronger? This is the unspoken question embedded in the American objection. The difficulty, of course, is that trade deals willingly arrived at do invariably benefit all partners. One of the continuing and deep-seated differences between the United States Administration and many governments of Western Europe turns on the European view that an economically healthy Soviet Union is a better neighbour than one perpetually on its knees.

The transfer of technology is in much the same case. Knowledge of how huge pipe-laying machinery works would no doubt be an advantage to the Soviet Union in the development of some of its remote fields of oil and gas, but that does not by itself imply that the world becomes a more dangerous place. The more serious of the United States' objections to what is proposed, however, is the decision that some of the high-capacity compressor turbines to be installed in the pipeline embody technology that could be of military value. This appears to be the reason why General Electric, the United States manufacturer, has asked its French licensee not to accept orders for the pipeline project. The decision is unlikely to make sense, for the same equipment can readily be had from elsewhere, for which reason it is hard to think it can be of crucial military value. But in any case, if President Reagan should give the pipeline project an airing in Versailles, he is likely to find M François Mitterrand, the President of France, taking a sharp but understandable line about the turbines — and the underlying principle.

Where now for UNEP?

On its tenth birthday the United Nations programme for the environment is stumbling.

The United Nations Environment Programme (UNEP), the principal offspring of the environmental jamboree at Stockholm in 1972 and a child of the 1960s, is in another bout of trouble. This week, the governing council of UNEP concluded its annual meeting in Nairobi, where it considered — among other things — the budget for the next two years. Predictably, there was a lot of heat and little light, but at least no delegation threatened to withdraw.

The budget is a constant worry, principally because of wavering by the United States, which has contributed $7 million a year since

0028-0836/82/220349-02$01 00

1973, more than a third of the total programme cost Last year's fear that the United States would contribute nothing at all did not materialize The State Department offer of $2 2 million was increased by Congress to $7 85 million — but UNEP is still waiting for the cheque This year, the Administration's offer is $3 million, but Congress may again vote more Whatever happens, and in spite of the surprise decision of the British government to increase its contribution by a quarter, UNEP's hope of doubling its budget ($17 million in 1981) now seems a dream So too must seem the first five years, when UNEP raised $60 million out of its target of $100 million within just a few months The peak budget ($21 million) was in 1977, since when, in spite of solid support from Scandinavia and the Netherlands, UNEP has gone downhill in strictly financial terms

In part, this is a negative consequence of the developing countries' growing attention to UNEP as a source of development aid One of UNEP's more successful exercises, the regional seas programme, began with Mediterranean pollution (which stems mostly from the French Rhône, Italian Po and Spanish Ebro rivers) but has now shifted to more southern seas This shift of attention is not just a UNEP quirk The environmental impact of poverty looms over that of affluence Growth is in fact faster in some countries of the developing world than in the "North", and where industrial development takes place, it is often without controls The air of Calcutta is now as bad as that of London in the smogs of the early 1950s, while London has clean air

Yet the Stockholm conference did not plan UNEP's $20 million a year to be an environmental action fund for the UN Rather, Stockholm saw UNEP as a coordinating agency within the UN system, drawing together and rationalizing the actions of the other UN agencies But the UN agencies — as always — proved jealous of their powers Moreover, the governing council of UNEP, which represents subscribing nations, ended up dealing almost exclusively with UNEP's small direct programme and budget, ignoring the wider role recommended by Stockholm

In the event, UNEP's programme comes to rest mainly on the Global Environment Monitoring System (GEMS), Infoterra (UNEP's information system), the International Register of Potentially Toxic Chemicals (IRPTC), and the Regional Seas Programme

The two last are generally thought to be the most successful They are based in Geneva, which gives them better relations with the other UN agencies (through the strong UN presence there), and they also happen to be headed by active and committed people Dutch biologist Jan Huismans for IRPTC, and Yugoslav marine biologist Stjepan Keckes for Regional Seas IRPTC is on the point of producing its first batch of complete data profiles of 330 chemicals of environmental significance — but it has been severely hampered by a halving of its budget (It relies now on Huismans, an assistant, and a secretary) Regional Seas is a little bigger (it has a professional staff of six), has fared better for funding with UNEP, and has scored a number of remarkable successes in the form of treaties controlling the pollution of coastal waters, notably the "Athens protocol" on land-based sources affecting the Mediterranean One reason for this success has been Keckes' decision to rely on local scientists — who often must be trained first — to assess pollution in an area, on the principle that governments are more willing to act on advice from their own scientists than on that of a fly-by-night international team The programme is now working on eight other regional seas around the world

Of the other programmes, GEMS — the global monitoring exercise recommended by Stockholm — has suffered from lack of resources A "colossal effort" is needed to strengthen this, says UNEP in a recent publication But an independent expert review of the 1972–82 decade, commissioned by UNEP, says that "even an imperfect series of environmental statistics would be an improvement on present ignorance" * And Infoterra, the information system, is barely used

UNEP's work on deserts — another great Stockholm concern — has also achieved little, not so much because of UNEP as because industrialized states have not wished to pay The UN Conference on Desertification held in Nairobi in 1977 produced good scientific papers and a plan of action, but the UN special account to combat desertification, set up after the conference, has remained almost empty By the end of 1981 total contributions stood at $5,000, all from a single contributor, Mexico

This is not the sum of UNEP efforts, however It can cite work on soils and pest control, its role in the World Conservation Strategy, which is seen as one of the successes of 1970s environmental management, reports on the impact of energy technologies, and a conference on renewables, its task force on pollution and human health (together with the World Health Organization), its promotion of a series of expert meetings on the preservation of tropical forests, international monitoring schemes for acid rain, and pollutants in food and fresh water The snag is that this part of UNEP's work is too much of a miscellany to make a mark

What next for UNEP? Apart from the cash problem, UNEP is concerned with defining its programme for the rest of the decade For the first time, the major UN agencies have got together to define a joint policy the "System-wide Medium-term Environment Programme" (SWMTEP) which covers the period 1984–89 But UNEP played little part in developing it, and it has been described as bland and highly generalized However, it distinguishes the roles that the different agencies should play, even if it is short on recommendations for specific action And it may help UNEP find its way through the UN thicket rather better than it did in the 1970s or it will, if this week's governing council gives UNEP the necessary backing

Universities in limbo

The British government's wish to save money on universities is forgivable; its way of doing so is not.

British universities now know that there will be no reprieve from the fate decreed for them by a thoughtless government The announcement last week by the University Grants Committee (*Nature* 27 May, p 258) that university budgets for 1982–83 will be essentially those forecast a year ago will have dispelled hopes that the government might not be serious The result is that contraction must continue for another two academic years There are two views of what the system will then be like The government seems ideologically committed to the belief that leaner means fitter Universities will have been forced to cut what is called "fat", and some will also have been forced to keep essential activities alive with help from local industry that will reduce demands on the public purse and be worthwhile in themselves What can be wrong with that, the government asks?

Plenty, is the simple answer The second and more gloomy view of the future starts from the observation that the contraction of the university system has been ordained within arbitrary constraints Last year's distribution of grants and, more important, the assignment of targets for student populations, has compelled some universities to shrink more rapidly than others And the restrictions on student numbers mean that no university can hope to work its way out of trouble by being more efficient — taking more students Yet demand for higher education in Britain continues to increase, with the result that students are shunted arbitrarily towards other institutions, the polytechnics for example All this arbitrariness arises, however, not from a belief that restricting access to higher education is in itself virtuous but because the government has not had the wit to devise a scheme for limiting the cost of maintenance grants for students, which are paid by local authorities and charged back to the central government

To seek to economize is within the government's gift, and may even be its duty To attempt to do so without solving a simple book-keeping problem, and while barriers persist between the two halves of higher education, amounts to maladministration

Clouds may lift over Brookhaven

Congress moves to reprieve ISABELLE plan

Washington

ISABELLE, the new particle accelerator at Brookhaven National Laboratory on Long Island, may be saved for at least another year. Recently, serious problems arose with the original magnets, necessitating major changes in design, and causing delays and a rise in the project's construction cost from $275 million to $500 million. And because the troubled ISABELLE began taking a bigger than expected bite out of the US high-energy physics budget the question of whether to finish it at all has become a burning issue among US physicists.

It is also a burning issue in Congress, which is sensitive to pleas from the Long Island community to rescue the big machine, and, by extension, the Brookhaven Laboratory itself. The President's 1983 budget request included no funds for the construction of ISABELLE, although approximately $24 million was included for work on alternative magnets and other research and development projects. Moreover, a high level panel representing the national physics community had just said that ISABELLE should not be finished unless the overall budget was increased. So ISABELLE seemed doomed.

Or so it seemed until 7 May, when Congressman Tom Bevill (Democrat, Alabama), chairman of a key House appropriations subcommittee which has jurisdiction over the high-energy physics budget, toured the buildings at Brookhaven and declared himself "impressed". Better to see the creature, he said, than read about her in reports. Bevill assured Congressman William Carney (Democrat, New York) that he would try to get as much as $10 million in construction funds added to the budget when it comes before his subcommittee. Both Carney, who represents the Brookhaven area, and Thomas Downey (Democrat, New York) want to see ISABELLE finished almost as much as the scientists at Brookhaven do.

But ISABELLE has received only a qualified endorsement from other quarters. Congressman Don Fuqua, chairman of the House Science and Technology Committee which advises on how high-energy physics money should be distributed, has recommended either proceeding with ISABELLE or building a less costly machine at Brookhaven and using the ring tunnel already built.

Fuqua's recommendation carries some weight with Congress, as his committee knows as much about science as any on Capitol Hill. Although it may be construed as an endorsement for ISABELLE, in reality it steers carefully among the factions that have emerged on the question.

More guarded still was the report of a panel headed by George Trilling of the University of California at Berkeley, appointed to evaluate future plans for high-energy physics. Possibilities considered included proceeding with ISABELLE, cancelling ISABELLE to keep other machines going at other laboratories, and building something else. One of the options was a lower cost machine at Brookhaven, and in January the Trilling panel endorsed this recommendation when it reported to the High Energy Physics Advisory Panel of the Department of Energy. Thus, the Trilling group's view carries the weight of the community at large.

The Trilling report said that ISABELLE should be completed only if funds for high-energy physics in the future "averaged" better than the 1982 level of $395 million, for then ISABELLE's increase would not hurt other projects. However, since the President has requested $429 million for 1983, which is equal to the $395 million level in 1982 dollars, then, according to the advisory panel reasoning, ISABELLE should not be built.

All concerned are trying to avoid an outright showdown between the major US accelerator communities involved in the scramble for funding commitments for future big machines. The issue, they all say, is US leadership in high-energy physics in the 1990s.

The argument is partly about what kind of physics should be done, partly about how experiments are shaped by the machines themselves and their costs and timetables, and partly about keeping the eastern portion of the country, in which Brookhaven is the only remaining big accelerator facility, on a par with the facilities in the Mid-West and the West. Congressman Bevill, it seems, is proposing to resolve all this with a stroke of his pen when the item comes before his subcommittee in the next month or so.

Deborah Shapley

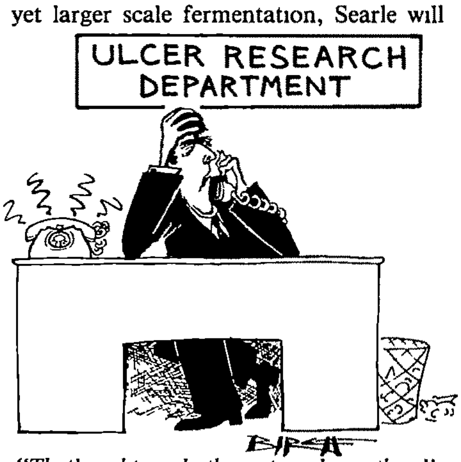
Ulcer cure sweetener for Searle

By the end of this year G. D. Searle and Co. Ltd expect to be testing their first recombinant DNA product in humans. It will be a peptide synthesized according to the instructions carried by a synthetic gene placed inside bacteria. Searle and Imperial Chemical Industries Ltd, initiators of the joint project, hope that the peptide, which is closely related to a gastrointestinal hormone, will prove to be an effective inhibitor of gastric acid secretion and hence of ulcers.

That is one indication that Searle's early attempts to capitalize on biotechnology have survived two setbacks. The first was the departure, in 1980, of two key members of staff to help start up Celltech. Searle's second setback was its failure to make a commercial success of producing beta-interferon from cultured fibroblasts.

Another indication of Searle's resilience in biotechnology came last week with the opening of a new £7 million biotechnology pilot plant at their High Wycombe site in the United Kingdom. The plant will come into operation next month, less than two years after construction started, despite a change in plan half way through. The change involved increasing the part of the plant designed for bacterial culture at the expense of that for cell culture. That shift in balance reflected both the failure of the beta-interferon project and, according to Brian Richards, vice-president of UK pre-clinical research and development, the discovery of several peptides of potential value that could best be produced by genetically engineered microorganisms.

The pilot plant still has facilities for the culture of cells but Searle anticipates more activity in the bacterial fermenters, the largest of which has a 450 litre capacity. The plant, however, is designed to accommodate a 4,000-litre fermenter, large enough to advance from pilot to manufacturing scale in some circumstances. For yet larger scale fermentation, Searle will



"That's right, we both create and cure them"

have either to build new plant or to arrange to use the vast fermentation facilities of the Japanese company Meiji Seika, using a recent agreement to exchange technology.

That, however, is for the future, when and if Searle has something worth fermenting. Bacterial products planned, apart from the anti-ulcer peptide, include interferons. Much effort is being directed towards making structural variants of interferons with greater or more specific activity than the natural compounds. If

0028-0836/82/220351-02$01.00

any are discovered the plan is to manufacture them with bacteria containing synthetic genes

Searle may also use biotechnology in the less glamorous pursuit of producing, more cheaply than at present, the two amino acids that are fused together to make aspartame, Searle's low calorie sweetener which was approved for tabletop use in the United States last year Both amino acids come from bacterial fermentation and so it is possible that the bacteria could be genetically manipulated to produce either amino acid more efficiently than at present **Peter Newmark**

Remote sensing

What war use?

Landsat, the US remote sensing satellite launched by the National Aeronatics and Space Administration (NASA) could have been used by the Argentine and British governments to obtain images of the Falkland Islands, but probably to little effect While Landsat can pick up data from all over the globe, it passes over the Falklands only every eighteen days and a further twenty-four hours are then required to process images Landsat has a resolution of 80 metres and could pick out — with luck and favourable weather conditions — an object as large as an aircraft carrier

Landsat-3 is a near-polar orbiting spacecraft launched in March 1978 It carries visible and infrared wavelength sensors which send back images used in agricultural surveys, mineral and oil exploration and pollution monitoring NASA collects the satellite data at Goddard Space Flight Center in Greenbelt, Maryland and it is then sold by the Interior Department through the Geological Survey's EROS (Earth Resources Observation Satellite) Data Center in Sioux Falls, South Dakota

Fresh images can be obtained from NASA by prior arrangement but the usual time-lag is anything from one to six months Ground stations within a 2,000 km range can pick up real time broadcasts by radio link The British defence department's National Remote Sensing Centre at Farnborough, Hampshire, is licensed under ESA's Earthnet programme to tune into transmissions over Europe Argentina also has a ground station at Mar Chiquita (600 km north-west of Buenos Aires), but to obtain fresh images of the Falklands, it would have to make a special arrangement with NASA so that the data would not be wiped off the recorders on board, which are limited in the amount of information they can store

The delay in obtaining fresh images and the coarseness of their resolution makes the strategic use of Landsat dubious Landsat images may, however, have provided information about prevailing terrain conditions **Jane Wynn**

Nairobi environmental meeting

More and less

A Japanese environmental delegation is this week trying to recover its pride, after its proposal for a "Brandt commission" on the environment took a battering at a series of environmental meetings in Nairobi

Japan had proposed that a group of independent and widely respected personalities get together to produce a weighty document on the global environment to the year 2000 Much to the delegation's chagrin, however, the Group of 77, representing developing nations, proved solidly opposed to the idea The group wanted direct development aid — for re-afforestation, for example — and not simply another expensive report for the bookshelves

This was only one of the little battles which have coloured Nairobi life in recent weeks, during the three meetings which celebrated the ten-year anniversary of the Stockholm environment conference The meetings held were one for non-governmental organizations concerned with the environment, a "meeting of special character" convened by the United Nations Environment Programme (UNEP) to review the decade, and the general council of UNEP itself

Environmentalists have left the meetings with mixed feelings A lot of hard political and scientific lessons had been learned over the decade, said one, but there was still a consummate lack of will to do anything practical

The current governmental attitude was represented by the level of the delegations sent by most countries to the "meeting of special character" UNEP invited all heads of state, but in the end there were just three — Presidents Mobutu (of Zaire), Nemeiry (Sudan) and Arap Moi (Kenya) The United States sent its head of the Environmental Protection Agency (EPA), Anne M Gorsuch, who made a fine speech recording US environmental support in the 1970s Ms Gorsuch has been generally regarded as President Reagan's axe-woman at EPA, so her speech came as a surprise However, she left her cutting comments for a press conference — the US contribution to UNEP would fall from $7 million in 1982 to $3 million next year, she said James Buckley of the State Department added that the US government saw UNEP as a "catalyst" rather than a prime actor

One bonus for UNEP, though, came from a surprising quarter Britain's junior environment minister Tom King promised an increase in the British contribution from £600,000 this year to £750,000 next Even allowing for inflation, this is a substantial increase, which the UK Department of the Environment must find within its cash-limited budget "We are conscious that resources are strained", said Mr King, and "now is the time for action"

Libya also promised its first ever contribution to UNEP — $1 million The Netherlands offered another 50 per cent, Japan, Finland, Malaysia, Uganda and Thailand also promised more But these increases would not cover the big cuts threatened by the United States

There was agreement on one thing, however a declaration, now to be known as the "Nairobi declaration", sixteen pages of fine prose "The world community of States solemnly reaffirms its commitment" says the declaration "to the Stockholm Declaration and Action Plan It also reaffirms its support for strengthening UNEP as the major catalytic instrument for global environment cooperation " The word "catalytic" is to be noted **Robert Walgate**

Information technology

Europe wakes up

Brussels

Europe's leading electronics and information technology companies are taking seriously the European Commission's grandiose plans to pool all their research efforts Dubbed "Esprit", the European Strategic Research Programme in Information Technology, it has evolved in a series of meetings that the Commission has held with leading European electronics firms during the past year

The first fruits of these discussions have been leaked from a communication sent to the Council of Ministers in preparation for the EEC's Science Council to be held on 30 June Yet despite industry approval, it is in the political arena that the real fight will take place to get the Commission's ambitious ideas implemented Discussions with UK government bodies such as the Department of Industry and the Science and Engineering Research Council have left officials in Brussels with the impression that although there is token acceptance of Esprit's principles, the national officials doubt that they can ever be realized

Europe is losing out to Japan and the United States in the race to develop information technology, argues the Commission, not for want of spending vast sums on research Siemens alone devotes around $800 million a year to research Yet Siemens, ICL and the others are in financial difficulties and failing to reap the rewards from their research investments

Industrialists feel strongly that to get the best out of Europe's research expenditure a new body should be set up to coordinate activities Far from wishing to build empires, Commission officials dismiss the idea that they themselves should tackle this A more professional body such as the United Kingdom's National Research and Development Corporation with experience in turning research into marketable products would be given the job It would be co-financed by the companies involved

0028-0836/82/220352-02$01 00

and the member states, and topped up from the EEC's budget.

The management of Esprit would be decentralized and controlled by industry. The aim would be to copy the Japanese by setting clear strategic objectives and concentrating research and exploitation on a few large companies. Areas already singled out for concentrated exploitation are: advanced microelectronics; advanced information processing systems usable by the man in the street; systems for office automation and computer integrated flexible manufacturing; and fourth and fifth generation computers. The Commission is also asking for some $11 million to spend on preliminary pilot projects to sort out the best ways of implementing cooperation.

Radical though the scheme is, the Commission is pressing for an agreement by December 1982 and a start in January 1984. Without such a European effort being launched quickly, officials in Brussels are saying, European companies will increasingly be forced to take minor roles in cooperative deals with Japanese or American competitors — in the United Kingdom ICL is already moving in this direction.

While the Commission may be accused of being over-ambitious, it is clear that Esprit is being taken very seriously by Plessey, GEC, ICL, Nixdorf, Siemens, AEG, Honeywell-Bull, CIT Alcatel, Thomson-CSF and Philips. **Jasper Becker**

Space research

UK goes national

For the first time in ten years, Britain is trying to devise a coherent space policy. The impetus has come from the recognition, later than in other Western countries, that there is money to be made from selling space technologies and services. The British government's apparently sudden decisions, earlier this year, to allow and even encourage direct broadcasting by satellite and cable television point to its fear of losing out on new technologies now coming of age elsewhere in Europe and which are already well established in the United States. The plans now being discussed for a national remote sensing programme, based on the European Space Agency's recently approved Earth Resources Satellite 1 (ERS1) are thus meant to prepare British industry for the time when money can be made from remote sensing data and hardware.

But if the spirit has changed, where will the money come from? Public money will not flow freely, so what about private investment? A select group of financiers and representatives from the space community met last week in the Surrey country house belonging to Logica, the software company, to address that question. Disappointingly the sound of money changing hands was muffled.

What little space policy Britain has had has been directed through its membership of the European Space Agency at the space segment, the hardware in orbit. Now it seems to be agreed that more attention must be paid to the use of data sent back from space — and to persuading people that they must pay for it.

Financiers, still wary of the risks involved in satellites, see more scope for helping to market space on the ground.

Based on the experiences of direct broadcasting and cable in the United States, they are convinced that there is a market in Britain, while industry seems keen to produce antennae and dishes for receiving direct satellite broadcasts. What the financiers want to know is how big the market will be.

Remote sensing, for which the market is diffuse and ill-defined, faces different problems. A programme of scientific research using ERS1 data has been worked out by the Natural Environment Research Council and the Science and Engineering Research Council, but nobody yet knows who will pay for remote sensing data. According to Sir Hermann Bondi, chairman of the Natural Environment Research Council, Britain is fortunate that ERS1 will be an oceanographic monitoring satellite. The need to analyse ocean data quickly because its usefulness is often only immediate will, he says, pave the way for the later use of land data.

Land remote sensing data may be more saleable, perhaps to mining companies and agriculture, but only in the long run. The experience of the National Aeronautics and Space Administration in running Landsat is, however, unhelpful; the early promises made for the data have not been fulfilled. The meeting last week seemed, however, confident that data from Landsat D, to be launched later this year, and from Spot, the French national remote sensing satellite, will be more attractive.

One problem that perplexed the meeting is that the applied science of remote sensing falls administratively between two stools, the Science and Engineering Research Council (science) and the Department of Industry (application). This is why there has been a spate of interest in the question whether Britain should have a space agency of its own. Given departmental jealousy, the outcome will probably be some kind of coordinating agency, more modest, for example, than the French.

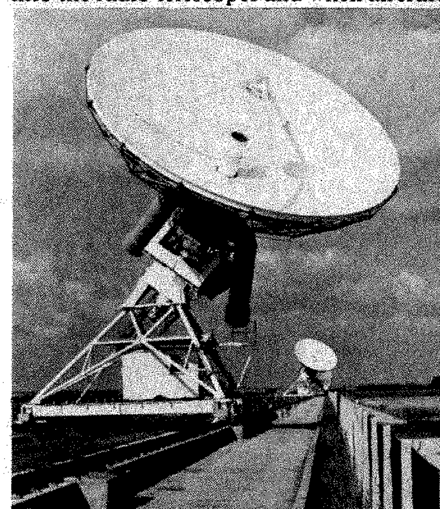
Judy Redfearn

British radioastronomy

Fear of flying

The British propensity to jetset may cause acute problems for Cambridge radioastronomers. In the next few months Graham Eyre, QC, the inspector at the public enquiry into the proposal to site the third London airport at Stansted in Essex, will hear evidence from the University of Cambridge that an expanded airport at Stansted would seriously impede work at Mullard Radio Astronomy Observatory.

The Mullard Observatory, which is situated some 35 miles from Stansted, has for many years had an agreement with the Home Office whereby aircraft interference is controlled. Interference occurs when ground transmissions are reflected back into the radio telescopes and when aircraft equipment gives out radio waves on the telescope's frequency.



In-line for interference — the 5-km radio telescope.

If Stansted were to be expanded to take 15 million passengers a year, the option favoured by the British government, the increase in air traffic would mean that aircraft approaching the airport would start their landing manoeuvres within 4 to 5 km of the observatory. Work using low frequency wavebands — observations of the solar and interplanetary medium and of supernova remnants, for example — could be completely disrupted.

In support of its evidence to the enquiry, the observatory will also present a technical document assessing the amount of interference and the consequences for research, which are not easily quantified. The problem is that the frequency bands allocated to radioastronomers are also shared by other radio users, at present not allowed within 50 km of the observatory. With aircraft, the range would need to be expanded to 200 km, which is not a practical option for a busy airport.

The observatory has occupied its present site since 1956 and the area, which was selected for its lack of radio interference, has been kept "clean" ever since. It would be expensive and difficult to find another suitable site. **Jane Wynn**

Kibbutz biotechnology

Farming today

Rehovot

The traditional view of the Israeli kibbutz — hard work in the fields under a blazing sun — may have to be changed. For the future of many kibbutzim may lie with small science-based industry using the techniques that are already spawning new biotechnology industries in the United States and Europe.

The kibbutz at Beit Haemek is typical of the trend from farming village to light manufacturing to science-based industry. In the mid-1970s, Beit Haemek was looking for a way of supplementing its income from the cultivation of avocados and the raising of cows. And when it failed in an attempt to balance its budget by building and selling pipe organs, the kibbutz decided to establish a company that would use advanced tissue culture techniques to propagate ornamental, specific pathogen-free plants. This move made sense as the kibbutz had several members with degrees in agriculture and microbiology, and others with scientific training and laboratory experience.

Further expansion of the enterprise, now called Biological Industries, was facilitated by the arrival of a new American member in what had been a predominantly British settlement. He is Dr Robert Levin, previously a research associate at Stanford University Medical School.

The kibbutz can do only a limited amount of research on its own, and so Levin works closely with Professor Jonathan Gressel and his group at the Weizmann Institute of Science. One result of this collaboration has been the exploitation at Beit Haemek of a new Weizmann Institute system to use plant tissue culture methods for rapid and inexpensive prescreening of potential herbicides. And in cooperation with scientists at other Israeli research centres, Levin and his colleagues are now utilizing such methods to develop plant varieties resistant to herbicides, diseases and other environmental hazards.

Each successful new project has brought an expansion of Biological Industries and so now Beit Haemek has caused some surprise in Israel by placing advertisements in the newspapers inviting biologists with PhDs to join the kibbutz and applicants are now being screened. The introduction of such specialists would be quite a change in traditional kibbutz practice. On the one hand, it will be necesssary for veteran members of the kibbutz to accept the fact that the newcomers will not be available, as kibbutz tradition decrees, to do any job necessary; they will expect to work in their professions. On the other hand, the new members themselves will have to come to terms with a society where there are no material rewards for their degrees or for their specific contributions.

Yet the egalitarian economic set-up of a kibbutz does seem to be consistent with making a success of a sophisticated science-based industry. Beit Haemek's enterprise expects a $1 million turnover this year, with 65 per cent of its tissue-culture-derived products being exported, mainly to the Netherlands and West Germany.

The kibbutzniks see themselves as a production arm of Israeli academics, in the words of Beit Haemek's general manager Mike Landis, "as a conduit between Israeli research centres and the world market".

Robert Levin of Beit Haemek sees a great deal of similarity between the science-based industries on kibbutzim and the new biotechnology companies in the United States, "which are", he says, "really cooperatives created by a few talented scientists. The only difference is that kibbutz scientists in Israel share modest living quarters while capitalistic scientists in the States share enormous profits".

Nechemia Meyers

Nature in Poland

Many readers will have been moved to ask how they can help by last week's report of the difficulties encountered by Polish scientists in acquiring scientific journals from abroad (see *Nature* 27 May, p.259). The chronic shortage of hard currency, which has apparently worsened since the introduction of martial law last December, has made the purchase of journals virtually impossible.

In the belief that many scientists outside Poland may wish to help colleagues thus deprived, *Nature* is introducing a scheme whereby scientists outside Poland may purchase a year's subscription to *Nature* in Poland at roughly half the usual price.

Those wishing to buy a subscription for a Polish colleague should write to *Nature* in either London or New York (the addresses are given opposite page 349), enclosing a cheque made payable to *Nature* for £50, or the equivalent in any currency, together with their full name and address and those of the intended recipient. Telephone orders may be charged to international credit cards. *Nature* will meet the extra cost of despatching the journal to Poland.

Immediately on receipt of an order, the intended recipient will receive a letter from the Editor describing the arrangement that has been made and identifying the donor. As soon as the order has been processed, copies of *Nature* should arrive in Poland within a week of publication. This offer will remain open at least until 1 August.

Grenoble neutron beam reactor

Working again

Europe's high flux neutron beam reactor, the Institut Laue-Langevin (ILL) at Grenoble, is likely to re-start in June with an unrepaired hole in its primary cooling circuit.

Admittedly, the hole is inside the heavy water primary cooling circuit, and is not considered dangerous, but careful experiments and calculations are being made to make sure that the reactor will work safely despite the fault.

The broken part is a section of perforated aluminium alloy, designed to break up the flow of the cooling water before it turns a corner in the piping. A 250 cm^2 section broke away, and parts of this interfered with the operation of a cooling pump. As soon as the fault was discovered, the reactor was shut down, and already nearly a month's experiments have been lost — a lot of work at ILL, which services dozens of visiting groups working simultaneously. The groups use the neutrons, often for only a few days, but the data so taken provide much more work on data analysis back at the group's home institutions.

Dr Brian Fender, ILL's British deputy director, said last week that he expected to be able to save the 1982 experimental programme by putting off a scheduled development period, due in November, until next February. Ultimately, some two months' experimental time at ILL will have been lost; but it will be somewhat less painful if the loss is taken next year, since 1983 experiments are still only in the planning stage.

The aluminium part broke because of ten years' cycling in turbulent water flow, ILL engineers believe. Well away from the reactor's fuel rod, it did not suffer significant radiation damage. Almost all the pieces have now been recovered. Reassembly of the jigsaw has shown a piece a centimetre across still to be missing, presumed lodged in the cooling circuits, but it is not expected to do more damage when the reactor is restarted.

Flow through the cooling circuit has been tested, using a dummy fuel element, and despite the hole in the aluminium section, no increased turbulence or vibration has been observed. The broken part has also been inspected by TV camera, from a distance of one or two metres, and seems firm enough. It is conceivable that the French licensing authorities would not allow ILL to restart without replacing the part, but, says Fender, "we work very closely together", and he does not expect any trouble from that quarter.

Why could the broken part not simply be replaced? Because it is awkward to reach, requiring the dismantling of most of the reactor, an exercise which could cost many more months than the present delay.

Robert Walgate

CORRESPONDENCE

A letter to Soviet scientists

The following document reached *Nature* on 21 May 1981, the 61st birthday of Academician Andrei Sakharov.

I have learned from foreign broadcasts that the "Scientists for Sakharov, Orlov and Shcharanskii" (SOS) Committee in the United States has issued an appeal to Soviet scientists to come to the defence of the family of Sergei Kovalev — that is, Sergei himself, his daughter-in-law Tat'yana Osipova, and his son Ivan. I feel sure that many of you also heard this appeal. I beg you to treat it with all seriousness and to undertake those actions to which each of you feels prompted by his feeling of responsibility as a citizen and by his conscience, both in this particular case, and in others where your intervention would be of special importance.

For many years now, I have observed an almost total lack of action on the part of my Soviet scientific colleagues in matters relating to the defence of human rights. It is shameful that foreign scientists (and deepest thanks to them!) show a greater concern for our affairs than we do ourselves. In this letter, I am speaking first and foremost to those scientists occupying a fairly high and independent position — more specifically to Members and Corresponding Members of the Academies. I know that some of you have negative or sceptical feelings regarding my statements on general questions. But this is not a general question (on these, I have always expressed my views in the form of a discussion, and have never thrust my opinions on to anyone). This is a matter of the fate of real people, including the fate of your colleague in science. Every one of you who has shown even the least interest will form his or her own independent opinions on these cases, of the total degree of injustice and the harshness of repression.

You cannot consider that these cases do not touch you; the historical experience of our country, professional solidarity, simple human sympathy for the fate of others, and often personal contact with the victims of repression (many of you were personally acquainted with Orlov, Kovalev and others), make such an attitude impossible. You must not invoke the interests of your job, the need to keep your professional post in the interests of science. In fact, most of you are in a fairly secure position. And the interests of science must include the defence of members of the scientific community from injustice; they include the responsibility of the citizen. This is not the Stalin era; practically speaking none of you *now* are under any kind of threat. But can you rule out completely a return to a new era of mass repression? For if this should come to pass, your lack of action *now* will be one of the causes. And conversely, could not the activity as citizens and the independence of even a few of the country's top scientists have a profound and beneficial effect on the whole situation?

And which of you can lay his hand on his heart and proclaim that this is not a vital necessity? It is precisely this which more than anything would promote international scientific relations, and, on a far far wider scale, trust and peace throughout the world. Such is the measure of the individual personal responsibility of every one of you.

In conclusion, I should like to cite several examples of scientists and scholars who are victims of repression — prisoners of conscience. For each of these cases there is information which is accessible to you.

(1) The case of Kovalev and his family, with which I began this letter. Kovalev has served a term of seven years imprisonment under the harshest conditions, and he is now in exile, under shocking conditions in the Magadan region. Tanya Osipova and Ivan Kovalev are in prison, and it is necessary to obtain for them, at the very least, the opportunity of meeting. After the arrest of his wife, and before his own arrest, Ivan had only one 30-minute meeting with her in 15 months.

(2) The case of Yurii Orlov. His fate, and the cruel torments he is suffering are widely known.

(3) The case of Anatolii Shcharanskii — also very well known.

(4) The case of the mathematician and cyberneticist, Dr Aleksandr Bolonkin. After imprisonment and exile which robbed him of nine years of his life, beatings-up, confinement in the punishment cells and provocations, he is back in prison again on a trumped-up criminal charge.

(5) The case of the philologist and poet, Vasyl Stus'. After many years in prison and exile, he was condemned to a further 15 years labour-camp and exile, simply for supporting the Ukrainian Helsinki Watch Group.

(6) The case of Anatolyi Marchenko. He is not a scholar; he is a worker and writer, the author of some remarkable books on present-day labour camps and prisons. But he has been sentenced again — his fifth sentence — to the monstrous term of 15 years imprisonment and five years exile; the central point of the charge being his open and noble-hearted letter on the "Sakharov case" to academician P. L. Kapitsa, who is one of those to whom I address this letter.

(7) The cases of Aleksandr Lavut and Tat'yana Velikanova (mathematicians), Mart Niklus (ornithologist), Leonard Ternovskii (radiologist), Viktor Nekipelov (a pharmacist and talented poet), Pyatkus (philologist), Meilanov (mathematician), Luk'yanenko (jurist), Airikyan, Altunyan and many others. None of them has had recourse to violence nor would do so. All of them have suffered cruelly for loyalty to their noble convictions, the principles of free expression and justice. Help them — this is our common duty.

Andrei Sakharov, Gor'kii, 30 March 1982.

POSTSCRIPT — **In defence of Ivan Kovalev.**

Ivan Kovalev has been sentenced. This is yet another blow to the champions of human rights in the Soviet Union, to free expression, and to the Helsinki Watch Group; a blow against the principles expressed in the Helsinki Final Act. And this is a new act of inconceivable cruelty towards the famous Kovalev family, the third of its victims. In December 1974, Sergei Kovalev, Ivan's father, was arrested. In May, 1980, Tat'yana Osipova, Ivan's wife was arrested. Both of them, like Ivan Kovalev himself, have received cruel sentences for their nonviolent defence of human rights, for their fidelity to noble convictions. In a letter which he wrote shortly before his arrest, Ivan Kovalev wrote about himself and his situation. And in his article "My Tanya", he told us about his wife, her fate and her struggle. There is little one can add to those documents — and having known Ivan for many years I am convinced of the justice of his case.

I call upon everyone who believes in justice, who can feel for the tragedy of this young family, to speak out in defence of Ivan Kovalev, his wife and, of course, his father. The possibility of a meeting between Tat'yana and Ivan must be obtained — this is their inalienable human right. And it is very important too to obtain their freedom, and the freedom of all prisoners of conscience.

Andrei Sakharov, Gor'kii, 2 April 1982.

ESA clarification

SIR — May I refer to your article "Antarctic research hit by crisis" published in *Nature* of 15 April (p.593) and in particular to the part of the article:

> "Although Argentina's own research efforts have been extremely limited, it is at present collaborating with the French in glaciological work, and plans exist to site a ground station for the first European Space Agency remote sensing satellite to be put into polar orbit, at the Argentinian base of Marambio".

There is no Argentinian connection with the European Space Agency/ERS-1 programme. There will certainly be some ERS-1 overseas ground-stations outside Europe, but no negotiations have been made with Argentina or indeed with any other South American state. If such plans were ever envisaged, they would require approval of ESA Council.

You will appreciate ESA's desire to have this point clarified.

W. BRADO
(Head of ESA Director General's Cabinet)
ESA, Paris, France

Editor in false garb

SIR — If both of your bizarre and intemporate recent leading articles ("Doves in false garb", 18 February, p.542; and "Professional propaganda", 1 April, p.380) had been published on 1 April, one might more easily have understood them. They are so full of rancid sarcasm, repetition to the point of perseveration, wild claims devoid of any supportive evidence, multiple errors in basic logic, frank contradictions and odd grammar, that they imply a writer almost incoherent with anger. They are also probably the most disgraceful abuses of editorial privilege I have ever seen in print.

You have used, however ineffectually, the anonymity of the editorial and the prestige of a hitherto distinguished scientific journal, to lend spurious respectability and authority to your personal and highly idiosyncratic views. You have jeered at a very large number of sincere, ethical, distinguished and honourable professionals throughout the world, impugning their honesty, without raising a

single justified or logical argument. You misrepresent the views and claims of those you disagree with, so as to more easily oppose them.

You criticize the professions (with biased inaccuracy) for ignoring public issues, and belittle them when they speak out on them. You graciously grant us the responsibility to contribute our special knowledge to the solution of such problems, but criticize us for failing to exceed the limits of such special knowledge. You insist that it's laudable for us to express ourselves singly, but dreadful to do so collectively. You sneer at the "catchy acronymic titles" of the groups concerned, though few of them are catchy, and none are acronyms. You complain that the groups "claim professional support" in a deceitful way. While the degree of professional support they have is significant and growing, their titles very specifically and accurately state their membership as limited to those members of each respective profession who are opposed to nuclear arms or war: how much more accurately could they describe themselves?

Take your own advice, Mr Editor. Put aside your pique about the professions you don't belong to; put aside your anonymity and the authority that belongs to *Nature* and not to you — take your courage in your hands as you exhort us to do (and as we have done) and join us on the hustings. If you can express your views coherently and support them with data, we will listen with interest and respect.

Amongst your hectic hubris, you graciously concede that "it would . . . be shocking if physicians were silent about the probable consequences of smoking". May we not also warn about the dangers of being smoked?

Michael A. Simpson
Health Sciences Center, Temple University, Philadelphia, Pennsylvania, USA

Ab what?

Sir — In the preamble to the first editorial in the edition of *Nature* dated 22 April (p.693), the word "abreact" is used. So far as I can discover the word is a term from psychoanalysis referring to the liberation of the individual from neurosis by the expression of repressed emotion. Is this what the leader article intends?

I feel it would be a pity if *Nature* were to start falling into the trap of employing jargon terms made meaningless by fashionable use.

It might cause some adverse reaction among the readers.

Robin H. C. Strang
Department of Biochemistry, University of Glasgow, Glasgow, UK

Data protection

Sir — I read with great interest the article "Big Brother's law" (*Nature* 1 April, p.694) about personal data protection. I would like to add a few comments.

In the summer of 1981, the European Commission addressed a formal recommendation to European Community member states to sign and ratify the convention of the Council of Europe by the end of 1982. Up to now, only five member states have signed it.

In this recommendation, the Commission stated that it would draft a Community directive if the member states failed to sign the convention.

The socialist group in the European parliament has long pressed for a European Community directive. Indeed, in March 1982 the European parliament adopted a report of its legal committee (the report was given by Herr Sieglerschmidt, SPD) asking among other things for a Community directive for personal data control.

We believe, however, that the most important point is the control of the transnational data transfer of private companies, although you are right in the statement that the transfer of information between governmental departments is very important.

Finally, I would like to say how important it is to lobby the British members of the European parliament. The international companies are very familiar with effective lobbying of MEPs. The electorate should do the same, but in the interest of maximum protection of data on individuals.

Fritz Gautier, MEP
Braunschweig, FRG

Patent sense

Sir — The report in *Nature* of 29 April (p.792) of the 21 April Colloquium at the Association of the Bar of the City of New York is inaccurate in stating that a European visitor may, under European laws, derive an invention from a seminar or talk in America and appropriately apply for a patent in Europe.

European and other patent laws do not permit patents to those who derive. Typically, they require that the subject of a patent be the original work of the applicant or its predecessor in interest.

The issue of whether or not an invention is original work is different from the issue of whether or not the inventor's (original) work preceded the work of another.

David W. Plant
Fish & Neave, New York, USA

Ageing controversy

Sir — I am writing to vehemently protest about the recent *News and Views* article from your ageing correspondent in the 1 April issue of *Nature* (**296**, 392-393;1982). The work of Dr Obispo and his colleagues on "longevin", the lifespan-extending protein from carp gut is described in excruciating detail, but no mention at all is made of Dr A. Huxley's pioneering work.

It was in the obscurity of his Oxford college rooms that the re-discovery of the rejuvenating effect of raw fish viscera was made (*Phil. Trans. R. Soc.* B **240**, 153-215, 1969). Furthermore, he has gone a long way in the characterization of the same protein. I am truly surprised that this work of a British scientist (who in addition comes from a very distinguished family indeed) should be overlooked in the pages of *Nature*. I think the reason for this is not only that the Obispo and Maunciple group has essentially unlimited funding from the Stoyte Foundation for Aging Research, but also that nowadays anything having to do with gene cloning receives immediate attention, while people like your correspondent tend to overlook standard protein chemistry work. It is sad that Dr Huxley's work has been ignored for so many years, but it is even more sad that the California group should be allowed to patent the longevin B-chain clone. The extension of human lifespan is of utmost ethical importance and should not be treated lightly; least of all in a patent office.

An Ageing Professor
Basle, Switzerland

Sir — I read the *News and Views* article on longevin (*Nature* **296**, 392-393; 1982) with keen interest but think, if I may say so, that this may prove to be the swan song of geriatrical biochemistry.

Jennifer Reed
Institute for Experimental Pathology, German Cancer Research Center, Heidelberg, FRG

Sir — Huxley in his seminal work *After Many a Summer* (Chatto and Windus, 1937) was the first to draw wider attention to the research of Obispo. It is regrettable that your correspondent's otherwise excellent report on anti-senescence factors (*Nature* **296**, 392-393; 1982) did not refer to Obispo's pioneering studies, even though these were conducted on whole carp *flambé* (*J. Carp Sci.* **1**, 69; 1936). Hauberk's results on raw carp viscera were not rediscovered until the regular visits of a member of the present shadow cabinet to Tashkent led to the realization that the famous mad ape in the local zoo was none other than the now fully evolved Lenin. Obispo himself, his procreative and creative powers equally unimpaired, will reach the age of 100 in 1984, by which time, we can be confident, gerontology will have experienced a timely death.

Richard Glendale
London W6, UK

Nuclear options

Sir — David Fishlock should keep his journalistic innuendos (*Nature* 22 April, p.700) for *Financial Times*. He implies that my letter in *Nature* of 18 March (p.192) on "Electricity costs" is equivalent to flat-Earth theory, ostensibly because it cites a paper of mine[1] as "in the press". He calls this "unpublished", but in fact Energy Policy No. 2, containing the paper, was published on 5 May, and the *Financial Times* was sent a copy of the page proofs before publication. In any case the scientific editor of the *Financial Times* was surely not unaware of the report of Sir Kelvin Spencer's committee[2], which was given wide publicity after a press conference in the House of Commons on 2 February, and which quoted or paraphrased the main results of the "unpublished" paper.

I can only assume that any conclusion which does not wholeheartedly support the nuclear case is necessarily flat-Earth theory to David Fishlock, and need not be looked at any further.

J. W. Jeffery
Department of Crystallography, Birkbeck College, London WC1, UK

Gravitational radiation and the binary pulsar

from Virginia Trimble

GRAVITATIONAL radiation not only exists, but it is apparently also doing exactly what general relativity says it ought to, at least in the binary pulsar PSR1913+16. This is the conclusion drawn by J.H. Taylor and J.M. Weisberg writing recently in the *Astrophysical Journal* (**253**, 908; 1982). It comes after more than six years of observing gradual changes in the eight-hour orbit of the pulsar and its invisible companion, probably also a neutron star.

The pulsar period itself (0.059 s) acts as the known emitted frequency from whose Doppler shifts the orbit is determined as part of a total solution including up to 20 variables. These represent intrinsic properties of the pulsar, classical orbital elements, and relativistic corrections for the advance of the perihelion (about 4° per yr compared with 43″ per century for Mercury) and variable parts of the gravitational redshift and the transverse Doppler effect. The relativistic parameters together define a small set of allowed values for the masses of the two stars. These, plus the orbit period, can be plugged into a standard formula for gravitational radiation from orbiting point masses to yield a unique prediction of the rate at which the orbit should be decaying, $\dot{P} = -2.4\times10^{-12}$. The measured value, from the multi-variable fit, is $-2.30\pm0.22\times10^{-12}$, in exact agreement to within the experimental errors.

The high precision and self-consistency of these results mean that they have interesting implications for three problems of current interest in astrophysics.

First, if no important effects have been left out, the binary pulsar orbit provides as accurate a mass for a neutron star as has ever been determined, and the first one for an honest-to-goodness radi pulsar. The other measured masses all come from X-ray binaries, for which the energy source is not the rotation of the neutron star (as in 'true' pulsars) but accretion of gas from a companion, an inherently messy process. The answer is $1.4\pm0.1\ M_\odot$ for each component. Existing data[1] are consistent with all known neutron stars having about this mass. It is just above the maximum stable mass (Chandrasekhar limit) for a star or stellar core supported by degenerate electron pressure and may reflect a fairly universal truth — you get a neutron star when an inert core builds up to the Chandrasekhar limit and so collapses.

Second, we are encouraged to ask more seriously than before how gravitational radiation will affect the evolution of other short-period binary systems, whose orbits are less clean than that of PSR1913+16, but which are astronomically at least as interesting. The classic case is that of the cataclysmic variables (CVs)[2-6] — novae and related systems consisting of a normal star transferring material to a white dwarf companion. Many kinds of binaries show such mass transfer. In some, the flow is driven from a more massive to a less massive star by newtonian effects; in others, a star spills over because it is trying to expand and become a red giant[7]. But in some low-mass CVs, neither of these explanations works. The shedding star is the less massive and has not yet begun to expand. What drives the transfer? Gravitational radiation must gradually bring the two stars closer together. The surprise is that it does so at precisely the rate needed to produce the otherwise inexplicable mass transfer in these short-period, low-mass CVs[8-10]. In addition, beyond a certain point, gravitational radiation-driven mass transfer begins to move the stars apart again, and so may also explain some puzzling gaps in the distribution of orbit periods of CVs.

Third, the binary pulsar provides a test of the standard formula, first derived by Einstein[11], for the gravitational radiation expected from a binary system. Over the years, many theorists have tackled the problem within the framework of general relativity. Some have confirmed the so-called quadrupole formula[12-14], whilst others have found different results, or, more often, concluded that a proper derivation has not yet been carried out and is currently beyond them, too[14-16]. The agreement to within 10 per cent between prediction and observation for the binary pulsar strongly suggests that the quadrupole formula is very nearly right, at least for relatively weak-field cases (again, unless some important effect has been left out of the multi-variable analysis). This should help theoretical relativity both with this particular problem (it is always easier to do a calculation if you know the answer in advance) and with others by suggesting appropriate approximation methods. General relativity is not the only theory of gravitation currently under investigation. But most of the others (except some cases of the Brans-Dicke theory) predict orbit changes due to gravitational radiation that disagree with the binary pulsar result[17]. We cannot, however, quite rule them out yet, if only because the calculations leading to that conclusion have been done with methods analogous to those that lead to the quadrupole formula for general relativity, which may, just possibly, not be appropriate.

What can we expect from PSR1913+16 and gravitational radiation in the future? Observations are continuing. And the nature of the problem is such that precision increases roughly with the square of the observing time. Thus another five years could narrow the error bars on the relativity parameters from about 10 per cent to about 1 per cent, providing neutron star masses with that precision and testing agreement (or disagreement) to 1 per cent between the quadrupole formula prediction and the observed value for the orbit decay due to gravitational radiation. Beyond this we probably cannot go. Fluctuations in the newtonian gravitational potential of the Galaxy (due to stars, clusters, gas clouds, spiral arms and all the rest) cause random, undecipherable accelerations of a test particle and so will put noise into the pulsar timing measurements at a level near 2×10^{-14} on time scales comparable with the effects being sought.

Finally, once a phenomenon has shown up indirectly in an astronomical context, it is natural to ask whether it can be seen directly in the laboratory. Detectors designed to search for gravitational radiation pulses have been in fairly continuous operation one place or another for

Virginia Trimble is in the Department of Physics, University of California, Irvine, California 92717, and the Astronomy Program, University of Maryland, College Park, Maryland 20742.

0028-0836/82/220357-02$01.00

about 15 years. Ferrari *et al.*[18] have reported a recent data set in which widely separated detectors were simultaneously excited by some sort of background and reference earlier results. Helium-cooled detectors of higher sensitivity are being developed or are in operation at Rome, Stanford, Maryland, Tokyo and other places. The expected gravitational radiation flux at the Earth from the binary pulsar is, however, only about 10^{-8} ergs $cm^{-2} s^{-1}$, less than 10 per cent that expected from the Crab Nebula pulsar, and some 10 orders below the sensitivity of foreseeable ground-based equipment at the relevant frequencies. Indirect methods will, therefore, clearly continue to be important for a long while, at least for PSR1913 + 16!

Antibodies and cancer therapy

from P.C.L. Beverley

A RECENT report describes the dramatically successful use of a monoclonal antibody in the treatment of a human B-cell tumour[1]. The patient has now been clinically free from disease for eleven months without further treatment. This striking success was largely due to the exquisite specificity of the antibody for the tumour cells, but is something of a special case. The monoclonal antibody was anti-idiotypic: that is, it was raised against specific determinants on the antibody expressed on the surface of the tumour cells. The method would thus seem limited because a different antibody has to be produced for each individual tumour and because only B-cell tumours, which are uncommon, are known to carry sufficiently specific determinants. Whether it will be possible to find markers that will allow a similar specificity to be gained against other tumours is not yet clear.

Several other patients have, however, already been treated with monoclonal antibodies and it is possible to assess something of the general potential of antibodies for therapy.

The questions to be faced are: are the monoclonal antibodies safe, and are they effective? So far, there is a clear answer to only the first question. Administration of mouse monoclonal antibodies produces remarkably few side effects even when free antigen is present in the serum and it must be presumed that the infusion of antibody leads to the formation of circulating immune complexes[1]. At first sight the apparent safety of monoclonal antibodies might be assumed to stem from their mono-specificity — they do not contain the contaminating specificities that give problems when conventional antibodies, for example anti-lymphocyte globulin, are administered. This may, however, be an over-simplification since it has been predicted that many monoclonal antibodies will give unexpected cross-reactivities[2]. Indeed, cross-reactivity has been demonstrated for some of the antibodies which have been used *in vivo*: for example, the J5 antibody used in treatment of acute leukaemias[3] was found also to react with renal tubules. The moral to be drawn is that before an antibody is used *in vivo* it is wise to screen widely for unexpected reactions with different tissues.

If the antibodies are safe the major problem of antibody specificity remains. Antibodies to differentiation antigens can be used when the loss of normal cells with the same antigens would not matter or when tumour cells have completely replaced the normal population. Thus, antibodies against T-lymphocyte antigens have been used to treat advanced stages of mature T-cell tumours. In the first patient, a significant response of skin lesions was seen and treatment was continued for 17 weeks until the tumour progressed in lymphoid organs[4]. This patient showed no immune response to the mouse immunoglobulin but in subsequent trials and in patients given anti-T cell antibody as immunosuppression for renal allograft rejection episodes, antibody to the mouse protein was produced and limited the duration of treatment[5].

While antibodies to differentiation antigens can be used for tumour therapy, their potential would be much greater if tumour-specific antibodies were available. Several claims for the existence of such antibodies have been made, notably of those to a common acute lymphoblastic leukaemia antigen (CALLA)[6]. However, further examination in another laboratory showed the antigen to be present on some normal bone marrow cells[7], suggesting it might be best to treat all claims with some scepticism, at least until candidate antibodies have been examined in several laboratories. Nevertheless, an anti-CALLA antibody (J5) was used to treat leukaemic patients and revealed another problem of antibody therapy, that the tumour cells rapidly lost the target antigen when antibody was administered. Similar antigenic modulation could be demonstrated *in vitro*.

While treatment *in vivo* has not yet produced spectacular results, with the exception of the anti-idiotype antibody, treatment *in vitro* holds more immediate promise. Bone marrow grafting has become a recognized treatment for leukaemia but has considerable problems, including graft-versus-host disease (GVH) caused by T lymphocytes in the donor marrow. Removal of T lymphocytes from bone marrow before grafting had been attempted with conventional antisera and it was a logical step to see if better results could be obtained with more specific monoclonal antibodies. So far the published data are limited to a single study in which the marrow cells were merely incubated with monoclonal anti-T cell antibody before infusion[8]. The procedure relies for effect on the removal of antibody-coated cells from the circulation by the reticuloendothelial system — hardly likely to be very effective in transplant recipients who have been irradiated and treated with cytotoxic drugs to condition them to accept the graft. Nevertheless, the early results are not discouraging and the use of antibodies with complement or coupled to drugs or toxins should improve its effectiveness. Leukaemia can also be treated by an autologous transplant. Remission bone marrow is collected and stored until the patient relapses. Aggressive chemo- and radiotherapy can then be administered and the patient rescued with the stored marrow. This approach suffers from the problem that the re-infused marrow may contain leukaemic cells but these might be removed if sufficiently specific antibodies can be produced[9]. *In vitro* treatment has the advantage that surplus antibody, or antibody–drug or antibody–toxin conjugate, can readily be washed away before the marrow is infused.

It is notable that the research discussed so far all deals with tumours of the haematopoietic system and common tumours (all carcinomas) have not been mentioned at all. This is in part because many of the earliest and best characterized monoclonal antibodies have been directed to leukocyte antigens, and also because the therapy of solid tumours poses additional problems, particularly the penetration of antibody into tumour masses. Nevertheless

0028-0836/82/220358-02$01.00

an initial trial has been made, although without great effect, in patients with extensive disease[10]. Once again, bone marrow clearance *in vitro* may soon be the most useful manouvre, at least for some solid tumours which are chemo- or radiosensitive.

What of the future? First it is clear that antibody alone is unlikely to be optimally effective and drug- or toxin-coupled antibodies may provide additional therapeutic advantage, particularly *in vitro*. *In vivo* therapy is frequently limited by the development of anti-mouse immunoglobulin antibody but it may be possible to induce tolerance or, in the future, to reduce the problem by the use of human monoclonal antibodies. Already the development of human anti-tumour antibodies has been reported[11]. While serotherapy will surely not be a panacea, there are grounds for cautious optimism.

Plant cells on the move

from Clive Lloyd

CORSETED in cellulose, plant cells have limited freedom of movement. As a result, their morphogenetic responses, rather than consisting of cellular migration, involve internal rearrangements of cytoplasm. The responses include alterations in the rates of cell division and of enlargement (which determine the overall size of cells). Fine tuning of tissue morphology is, however, largely a product of the shapes adopted by cells and of the orientation of the walls which are deposited between them at cytokinesis. A common element uniting all these processes is the microtubular cytoskeleton since microtubules: (1) help to determine the polarized shape of interphase cells by somehow guiding the deposition of cellulose; (2) as the preprophase band (PPB) they foretell where the cytokinetic cell plate will be deposited; (3) help form the mitotic spindle; and (4) contribute to the cytokinetic apparatus, the phragmoplast. The microtubule cycle can therefore be regarded as at the hub of key morphogenetic processes. To come to terms with this at the level of control it will be important to obtain a molecular description to complement the existing ultrastructural one. For instance, where are the microtubule-organizing centres located? Is there one set responsible for all microtubule arrays or are there several? If several, how are their functions coordinated?

In comparison with animal tissue culture cells, plant cells are much less tractable and, as a consequence, the successful application of molecular probes to the study of the cytoskeleton has been slow. But over the last year several studies have emerged which present real technical advances that should lead to a more dynamic picture of the microtubule cycle.

One possibility when considering the microtubule cycle is that different tubule arrays are composed of different tubulins produced, perhaps, in a cycle-dependent manner. The multitubulin concept was reviewed by Fulton in a recent *News and Views* article[1] which outlined that non-mammalian organisms do contain multiple genes for tubulins and that the α-subunits of their tubulin heterodimers may differ from those of vertebrate brains, which, unlike most other tissues and unicellular organisms, constitute a rich source of microtubule proteins. Until now the lack of grey matter has held back research into plant tubulin, but in this issue of *Nature* (p.426), Morejohn and Fosket report its isolation from Paul's scarlet rose suspensions and, for the first time, its reassembly into microtubules.

Plant extracts, prepared according to methods for brain tubulin and containing leupeptin as a protease inhibitor, were fractionated on DEAE-Sephadex. One fraction was enriched in proteins which migrated on SDS gels in the vicinity of brain tubulins. Indeed, microtubules could be produced from this fraction either by self-assembly in glycerol or by 'precipitation' with the plant metabolite taxol which enhances the polymerization of tubulin[2]. It is of interest that comparative peptide maps suggest that whereas brain and plant β-tubulins are very similar, the α-subunits are different. As Clayton *et al.* have suggested[3], this could be the basis of the relative resistance of the microtubules of microorganisms to drugs such as colchicine and this explanation would now seem to apply to higher plants as well. Provided that satisfactory cell synchrony can be obtained, the stage is now set to see whether there are cycle-specific classes of plant tubulins.

Clive Lloyd is at the Unilever Research Colworth Laboratory, Sharnbrook, Bedford MK44 1LQ.

Several recent histological studies have outlined the dynamic nature of plant microtubules. De Mey *et al.*[4] reported the staining of microtubules in the endosperm of *Haemanthus* (giant African blood lily) by an immuno-gold method. Using this technique, anti-tubulin antibody-decorated microtubules can be made visible by the subsequent addition of colloidal gold-tagged antibodies and beautiful pictures have been obtained of interphase and mitotic arrays. One point to emerge from this work is that cytoplasmic microtubules seem to be grouped around the nucleus to the extent that it is concluded "that the nuclear envelope or the nucleus, or both, is instrumental in tubule nucleation and arrangement". This is intriguing since sites of microtubule nucleation in acentriolar plants are poorly understood and difficult to pinpoint, and this study gives (some of) them a definite perinuclear location. The function of these cytoplasmic microtubules in endosperm (which, at stages, is liquid; containing wall-less nuclei in a syncitium) is enigmatic and had not been previously detected. It is therefore possible that they have a different function to the plasma membrane-associated microtubules believed to help orientate cellulose microfibrils and which have been reported to emerge, in *Azolla* roots, from nucleation sites located at the cell periphery[5]. Another interesting feature of this study is that it shows cytoplasmic microtubules co-existing with phragmoplast tubules which, in turn, overlap in time with the anaphase mitotic spindle. This implies separate microtubule-organizing centres or nucleation events for different microtubule assemblies whose bouts of activity are not mutually exclusive.

The large nuclei of *Haemanthus* endosperm make it ideal material for the study of mitosis and, as Euteneur and McIntosh[6] have shown with their work on microtubule polarity, for phragmoplast formation also. Interphase cytoplasmic hoops of microtubules are absent from this tissue, however, and other material must be used to study them. The difficulty with applying antibody-based techniques to walled cells is that the wall generally excludes antibodies, but there are now ways around this problem. By pre-fixing roots with aldehydes, Wick *et al.* [7] were able to preserve cell shape before degrading the wall with enzymes and with EGTA (which presumably weakened intercellular calcium pectinates). Following this treatment, gentle squashing released cuboidal cells which could at this stage be permeabilized with acetone before carrying out double immunofluorescence using anti-tubulin antibodies. For the first time, the PPB has been visualized by immunofluorescence and all four assemblies are beautifully illustrated. Some interesting aspects deserve comment. For example, at the same time as the PPB is stained, so is the nuclear envelope, which appears to have

0028-0836/82/220359-02$01.00

microtubules — not of the PPB — associated with it. In some cases where the nucleus has been freed from the rest of the cell, the PPB segregates with the nucleus and not with the cell cortex.

It is early days in this more detailed phase of plant cell biology but already the new approaches are presenting tantalizing and unexpected findings. With such techniques now successfully applied to higher plants, we can expect to learn more about the spatio-temporal aspects of microtubule nucleation which accompany key processes in plant morphogenesis. □

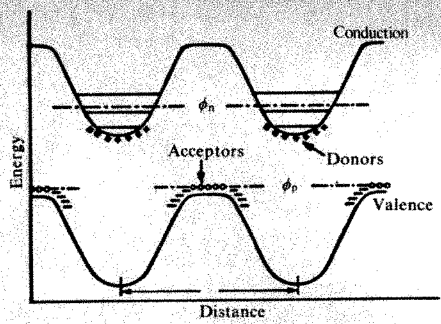

Fig. 2 Spatial variation of the conduction and valence bands in an excited state of the superlattice. The extra electrons (gathered in conduction valleys) and holes (gathered near peaks in valence band) are implied by the separation of chemical potentials, ϕ_n and ϕ_p, for the two species. Recombination is slowed by the spatial separation of electrons from holes. After ref. 1.

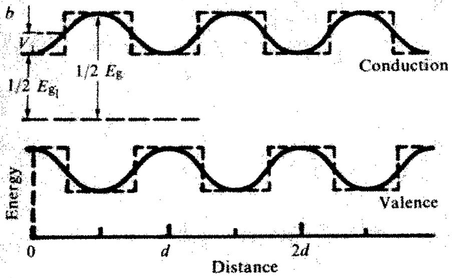
Electrons in novel two-dimensional structures

from J.M. Worlock

THE report that Gottfried H. Döhler and his colleagues have been able to grow a specimen of gallium arsenide (GaAs) in the form of a doping superlattice[1] is an exciting landmark in semiconductor physics. For Döhler, primarily a theoretician, at the Max-Planck Institut fur Festkorperforschung in Stuttgart, the development is the culmination of ten years' work. Having discerned the properties expected of a doping superlattice[2], he has now persuaded colleagues in Stuttgart and Munich to grow the new lattice and to confirm his predictions.

Interest in semiconductor superlattices goes back to 1970 when Esaki and Tsu[3], at IBM, perceived that it was possible, at least in principle, to improve on nature and design semiconductor microstructures with carefully tailored properties.

Fig. 1 Spatial variation of the conduction and valence bands in two types of semiconductor superlattice: *a*, doping superlattice of alternating n-type and p-type layers; *b*, compositional superlattice with alternation of crystal composition. The solid and dashed lines represent simply sinusoidal and sharp-edged band variation respectively. E_gs are bandgap energies of the constituents and V_1 is the amplitude of the superlattice potential, fixed by the doping levels in *a*, and depending on both the E_gs and electron affinities in *b*, where the amplitudes of variation in valence and conduction bands need not be equal. After ref. 3.



They envisioned two types of semiconductor superlattice. One, a doping superlattice, is that analysed by Döhler (and independently by Yu. A. Romanov[4]) and recently realized. The other, a compositional superlattice, was realized as early as 1974 by groups at IBM[5] and Bell Laboratories[6] and has been much studied[7].

Figure 1 shows the spatial variation of the electron bands in the direction of the superlattice. The doping superlattice (Fig. 1*a*) is seen to those familiar with semiconductors to be simply an alternation of p–n and n–p junctions. The periodic rise and fall of the conduction and valence bands is caused by a periodic variation of impurity concentration. The rise and fall also mimics on a more macroscopic scale the periodic attraction and repulsion that electrons experience in the microscopic atomic lattice: electrons are attracted to minima in the conduction band while holes are attracted to maxima in the valence band.

In a compositional superlattice (Fig. 1*b*), on the other hand, alternating layers are of different elemental composition. Locally, each composition has its own band structure, so that within limits the periodic variation of the conduction and valence bands can be arbitrarily chosen. The periodic structure shown in the figure resembles the familiar case of the combination of GaAs, with bandgap E_{g1}, with an alloy semiconductor aluminium–gallium arsenide (AlGaAs) having a slightly larger bandgap. A more recent development, the type 2 superlattice, conceived at the IBM laboratories[8], is exemplified by the combination of indium arsenide (InAs) and gallium antimonide (GaSb). Here the valence and conduction bands interpenetrate, resulting in a much more complicated superlattice.

Döhler *et al.*'s doping superlattice has been produced by growing a crystal of GaAs by the technique of molecular beam epitaxy (MBE). Planar layers of ~40 nm thickness (~150 atomic layers) were doped alternately with silicon (n-type) and beryllium (p-type) atoms, at densities of about 10^{18} atoms per cm^3. The resulting structure of the superlattice crystal is shown (Fig. 2) in the excited state resulting from illumination, which puts extra holes in the valence band and extra electrons in the conduction band. The extra electrons and holes are spatially separated with the interesting consequence that they can have anomalously long lifetimes, their mutual annihilation or recombination is slowed by their inability to approach each other. A second consequence is that some of the bending of the bands is undone by the extra carriers, leading to a crystal with a 'bandgap' uniquely sensitive to illumination.

Dohler *et al.* have produced unambiguous evidence for this sensitivity (Fig. 3). The quantum energy of the photoluminescence measures this bandgap, since the luminescence is annihilation radiation. At low excitation intensity, the bands shown in Fig. 2 are strongly bent and the gap energy is small, around 1.3 eV; but as the excitation intensity is increased, the gap energy shifts higher, approaching the energy of the bandgap of undoped GaAs, at about 1.53 eV.

Further evidence for the formation of a

high-quality doping superlattice is given in the form of inelastic light-scattering spectra, which show how the electrons are distributed in their valleys, and how these distributions can be changed by optical excitation.

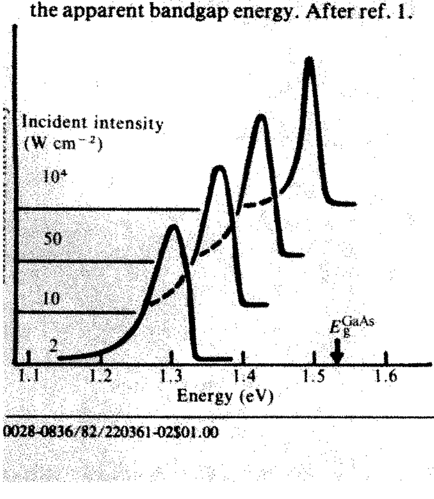
The techniques used in growing semiconductor superlattices are potentially of great importance. MBE, which originated at Bell Laboratories in the late 1960s, is one of a class of epitaxial crystal growth processes in which new material forms in thin layers on top of and in register with an existing crystalline substrate. These processes differ from each other in the manner in which new atoms are brought to the growth surface. Although other epitaxial processes have grown excellent crystals, precise control down to monatomic layers is still attained only with the MBE technique. Of course, it is not only superlattices which are grown: many of the most important structures involve simply one or two interfaces or heterojunctions between dissimilar semiconductors.

Among the important optical devices that have been fabricated starting with epitaxial growth are light-emitting diodes (LEDs), lasers and detectors; all of these are useful in the expanding field of optical communications, while LEDs also have important applications as display devices.

Because of the precise control which is possible in MBE growth and because of the invention, at Bell Laboratories, of modulation doping, researchers have been able to construct extremely smooth planar (two-dimensional) pathways for electronic conduction. Highly mobile electrons travelling in these layers may be involved in tomorrow's high-frequency electron devices.

But equally important is the 'pure physics' excitement which has attended the refinement of the MBE technique. Some of the earliest experiments were used to demonstrate the quantum-mechanical particle-in-a-box behaviour of electrons and Wannier excitons in AlGaAs–GaAs superlattices[9]. More recently some

Fig. 3 Optical spectra of the recombination luminescence emitted from a doping superlattice, showing how the increasing incident intensity shifts the radiation to higher frequency, implying that larger populations of electrons and holes change the apparent bandgap energy. After ref. 1.



unexpected peculiarities of matter in two-dimensional space (2D) have received attention. The effects of randomness or roughness of the pathway have a powerful influence on the localization of mobile particles in 2D, and studies of electron localization in epitaxial layers have increased our understanding of this concept.

A startling effect in 2D transport was discovered in 1980 by Klaus von Klitzing and his co-workers[10]. Their anomalous Hall effect has been developed in MBE-grown AlGaAs–GaAs heterostructures to give a new precision to the value of the fine structure constant[11], and has also led to deeper theoretical insight into matter of reduced dimensionality.

Many more examples of exciting developments could be adduced, showing that new structures can be exploited both for new devices and for new science. I expect the doping superlattice to follow in this honourable tradition. □

Isotopic anomalies in meteorites

from Edward R.D. Scott

WHAT D.D. Clayton[1] has called a new field of astronomy, 'astrochemistry', is developing from an appreciation[2] that the Solar System did not form from a hot well-mixed cloud of uniform chemical and isotopic composition, as was once believed. Exciting discoveries of isotopic anomalies in meteorites, made during the past decade, are being used to test and develop theories for the formation of elements in stars, the formation and history of interstellar dust and the origin of the Solar System. Studies of the isotopic composition of oxygen and magnesium in chondrites provide crucial evidence for a dust component in the early Solar System containing essentially pure ^{16}O, and ^{26}Mg excesses that result from the decay of ^{26}Al. Relatively simple, attractive and testable models have been proposed to explain the oxygen isotopic abundances, but the interpretation of the ^{26}Mg excesses is more controversial.

R.N. Clayton and his associates[3–6] have established that the oxygen isotopic compositions of minerals and components in chondrites are a result of various degrees of mixing between reservoirs with intrinsically different isotopic compositions. On a plot of $^{17}O/^{16}O$ against $^{18}O/^{16}O$, data for chondrules and nearly all Ca–Al-rich inclusions define a set of closely spaced lines with slopes of 0.94–0.97. (Terrestrial samples define a single line with a slope of 0.52, because of mass-dependent fractionation processes.) Three lines have so far been identified for H-L-LL, CM and CO-CV chondrite groups, but others may be resolved. On the three-isotope plot, the lines appear to radiate from a point marking the oxygen composition of spinels, which occur in Ca–Al-rich inclusions and have the lowest $^{17}O/^{16}O$ and $^{18}O/^{16}O$ ratios of all minerals. Isotopic compositions of minerals may also depend on the nature of the host chondrule or inclusion; the largest variations are found in the Ca–Al-rich inclusions of carbonaceous chondrites.

Oxygen isotopic data suggest that meteorite components largely formed from two ingredients: interstellar gas with a slightly variable isotopic composition, and well-mixed interstellar dust, about 5 per cent of which contained essentially pure ^{16}O (refs 3,7,8). Dust, or chondrules and inclusions derived from this dust, exchanged oxygen with the gas to various degrees. Minerals such as spinel are presumed to preserve the original isotopic composition of the dust because of their low oxygen diffusion rates. (Oxygen diffusion rates in these minerals have not yet been measured.) FUN inclusions, which are those with many large isotopic anomalies[2], may have formed from poorly mixed interstellar dust balls[8]. During their formation, these inclusions experienced large isotopic fractionation, before partial exchange of oxygen with the gas[9]. Oxygen shows the most widespread isotopic anomalies because it was the only element that was abundant in both nebula gas and dust[8].

Wood[8] deduces from these and other data that the Ca–Al-rich inclusions and chondrules did not form by condensation from a gaseous solar nebula[10], as many once believed. He supports D.D. Clayton's view[11] that they formed from unvaporized aggregates of interstellar grains. Ca–Al-rich inclusions probably formed either as distillation residues during unspecified heating events in the solar nebula[8], or as condensates from supernova ejecta[11].

In contrast, the picture obtained from studies of magnesium isotopic abundances is relatively confusing. Excesses of ^{26}Mg formed by decay of ^{26}Al have been found in several minerals with high Al/Mg ratios[12]. About 15 Ca–Al-rich inclusions in the Allende meteorite have been found to contain ^{26}Mg excesses that are correlated with the Al/Mg ratio. However, the proportion of their Al atoms that were radioactive when the inclusions formed (the initial $^{26}Al/^{27}Al$ ratio) varied widely from $< 2 \times 10^{-7}$ to 10^{-3} (see ref. 12). Some types of inclusion (type B1) have values of

Edward R.D. Scott is at the Department of Geology and Institute of Meteoritics, University of New Mexico, Albuquerque, New Mexico 87131.

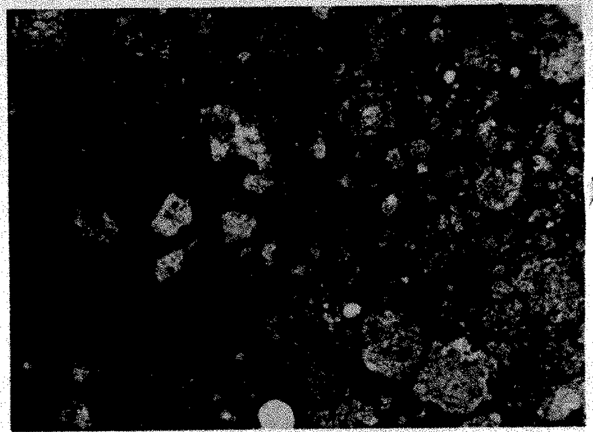
0028-0836/82/220361-02$01.00

5×10^{-5} for this ratio, but in other inclusions, various crystals or minerals may give diverse values[13]. These differences may be due to a difference of up to 9 Myr in their times of formation (or final internal equilibration). Alternatively, $^{26}Al/^{27}Al$ ratios may have varied widely in the solar nebula[12]. However, the size of isotopic variations that would be needed to account for simultaneous formation of these inclusions is much larger than has been found for other elements.

Bar-Matthews *et al.*[14] have recently analysed an unusual Ca–Al-rich inclusion, which contains corundum (Al_2O_3), in the Murchison meteorite. If the inclusion had formed by equilibrium condensation from a slowly cooling gas of solar composition (which now seems rather unlikely), corundum should contain a large ^{26}Mg excess, as it is the first major mineral predicted to condense[10] and has a very high Al/Mg ratio. Instead, the authors found only small ^{26}Mg excesses, which were uncorrelated with the Al/Mg ratio and which they attributed to Mg isotopic heterogeneities.

The lack of excess ^{26}Mg in Murchison corundum and the wide variation in the initial $^{26}Al/^{27}Al$ ratios of Allende inclusions are cited by D.D. Clayton[1,15] as evidence against decay of ^{26}Al in the Solar System. He rejects explanations of time differences or isotopic heterogeneities and argues that ^{26}Al decayed in interstellar grains. He attributes correlated ^{26}Mg excesses in individual anorthite crystals to precursor Al_2O_3 stardust. This controversial idea has stimulated more precise experiments, but is still a minority view.

Analogous problems have arisen in the interpretation of ^{129}Xe excesses in ordinary chondrites due to decay of ^{129}I, which has a half life of 17 Myr. If ^{129}I was homogeneously distributed in the solar nebula, then two chondrules in the Bjurbole chondrite formed 2 Myr apart[16], a surprisingly long time. D.D. Clayton has also questioned the existence of live ^{129}I in the Solar System[1], but the best working hypothesis seems to be that the I–Xe time differences, like those for the Al–Mg chronometer, may be real. Some authors have invoked planetary, rather than nebular, processes to form chondrules[17,18] and Ca–Al-rich inclusions[19]. This might help to explain the large spread of formation ages of chondrules and inclusions, but the oxygen isotopic data strongly suggest that chondrules and Ca–Al-rich inclusions are all primitive objects, which may have formed during similar high-temperature events[20].



Transmitted light photograph of the Vigarano carbonaceous chondrite showing Ca-Al-rich inclusion with complex rims and smaller chondrules. Actual size: 8 × 11 mm.

Progress in astrochemistry will be greatly advanced when the origin of the chondrules and Ca–Al-rich inclusions is better understood. This probably requires a realization that all the inhabitants in the exotic menagerie of chondritic components — Ca–Al-rich inclusions and chondrules, mafic chondrules, aggregates and matrix, and metallic Fe, Ni — have interrelated origins. The origin of chondrules in enstatite chondrites, for example, cannot be divorced from an understanding of the formation of Ca–Al-rich inclusions in carbonaceous chondrites.

A new model for nitrogen control

from M.J. Merrick

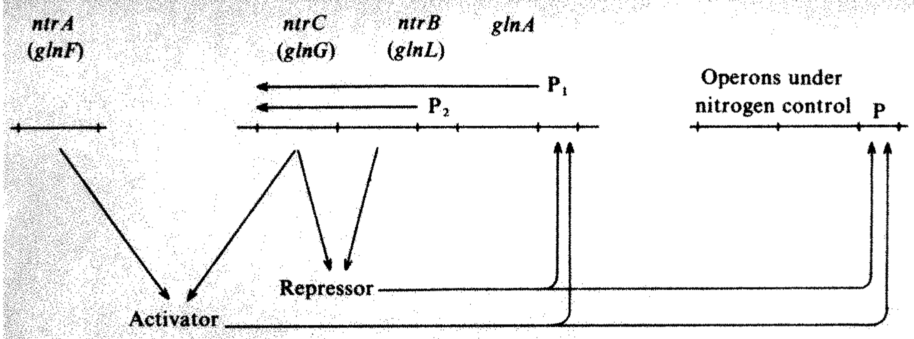
IN *Escherichia coli* and other enteric bacteria, the induction of a number of operons involved in carbon assimilation, for example, *lac, ara, gal,* is affected by the intracellular concentration of cyclic AMP, which is in turn determined by the carbon source available to the cell. This phenomenon is termed catabolite repression and is mediated by a complex of cyclic AMP and the cyclic AMP receptor protein (CRP) which together form a transcriptional activator. There has long been evidence[1] for another regulatory system controlling the balance of nitrogen assimilation enzymes in bacteria, for example, histidine (*hut*)and proline (*put*) utilization, and nitrogen fixation (*nif*). This phenomenon, which has been termed 'nitrogen control'[2], has received considerably less attention than catabolite repression although a model for control of nitrogen assimilation was proposed in 1973 (refs 3,4). Recent evidence from genetic studies in a number of organisms suggests that the system is considerably more complex than originally proposed and involves both positive and negative regulatory elements.

Studies on the regulation of histidase synthesis in *Klebsiella aerogenes* originally led Magasanik and co-workers to formulate a model[5] in which the principal regulator of nitrogen assimilation was the enzyme glutamine synthetase (GS). They postulated that GS was responsible not only for the biosynthesis of glutamine and the assimilation of nitrogen into glutamate, but also for the activation of transcription of operons such as *hut* and *put*. The enzymatic activity of GS is regulated by the reversible adenylylation of specific tyrosyl residues on each subunit of this dodecameric protein. In conditions of nitrogen starvation, GS is deadenylylated and highly active, and Magasanik *et al.* proposed that this deadenylylated form of GS was an activator of transcription. Evidence for the model included the isolation of mutants, believed to be in the GS structural gene (*glnA*), which showed altered regulatory properties[5].

In the last five years, studies of nitrogen control have been extended to *Salmonella typhimurium, E. coli* and *Klebsiella pneumoniae* as well as *K. aerogenes.* A very different model for regulation of nitrogen assimilation has now emerged in which GS is no longer considered to be a regulatory protein and instead three specific genes, *ntrA, ntrB* and *ntrC* (or their equivalents), have been identified in all the above four species. Two of these genes, *ntrB* and *ntrC,*

M.J. Merrick is in the Agricultural Research Council Unit of Nitrogen Fixation, University of Sussex, Brighton BN1 9RQ.

0028-0836/82/220362-02$01.00



Model for nitrogen control in *S. typhimurium* and *E.coli*.

are contiguous with the GS structural gene, *glnA*, and this close linkage confounded the earlier analysis of mutants.

The *ntrA* gene (originally designated *glnF*) was first identified in *S. typhimurium*[6]. *NtrA* is not linked to *glnA* but mutations in this gene result in constitutive low levels of GS and glutamine auxotrophy[6–8]. These mutants are also unable to activate other genes under nitrogen control.

Following identification of *ntrA*, another regulatory locus closely linked to *glnA* was described in *S. typhimurium*[2], *E. coli*[9] and *K. pneumoniae*[8,10,11]. Then at the 1981 meeting of the American Society for Microbiology in Dallas, it was reported that in both *S. typhimurium* (Kustu and colleagues at the University of California, Davis) and *E. coli* (Tyler and colleagues at the Massachusetts Institute of Technology), this regulatory locus consists of two cistrons (*ntrB* and *ntrC* in *S. typhimurium*, and *glnL* and *glnG* in *E. coli*). Tyler *et al.* have shown that in *E. coli*, the two genes constitute a single operon transcribed from *glnL* to *glnG* and it has been proposed that this operon may be transcribed either from its own weak promoter (P_2) or by stronger read-through transcription from the *glnA* promoter (P_1)[12]. The products of the *E. coli ntrB* and *ntrC* genes have been identified as polypeptides of molecular weights 36,000 (*ntrB*)[14] and 54,000 (*ntrC*)[13,14].

The glutamine auxotrophy induced by *ntrA* mutations can be suppressed by mutations in either *ntrB* or *ntrC* with a resultant constitutive low level of GS synthesis. Hence it seems that in *ntrA* mutants, GS is permanently repressed and this repression is relieved by *ntrB* or *ntrC* mutations, leaving a low level of unregulated *glnA* transcription from P_1. This suppression does not, however, extend to other operons under nitrogen control which fail to be activated in all *ntrA*$^-$ strains. In an *ntrA*$^+$ background, *ntrB* mutations result in constitutive expression of *glnA* whereas most *ntrC* mutations prevent expression of *glnA* and other genes under nitrogen control.

From the extensive genetic analysis in both *S. typhimurium* and *E. coli* a consensus model (see the figure) has emerged for nitrogen control in the two organisms. It is proposed that the *ntrB* and *ntrC* products can repress or activate transcription of genes under nitrogen control, including *glnA*. Repression requires both the *ntrB* and *ntrC* products (possibly acting as a complex), hence the suppression of the *ntrA* Gln$^-$ phenotype by mutations in either *ntrB* or *ntrC*. However, activation apparently requires only the *ntrC* (and *ntrA*) product(s) because *ntrB* mutants express *glnA* constitutively. The Gln$^-$ phenotype of certain *ntrC* mutants is proposed to be due to the *ntrB–ntrC* complex being permanently locked in the repressor form, a model which is supported by the isolation of Gln$^+$ suppressors of such *ntrC* mutations in both *ntrB* and *ntrC*[15].

The *ntrC* product therefore seems likely to be a DNA-binding protein which can activate transcription. The *ntrB* product could also bind to DNA in the manner of a conventional repressor or alternatively could modify the activator properties of the *ntrC* product. The *ntrA* product is a positive regulatory factor necessary for the formation of a functional *ntrC* activator and hence *ntrA* mutants cannot derepress genes under nitrogen control. Analogies between this system and the cyclic AMP–CRP system for carbon and energy regulation are striking and extension of such analogies suggests that *ntrA* may encode an enzyme that synthesizes a low molecular weight co-regulator of transcription — a signal of nitrogen deficiency[2]. It is of interest that certain operons, for example, *hut*, are subject to regulation by catabolite repression and by nitrogen control mediated by the elements described above.

The *ntrB*, *ntrC* regulatory system in which two genes in a single operon encode a repressor and an activator respectively is almost unique among the bacterial control systems so far analysed. However, one other system shows striking analogies to that proposed for *ntrB* and *ntrC*.

The nitrogen fixation (*nif*) regulon in *K. pneumoniae* is controlled by two *nif*-specific regulatory genes, *nifL* and *nifA*, which act respectively to repress or activate *nif* transcription[16,17]. These two genes comprise a single operon, *nifLA*, and their products may also function as a protein complex. As with *ntrB,C*, the product of one *nif* gene, *nifA*, is alone sufficient for activation of transcription[18]. Interestingly the *nifLA* operon is in turn regulated by the general nitrogen control system which our recent studies have shown to be essentially identical to that described for *ntrA,B,C* in *E. coli* and *S. typhimurium*.

The recent work described above should stimulate new interest in the regulation of nitrogen assimilation, but just as the mechanism of catabolite repression is still not completely understood[19], the details of nitrogen control will probably take considerable time to dissect. In the meantime, a recent report of a regulatory locus closely linked to the structural gene for GS in *Bacillus subtilis*[20] prompts speculation as to whether nitrogen control in organisms other than the enteric coliform bacteria is mediated by a similar genetic system. □

Vitamin D: sunlight and precursors

from Alastair Hay

WITH some twenty metabolites of vitamin D now identified (see the figure for some of them) chemists in the field have much to be satisfied about. There is less satisfaction, however, for those concerned with the biological importance of these metabolites and a recent workshop* on vitamin D raised more questions than it answered.

Take, for example, the role of the two kidney metabolites of vitamin D, 1,25-dihydroxyvitamin D (1,25-$(OH)_2D$) and 24,25-dihydroxyvitamin D (24,25-$(OH)_2D$). The former is the active hormonal form of vitamin D. The controversial suggestion that 24,25-$(OH)_2D$ is also a potential hormone active in bone was made several years ago but it is still far from clear whether 1,25-$(OH)_2D$ alone is necessary to cure the bone disease osteomalacia — caused by a deficiency of vitamin D — or whether both metabolites are required.

Obtaining an adequate supply of vitamin D is a greater problem for old people than for the young. The two main sources are from food and exposure to UV light in the summer. For most people in Britain, including the elderly, it is the latter source which is the most important (Lawson *et al. Br. med. J.* **II**, 303; 1979).

Although both young and old are said to produce equivalent amounts of vitamin D when exposed to UV light (Davie & Lawson *Clin. Sci.* **58**, 235; 1980), the concentration of the precursors of vitamin D_3 in the skin seems to fall with age. M.F. Holick (Massachusetts General Hospital) reported that the epidermal stores of 7-dehydrocholesterol (7-DHC) are inversely related to age, as is the amount of pre-vitamin D_3 (pre-D_3) formed from 7-DHC after UV irradiation.

One possible regulator of 7-DHC stores is the kidney metabolite 1,25-$(OH)_2D$. Holick has detected a high-affinity, low-capacity receptor for 1,25-$(OH)_2D_3$ in fibroblasts and keratinocytes cultured from skin biopsies taken from normal volunteers that was absent in cells cultured from a skin biopsy of a patient with vitamin D-dependent rickets type II. The kidney metabolite increased the ratio of 7-DHC to cholesterol in cell cultures of keratinocytes and Holick suggested that stores of 7-DHC in skin may be controlled by 1,25-$(OH)_2D_3$ inhibiting the conversion of 7-DHC to cholesterol.

The steps in the conversion of 7-DHC to pre-D_3 and then vitamin D_3 are controlled by UV light and temperature respectively. The vitamin is removed from the skin attached to a specific vitamin D-binding protein (DBP) which has a much higher affinity for vitamin D_3 than for pre-D_3 and so allows only the former to enter the circulation.

There has been much speculation about the function of DBP and argument about the importance of free and bound vitamin D_3 metabolites in plasma. It now seems clear that the major role of DBP is as a storage protein for vitamin D metabolites, for which it has a high affinity.

Recently Haddad *et al.* (*J. clin. Invest.* **67**, 1550; 1981) suggested that vitamin D and its metabolites attached to DBP might first bind to a membrane receptor and then be pinocytosed into cells. R. Bouillon (University of Leuven) reported, however, that he could find no sign of a membrane receptor for DBP. Labelled DBP did not bind to kidney cells in culture in any appreciable quantity and the little that did bind was not altered by the presence of either vitamin D metabolites or unlabelled DBP. The binding was therefore not specific, a finding which Bouillon confirmed using immunofluorescent techniques.

Thus Bouillon concluded that DBP acts like other transport proteins for hormones and that it is the free hormone which crosses cell membranes. In normal subjects, a positive correlation was found between the serum concentrations of DBP and 1,25-$(OH)_2D$. As vitamin D status does not affect DBP levels, the correlation suggests that 1,25-$(OH)_2D$ levels are related to changes in DBP concentration and that the free, rather than the total, 1,25-$(OH)_2D$ concentration is feedback regulated.

Despite a 1,000-fold difference between the total concentrations of the liver metabolite 25-hydroxyvitamin D and 1,25-(OH)D, the difference between the free concentrations and these metabolites is only 10-fold (Bouillon). If it is the free hormone which is important, it is clear that some thought will have to be given to the value of the current assays which measure total concentrations of vitamin D metabolites.

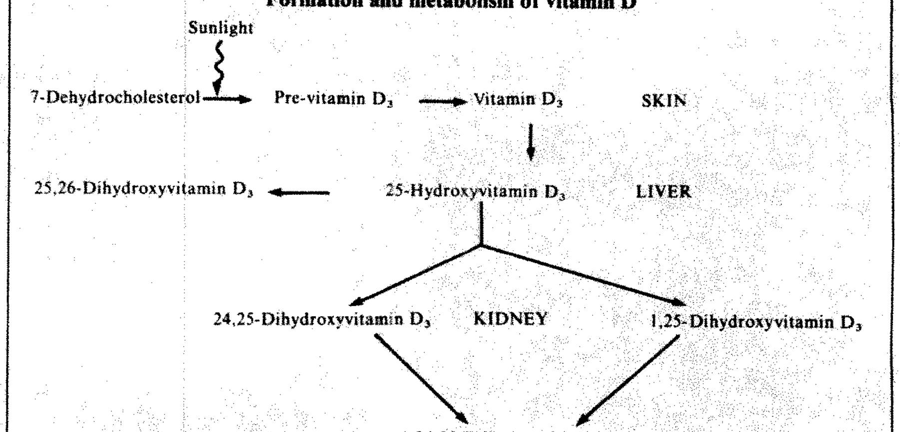
Another function of 1,25-$(OH)_2D$ which is becoming increasingly controversial is the hormone's action on the gut, where it increases the active transport of calcium. R.T. Franceschi and H.F. De Luca (*J. biol. Chem.* **256**, 3848; 1981) and D.E.M. Lawson (Dunn Nutrition Laboratory, Cambridge) believe that it is new proteins synthesized in the mucosa in response to 1,25-$(OH)_2D$ which facilitate calcium transport across the gut. But H. Rasmussen (Yale University) argues that the increase in calcium transport is not affected when protein synthesis is inhibited. He has observed that 1,25-$(OH)_2D$ increases the synthesis of phosphatidylcholine in mucosal cells — in the absence of protein synthesis — and he believes that this change is necessary for active calcium transport.

Rasmussen claims that the increased phosphatidylcholine concentration is eventually reflected in changes in the phospholipid composition of the brush border membrane. D.D. Bikle (University of California) would probably support this view. He ruled out newly synthesized protein within brush border membrane, or altered phosphorylation of proteins in response to 1,25-$(OH)_2D$, as the explanation for the increased calcium flux across the membrane. He found that calcium transport occurred in the absence of both these changes.

J.A. Putkey (University of California), however, could find no evidence to support the lipid hypothesis. Use of a spin label probe, 5-nitroxide stearate, showed that dietary vitamin D has no detectable effect on either the polarity, or lipid fluidity, of the membrane; neither does it alter its cholesterol or lipid phosphorus content. It seems, however, that some consensus view, which relies on both protein synthesis and lipid turnover to explain the action of 1,25-$(OH)_2D$ in the gut, is sure to emerge sooner or later.

If just one or two of vitamin D's metabolites can generate so much controversy, then the chemists would seem to have provided ample ammunition to allow the disputes to continue for some time yet. □

Formation and metabolism of vitamin D



*The 5th Workshop on Vitamin D was held at Historic Williamsburg, Virginia on 14–19 February 1982. Proceedings will be published by Walter de Gruyter later this year.

REVIEW ARTICLE

Variety in the level of gene control in eukaryotic cells

James E. Darnell Jr

The Rockefeller University, New York, New York 10021, USA

In light of present progress in the understanding of how messenger RNA is constructed in eukaryotic cells, the levels of gene control are discussed. Transcriptional control, assessed by the rate of synthesis of specific nuclear RNA, is strongly indicated to be the most frequent level of control. Definition of eukaryotic transcription units as simple (encoding one protein) and complex (encoding two or more proteins) affords a framework in which to discuss control at the level of RNA processing for which several examples also are known. Finally, differential stability of cytoplasmic mRNAs and differential translation, both well established, are briefly described.

THE study of gene control in eukaryotic cells has matured over the past five years into one of the most active and productive fields in experimental biology Earlier conclusions about eukaryotic gene control were deferred because mRNA production in eukaryotes is not a simple matter of transcribing the RNA Especially in vertebrate cells, the transcription units for mRNAs are longer than the final mRNA product[1-6] Several 'processing' steps occur to primary RNA transcripts in the cell nucleus before the mRNA emerges to be translated in the cytoplasm, involving the addition of a methylated guanylate residue—a 'cap'—at the 5' end of primary transcripts[7], the addition of adenylic acid residues to a site in the primary transcript to create a 3' poly(A) segment[8-13] and finally the removal of specified internal sequences (introns)[14] and rejoining or splicing of the remaining RNA pieces (exons)[14] to create a finished mRNA (refs 15-17, Fig 1)

This complicated mRNA formation, together with the ordered, complex structure of the nucleus and cytoplasm of eukaryotic cells and the different fundamental needs served by a genetic programme in slowly growing or non-growing differentiated eukaryotic cells and rapidly adaptable bacterial cells, have long spurred speculation[5,18,19] that eukaryotic gene control might differ from that in bacteria In particular, it has been suggested that eukaryotic genes are subject to regulation at more levels than are bacterial genes In addition to transcriptional regulation, there might be regulation of RNA processing in the nucleus, mRNA transport from the nucleus, and mRNA stability and frequency of translation in the cytoplasm

With the major mechanical steps of eukaryotic mRNA formation now understood, it is possible to describe more accurately the anticipated levels and varieties of eukaryotic gene control[5] In fact, regulation of the amount of specific mRNA molecules has been demonstrated at the level of transcription, nuclear RNA processing and mRNA stability Here I shall cite evidence supporting a variety of levels of eukaryotic gene control The experiments reviewed mainly demonstrate the levels of control mRNA concentration, and not the biochemical mechanisms underlying the controls No attempt is made to review the control of transcription units encoding ribosomal RNA, transfer RNA or 5S RNA (RNA polymerase I and III transcription units, transcription of 5S RNA has been recently reviewed[20]) The relationship between gene control and chromatin structure is not discussed but has been the subject of a review recently published[21] It is clearly possible to envisage gene control at the level of differential translation of mRNAs and potential differential post-translational events, but these subjects have received less experimental attention, so they will be mentioned only briefly

RNA transcription and transcriptional control

The first level of control in eukaryotic cells is in the choice of RNA polymerases In contrast to bacteria, eukaryotes have three RNA polymerases polymerase II transcribes genes that encode proteins[22,23], polymerases I and III have already been mentioned Both *in vivo*[24] and *in vitro*[23,25], RNA polymerase II initiates transcription at a site located at least in part by a conserved 8-10 nucleotide region 25-30 nucleotides upstream (in the 5' direction) from the RNA start site The nucleotides TATA are strongly conserved at this site[23,26] and the region is known as a 'TATA' or Goldberg-Hogness box[27] Undoubtedly other sequences are important in regulating access of polymerases to DNA Reports on viral, yeast and individual mammalian genes point to the importance of sequences upstream

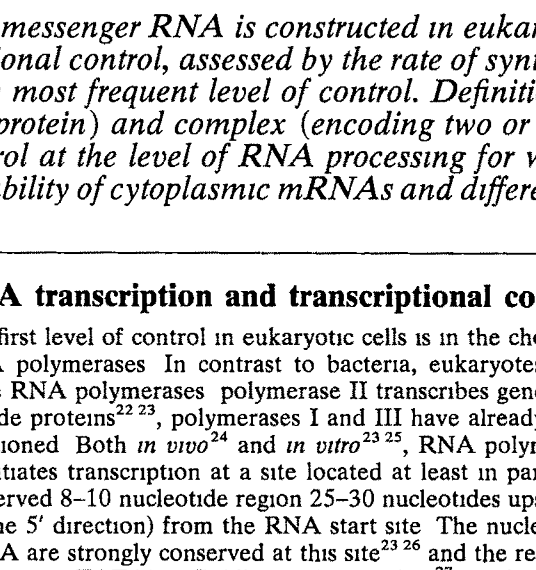

Fig. 1 Steps in mRNA formation (1) DNA indicating the sites of initiation (INIT), about 30 nucleotides to the 3' site of a TATA box, and of termination (Term) of transcription (2) Initiated transcript with cap (m^7Gppp) added to the first nucleotide (N) (3) Transcript after polyadenylation—the addition of a sequence of about 200 adenylate residues (A_{200}) at the poly(A) site, which is 10-20 nucleotide bases downstream from the conserved hexanucleotide AAUAAA Between steps (2) and (4), mammalian mRNAs acquire methyl groups ($-CH_3$) on the 6 position of about 1 of every 100 adenylate residues The exact time of methyl group addition is not known (4) Messenger RNA formed by splicing X, poly(A) site, s, splice site

0028-0836/82/220365—07$01 00

from the TATA box (see, for example refs 28–33) Although no consistent picture has yet emerged for the role of these upstream sequences in transcriptional control, intense research in this area should yield important conclusions soon

Here we are concerned more with establishing the variation of transcription rates than with the basis for the variation Transcription initiation is widely believed to be the major controlling step in transcriptional control Little is known, however, about transcriptional termination, which might also be a level of control For example, all RNA polymerase II complexes that begin a chain do not transcribe the entire chain Prematurely terminated transcripts are produced from viral[34] and probably cell[35] transcription units Little is known about the specificity of transcriptional termination sites although polymerases seem regularly to pass poly(A) sites[10–12] Recent evidence suggests that, for the major late adenovirus[10,11] and the major β-globin transcription units[1,50] there exists a region of termination, if not a specific site

Transcriptional control

The various mechanisms for transcriptional control are very familiar from the classic studies of bacterial gene regulation[36,37] In bacteria, both regulated increases and decreases of transcriptional initiation are possible and two types of regulation of termination can occur—'readthrough' to the next gene and premature termination or 'attenuation' which stops transcription before the coding portion of the gene is reached[38] Apparent control of transcriptional initiation that results in an increase or decrease of mRNA has been documented in several cases in eukaryotic cells and one case of differential termination has been described The evidence reviewed here shows clearly that the most frequent mode of eukaryotic gene control is at the transcriptional level

Measurement of transcription control. Bacterial geneticists used RNA–DNA hybridization to document the existence and very short half life of mRNA[39] and to map transcription units[37,38,40,41] The simple presence or absence of specific mRNAs was taken as evidence (correctly in most cases) for transcriptional control However, in eukaryotic cells, a changing level in the steady-state concentration of a given mRNA or an increased labelling of mRNA after relatively long label times could partly be due to differential nuclear or cytoplasmic stabilization To avoid this difficulty it is necessary to hybridize very briefly labelled ('nascent') nuclear RNA to DNA sequences corresponding to a specific mRNA[5] The ideal method to label nuclear RNA is expose cells to radioactive RNA precursors for say ≤ 5 min, and thereby sample the labelled nuclear RNA even before the acid-soluble triphosphate pool has become fully labelled[10,35] But this is often not practicable because so little of the total RNA output (usually 5×10^{-6}–5×10^{-5} of the total) from the nucleus is due to transcription of a single gene[4,42,43] Fortunately there is another suitable method for labelling nascent nuclear RNA In isolated nuclei, previously initiated RNA polymerase II molecules elongate growing RNA chains by less than 500 nucletides in 10–20 min of incubation[1,4,44] RNA synthesis in isolated nuclei depends on nucleoside triphosphates (NTPs) and thus nuclear RNA can be highly labelled with high-specific activity NTPs Two studies suggest that *in vitro* chain elongation is an accurate reflection of a brief label inside cells First, in the cases of adenovirus-2 transcription units[1] and the major β-globin transcription unit[4], the polymerases in isolated nuclei elongate intact molecules covering the entire transcription unit Second, the fraction of total *in vitro* or *in vivo* labelled RNA complementary to various specific DNA segments is similar[1–4,45–48]

Therefore isolated nuclei are widely used to prepare nascent RNA for the measurement of differential transcription of specific genes All the experiments I cite as establishing transcriptional control have used RNA from either pulse-labelled cells or isolated nuclei to estimate transcriptional rate

Adenovirus transcriptional control. The changes in virus protein and virus mRNA synthesis during adenovirus infection have been thoroughly explored (Fig 2) Specific increases and decreases in rates of transcription, presumably mediated at the initiation step, occur at several sites on the adenovirus genome during virus infection In addition, one case of apparent termination control has been described The following conclusions can be drawn about adenovirus transcriptional controls

(1) During the first 1–2 h of infection, transcription units 1A, 1B, 3 and 4 all increase in transcription rate[49] Of this group, transcription of 1A appears to peak first In comparison, transcription unit 2 is delayed[49,50] and the transcription unit for protein IX produces no mRNA or nuclear RNA at all for the first 4–6 h (refs 51, 52), although the protein IX transcription unit resides entirely within the early transcription unit 1B (refs 26, 52, 53, Fig 2) At ~6–8 h after infection, protein IX transcription increases without affecting the rate of transcription of 1A or 1B (ref 52) Among the tests for early activity of the protein IX transcription unit was an assay for promoter-proximal RNA capable of detecting minimal (~1%) synthesis of the first 100 bases of the transcription unit, but still no activity was evident[52] This is one of the clearest cases in eukaryotic cells or viruses of transcriptional control at the level of initiation

(2) Mutations in transcription unit 1A lead to a failure during infection of mRNA accumulation from regions 1B, 2, 3 and 4 (refs 54–57) This failure is due to the absence of transcription when a 1A protein product is defective[57], but the exact mechanism of action of the 1A protein remains unknown[52]

(3) P16 (the major late adenovirus promoter) functions both early[59–62] and late[1,3,24,34] in infection, but after DNA synthesis, it is 100–1,000 times more active per cell[34,60] This increased transcription is presumably on new DNA templates In comparison, transcription units 1A and 1B on the same strand remain equally active throughout infection[34,52,63] Thus there seems to be a mechanism for restricting polymerase initiation to P16 on the new DNA

(4) Controlled termination of transcription also occurs during adenovirus infection[60–63] The same P16 promoter produces RNA beginning at the same cap site both early and late in infection From the late transcripts, five 3' co-terminal groups of mRNA are formed[10,64–66], but early in infection only the L1 poly(A) site is found in mRNA[60,62] Early transcription does not seem to pass map unit 60 and perhaps ends between 40 and 50 (refs 60–62), whereas late transcription continues to around map unit 98 (refs 10, 11) This is equivalent to readthrough transcriptional control[37,38] As there is an enormous increase in transcription from P16 when DNA is replicated it seems likely that transcription of the same DNA molecule is

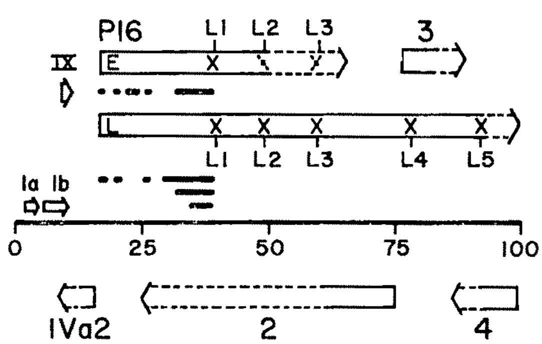

Fig 2 Features of the transcription map of adenovirus transcription units (adapted from refs 5, 6, 52, 59–63) The genome is 36 kb long, so each map unit equals 360 bases Each open bar, 1a, 1b, 1X, 3, represents a transcription unit The transcription unit P16 beginning at map position 16 is shown both early (E) and late (L) in infection The arrowheads show direction of transcription and dashed lines indicate cases where transcription proceeds beyond poly(A) sites Only for P16 are the poly(A) sites marked(X) Special prominence is given to P16 to show that early in infection, transcription definitely terminates before reaching L3, L4 and L5, the thick black lines under P16E and P16L indicate the different regions retained after splicing in early and late L1 mRNAs

not terminated in two different ways, but that one transcription unit in the adenovirus genome can have different termination sites early and late in infection

(5) Transcription of region 4 peaks early in infection and then at 4–8 h declines to ≤10% of the rate it reached by 4 h (ref 67) Protein synthesis is necessary for this programmed decline, particularly a protein from region 2 as mutations in region 2 block the decrease

SV40 transcriptional control. A specific decrease in the early transcription unit of simian virus 40 (SV40) has been documented during the later periods of infection[68] At the beginning of infection, the overall rate of transcription of SV40 is quite low and there is five times as much RNA complementary to the early transcription unit as to the late transcription unit Late in infection, after a very large increase in total SV40 RNA in infected cells, there is only 1/20th as much RNA complementary to the early transcription unit as to the late transcription unit This change in ratio of mRNAs from the two transcription units is probably due to the T antigen, the protein encoded by the early transcription unit[69] T antigen has been shown to bind three identical sites within a 100–150 base pair region that overlaps the early promoter[70,71] This binding is necessary for DNA replication[72] but also stops or slows considerably the early transcription of SV40 The effect of T antigen is specific to the early promoter as transcription of recombinant DNA molecules, in which the adenovirus major late promoter has been inserted no more than 50 bases away from the early SV40 promoter, is unaffected by the *in vitro* binding of the T antigen to the SV40 promoter[71]

Hormone-induced increases in transcription. Many proteins in differentiated cells are known to be produced in increased amounts in tissues stimulated by the appropriate hormone Transcription in isolated nuclei shows that this stimulation is due, at least mainly, to transcriptional control

One example is the stimulation of production of egg white proteins in the chicken oviduct by oestrogen cDNA clones to the egg white proteins ovalbumin[73,74], conalbumin[74] and ovomucoid[75] all hybridize 10–50-fold more labelled nuclear RNA from the nuclei of hormone-treated chick oviduct epithelial cells than from control cells Nuclei from other tissues such as liver or spleen do not make labelled RNA complementary to ovalbumin or ovomucoid cDNA Maintenance of a high level of transcription in the oviduct requires continuous hormone treatment

Liver cells of roosters also respond to oestrogen treatment by producing vitellogenin and very low density lipoprotein (VLDL)[76,77] The cDNAs corresponding to these mRNAs detect a greatly increased rate (>50-fold) of RNA synthesis in chromatin fraction (lysed nuclei) from treated compared with untreated animals Thus increased transcription of specific genes by steroid hormones seems well established

In addition to these cases of cell genes, RNA synthesis from the integrated mammary tumour virus DNA also is increased by oestrogens[29]

Transcriptional control of chick globin. For the first few days after fertilization, chick embryos synthesize embryonic forms of α- and β-globin Later on adult forms of the two globins are synthesized The same cell does not differentiate first to form embryonic and then an adult globin Rather, erythroblastic cells choose one of the two pathways[78,79] Genomic DNA clones have been used to show that isolated nuclei from 5- or 12-day-old embryos produced labelled RNA complementary only to embryonic or adult globin DNA respectively Thus the differential expression of these two forms of chick globin appears to be controlled at the level of transcription

Liver-specific transcriptional control. A series of cDNA clones prepared from mouse liver mRNA were screened to select mRNA sequences present in many cell types ('common' mRNAs) and mRNA sequences present only or mainly in liver[46] Nuclei from liver cells, cultured undifferentiated cells and brain cells were then used to prepare labelled nascent RNA All 11 liver-specific mRNA sequences were labelled in liver nuclei but not in brain or cultured cell nuclei Sequences complementary to the common cDNA clones were labelled in all nuclei As the clones used in the test represented mRNAs that ranged from ~100 to >10,000 copies per cell, it seems that, in general, specific mRNAs in liver cells are controlled transcriptionally A further experiment with liver nuclei reveals a specific case of changing transcriptional controls Adult male mice excrete a protein in urine, the major urinary protein (MUP), which is not excreted by newborn mice[80] Liver nuclei from adult and newborn animals were used to score transcription of MUP genes The adult nuclei synthesized at least 100-fold more MUP-specific RNA than did the nuclei from the livers of newborns[81]

Transcriptional control by choice of initiation sites. More of the same α-amylase enzyme protein is produced in rat salivary glands than in liver When the cDNAs complementary to α-amylase mRNA from the two tissues were sequenced, the 5′ nucleotides of the two mRNAs were found to differ while the remainder of the mRNA chains were identical[82] Examination of genomic DNA[83] and nulcear RNA (U Schibler, personal communication) revealed that the cap sites for the two amylase mRNAs lie ~2 8 kilobases apart but the two overlapping transcription units cover the same protein coding region and the same poly(A) site(s) This necessitates a different splice to join the two different cap and leader sequences to the same mRNA 'body' However, as cap sites always seem to be start sites for RNA synthesis[4,23–26], α-amylase production would appear to be controlled by selecting specific transcriptional start sites Different overlapping transcription units in adenovirus (1b and protein IX, and region 3 and P16) are also regulated by choosing the proper start sites (ref 41, Fig 3), as are the induced and constitutive forms of yeast invertase[151]

Transcriptional control dependent on DNA rearrangement. Such interest has attended the possibility that rearrangements affect gene control that the proved examples of such rearrangements must at least be mentioned Immunoglobulin formation, the variation in surface glycoproteins of trypanosomes, switching of the yeast mating-type locus and promoter insertion brought about by retrovirus movement in chromosomes all appear to be cases where gene activation, probably transcriptional activation, depends on DNA rearrangement Actual transcriptional rate studies have not been done in most of these cases (see ref 84)

RNA processing and its control

Although transcriptional control may be the predominant level of gene control, it is not the only one To help understand post-transcriptional control, it is best first to consider more fully the steps in mRNA manufacture (see Fig 1)

The sequence of events that convert a primary RNA transcript to a mRNA are collectively known as 'RNA processing' These events begin very soon after initiation of an RNA chain Before the new RNA chain is longer than 50 nucleotides[34,85], and perhaps before the RNA polymerase II moves past the initiation site, a 'cap', a m^7Gp residue[7], is added to the first nucleotide (N) The middle phosphate of the m^7GpppN cap structure is not derived from the GTP but from the pppN that starts the RNA chain[86–88], strong evidence of RNA chain initiation at the cap site Few, if any, polymerase II products escape this 5′ end addition, even prematurely terminated RNA chains[33,34,85] and chains synthesized *in vitro* by cell extracts supplemented with RNA polymerase II[25] are capped

The poly(A) segment is added post-transcriptionally to heterogeneous nuclear RNA (hnRNA) in the cell nucleaus[8,9,20] Although the precision of termination sites is not yet understood for polymerase II transcription, the enzyme has been shown to transcribe past the site for poly(A) addition in at least three adenovirus transcription units[1,10–12], both early and late SV40 (refs 13, 94) and polyoma transcription units[95,96], the β-globin transcription unit in mouse cells[4] and chicken cells[78,79], and probably the transcription unit for the heavy chains of immunoglobulins[97–99] No clear cases of termination at the poly(A) site

have been documented by studying briefly labelled nuclear RNA Thus addition of poly(A) may always require endonucleolytic cleavage and terminal addition of poly(A) to the cleaved 3′ end of a nuclear RNA molecule At least part of the signal for poly(A) addition is the AAUAAA sequence found 10–25 bases upstream from the poly(A) addition site[100 101]

Poly(A) addition usually, if not always, precedes in time the final, splicing[15–17] steps of mRNA processing[10 102–104] Splicing, however, can occur in the absence of poly(A) addition[105] and mRNA formed during inhibition of poly(A) synthesis can at least in part enter polyribosomes[106], although it does not accumulate there as stable mRNA These recent results suggest that the major (or perhaps sole) role of the poly(A) is cytoplasmic stabilization of the mRNA[106–108] and that splicing for most transcripts might be an automatic event Methylation of mRNA[7], which is known to occur (on the average) to 1 out of 400 Ap residues in mammalian mRNAs[109–111], may occur before splicing, but its timing and role in mRNA formation remain speculative[111] Finally mRNAs leave the nucleus and enter the cytoplasm still bearing their poly(A) segment[8 19] With time, the poly(A) tail shortens[8], which causes some mRNA sequences, >90% of which initially partition experimentally in the poly(A)-containing fraction, to fractionate in the poly(A)-lacking fraction[92 93] Extensive attempts with sea urchin material have failed to isolate any cloned DNA segment complementary to the mRNA molecules of the latter fraction that are not also present in the poly(A)-containing fraction (M Nemer, personal communication) other than histone mRNA[89]

Transcription unit design and differential processing. Two categories of transcription units can be identified (Fig 3) (1) Simple transcription units encode a single protein, whether or not processing of the primary transcript is required Histone genes are simple transcription units that do not, in most cases, require either poly(A) addition or splicing[90] Protein IX mRNA of adenovirus[112] and the α-interferon mRNAs[113] derive from simple transcriptional units whose products have poly(A) added but do not require splicing The α- and β-globin transcription units are simple because, although their primary transcripts require poly(A) addition and splicing, only one functional mRNA is formed from the transcription unit[114 115]

(2) Complex transcription units are those whose primary transcript can give rise to two or more mRNAs that encode two different proteins Two different structural arrangements are known for these units two or more poly(A) sites and two or more variations in splicing patterns Both virus and cell transcription units with multiple poly(A) sites are known—the major late adenovirus transcription unit[10 63–65], the heavy chains of immunoglobulins[97–99] and the transcription unit encoding the peptide hormone calcitonin (R Evans and G Rosenfeld, personal communication) Thus far only virus transcription units are known that have one poly(A) site and two or more splicing sites—both transcription units of SV40 (refs 94, 117) and polyoma[95 118], most of the nine known adenovirus transcription units[16 58 116 119] and many different retroviruses[120] A number of virus transcription units with multiple splicing arrangements can be integrated into cell DNA and still produce multiple mRNAs Thus, it is clearly possible for DNA in the cell genome to encode primary transcripts that can be spliced in alternative ways (Transcription units can have two or more poly(A) sites and variable splicing at one or both poly(A) sites, such as in the major late adenovirus transcription unit, Fig 2)

From these two types of complex transcription unit follow two general types of processing control[5] (1) Differential processing each transcript from a complex transcription unit must be processed in one of two or more ways Several cases are known in which various poly(A) sites or splice sites can be chosen on the same primary transcript (2) Process versus discard decisions In this hypothetical possibility, there would be little or no processing of a particular transcript in one cell type or a cell in one particular physiological condition but successful processing of the same primary transcript in another cell type or another physiological condition (reviewed in ref 5) Candidate transcripts of this type do exist in cultured cells and probably also in tissues but no specific case of gene control through process versus discard decisions is yet proved

Adenovirus processing control. A differential choice of both poly(A) and splicing sites has been documented in the primary transcript of adenovirus mRNA, P16 (major late promoter, Fig 2) Differential choice of poly(A) sites is also suspected to occur in at least one other transcription unit (region 2 transcripts that lead to mRNA formation with sequences in the 20–30 map unit region)[58 121]

Early in infection, in transcripts beginning at P16, the poly(A) sites at both 38 5 (L1) and 50 (L2) map units are used to generate poly(A)-containing nuclear RNA[59–61] About two L1 molecules are produced for each L2 Late in infection, in addition to the whole transcription unit being transcribed and the L1–5 being available for use, a change occurs so that L2 is used about twice as often as L1 (ref 10) This change in ratio of poly(A) site usage accords with the change in amount of L1 versus L2 mRNAs in the cell nucleus Late in infection, when five poly(A) sites are available, L3 is more frequently chosen than any other site but the ratio of L1–5 remains at 1 2 3 2 2 throughout the late course of infection (ref 10 and J R Nevins, unpublished)

In addition to differential poly(A) choices, the early splicing pattern is different from the late one in the L1 poly(A)$^+$ nuclear molecules Examination of nuclear RNA indicates clearly that three products are made late in infection but only one major product early in infection[60] In addition, the initially labelled cytoplasmic molecules late in infection contain all three species of L1 mRNA whereas early in infection only a single species of labelled mRNA emerges in the cytoplasm after a brief label[60] Finally, the protein translated from the early L1 mRNA is encoded mainly, if not exclusively, in the 400 nucleotides that are retained in early L1 mRNA but are lost in the late mRNA[61] Thus the evidence seems very strong that a change in splicing takes place in the handling of the same sequence of nucleotides contained in the nuclear poly(A)$^+$ precursor molecule that is encoded in the 16–38 5 region on the adenovirus genome

Immunoglobulin mRNA formation. Only two cases of differential processing are known for cellular mRNAs During B-lymphocyte development and immunoglobulin synthesis, the μ heavy chain is first inserted as an integral protein in the plasma membrane[97–99] Later a similar μ chain is found as part of secreted immunoglobulins Analysis of cDNA clones of the two

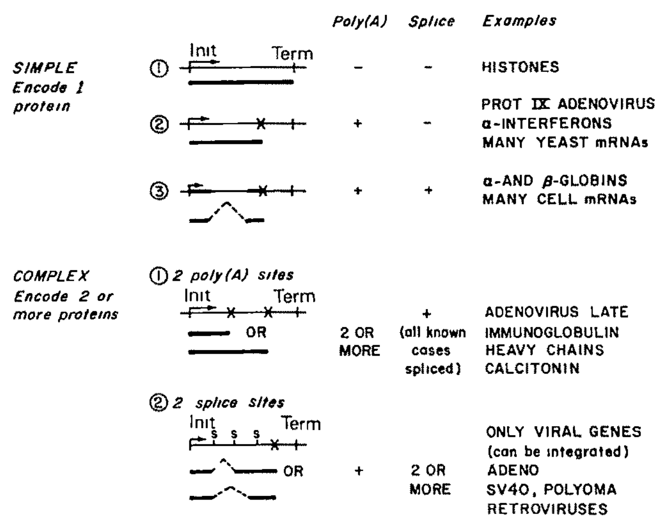

Fig. 3 Definition and examples of simple and complex transcription units In each case, DNA is shown at the top and the mRNA(s) underneath On the former are indicated sites of initiation (INIT) and termination (TERM) of transcription, splicing sites (s) and the position of the sequence which will become the site of poly(A) addition to the processed transcript

mRNAs showed that the deduced carboxyl terminus of the μ membrane and μ secreted chains was different but the deduced amino termini were the same Analysis of the genomic cloned DNA revealed two poly(A) sites in the same transcription unit and the primary transcript seems to cover both of them (ref 97 and R Wall, personal communication) Depending on the choice of poly(A) site two μ heavy chain mRNAs with different 5′ most sequences can be formed, one for the μ membrane chain and one for the μ secreted chain Further studies suggest that the same five exonic regions common to both μ chains also appear in δ chains[99] In this case, the 3′ exonic component of the μ mRNA may be a consequence of choosing a poly(A) site more than 25 kb downstream These studies were carried out on lymphocytic tumour cells in culture, but it is thought that a similar set of events occurs in the normal differentiation sequence in B cells

Note that the molecular basis for none of these presumed differential choices of poly(A) and splice sites is known and it remains possible that template changes may dictate the post-transcriptional outcome For example, rather than there being a single completed transcript in which a poly(A) site is chosen, a selective protein that bound to the DNA at one or the other poly(A) site might instead trigger the choice of poly(A) site during transcription

Process versus discard decisions. Differential processing of nuclear RNA from either simple or complex transcription units might include the processing or discard of a particular nuclear RNA sequence[5 18–20] This type of processing is different from differential poly(A) choices or differential splicing choices where a transcript has a high probability of yielding one or another mRNA[10] Although there is no evidence of variable process versus discard between two different cells, nuclear RNA turnover is substantial[122] and nuclear RNA 'complexity' (average nucleotide content) is some 10–20 times greater than the complexity of the mRNA[123], perhaps greater than the difference expected on the basis of intron loss during nuclear RNA processing

More recent analyses of nuclear RNA in cultured cells divide the nuclear RNA primary transcripts into two classes—those that produce mRNA sequences and those that do not While all transcripts contain a cap[34] and >90% of newly capped mRNAs that enter polyribosomes (excluding histone mRNAs) contain poly(A)[42 91], poly(A) is added in the nucleus only to about one-quarter of the total primary transcripts[91] Thus the rate of synthesis of caps is about four times that of poly(A) Moreover, when sequences complementary to eight cloned CHO cDNAs were examined in the poly(A)$^+$ and poly(A)$^-$ nuclear RNA fractions[24 42], whereas 70% of the sequences complementary to these clones were in the poly(A)$^+$ fraction, only 20–25% of the capped molecules were in the poly(A)$^+$ fraction It therefore seems that capped poly(A)$^-$ molecules whose sequences are not part of stable mRNAs make up a significant part of the nuclear RNA in cultured cells Can these primary transcripts at some other time and place (embryonic cells? specifically differentiated cells?) be shifted from the poly(A)$^-$ to the poly(A)$^+$ category and then appear as stable mRNA[5 20 125]? Specific clones complementary to these 'nucleus-confined' RNAs molecules are necessary to answer this possibility

Cytoplasmic gene control

Too little is known about nuclear RNA transport to suggest the existence of differential transport After the mRNA has reached the cytoplasm, however, the fates of mRNA molecules differ Evidence exists for both a wide range of half lives for different specific mRNAs in the same cells[62 92] and different half lives for the same mRNA in the same cell under different circumstances

Of these possible control mechanisms the first would, of course, allow the cell to accumulate differential concentrations of two different mRNAs although the synthesis rates of the two were identical, but its physiological significance remains obscure Changes in the half life of specific mRNAs under different circumstances has attracted more attention Two cases involving hormones are well documented

Breast tissue can be explanted and continue to respond to hormonal stimulation by the production of casein mRNA and casein protein[126] When explants are cultured without prolactin for 48 h they lose 95% of their casein mRNA but can, when given prolactin, accumulate about 25,000 copies of the casein mRNA in 24 h This accumulation is associated with an ~20-fold increase in the mRNA half life, but only a two- to threefold increase in the synthesis of casein mRNA sequences assayed by hybridization to casein cDNA

A second reported instance of mRNA stabilization occurs with oestrogen treatment of roosters[76,77] As described earlier, mRNA sequences, for both VLDL and vitellogenin are synthesized at least 20–100-fold faster in liver nuclei from treated than from untreated animals The rate of mRNA accumulation is maximal within about 6–8 h and from the curve of accumulation of vitellogenin and VLDL mRNAs during the first week of oestrogen treatment a half life of >24 h can be calculated If, after the mRNA has reached a plateau value, the oestrogen is abruptly withdrawn, the vitellogenin and VLDL mRNA decline with a half life of ~3 h Thus the half life changes from 24 to 3 h by removal of the hormone Calculations of similar hormone-dependent changes in half life for steriod-induced hormones have also been reported[127], although the changing steroid levels were not so carefully controlled

Differential half life of specific mRNAs also occurs during the growth cycle of adenovirus[62] Transcriptional unit 1B produces two mRNAs—one 20S and one 14S Early in infection the 20S form predominates while late in infection the 14S is predominant[129] The transcription rate of 1B sequences is constant from 5 to 24 h of infection[62] When labelled nuclear RNA was examined early and late in infection no changes were noted, suggesting that differential splicing was not occurring[62] However, cytoplasmic accumulations of 14S relative to 20S was greater late in infection than early in infection, pointing to an increased half life of the 14S mRNA This mRNA appears to have the same cap site, the same splicing and poly(A) sites late in infection as it does early and thus the same mRNA has a different half life at two different times in the infectious cycle

Finally, there are two established cases (and many others suspected) where preservation of a specific group of mRNAs occurs in the face of destruction of a large fraction of total cell mRNA[130–132] During erythroblast differentiation in mammals, the developing cell makes many different mRNAs including, in the final stages, globin mRNA Globin RNA synthesis,

Table 1 Summary of frequency of various types of control

Nuclear	Examples proved or strongly suggested	Possible
Transcriptional		
Initiation	Many, >100	
Termination		
Premature (attenuation) readthrough	1	+
Nuclear RNA processing		
Poly(A) choice	~3	
Splicing choice	1	
Process versus discard		+
Cytoplasmic		
mRNA stability	~5 Specific, many general	
mRNA translation efficiency	~10 Specific, many general	

For those cases of control where only one or a few cases are proved, it is anticipated that these numbers will increase It is not possible at present to even guess at the true frequency with which various mechanisms will be found ultimately to be used

however, represents a tiny fraction of total nuclear RNA synthesis During the final four or so cell divisions the cell becomes a highly specialized reticulocyte synthesizing over 90% globin plus a limited number of other specific proteins These differentiative steps appear to represent conservation of the globin (and a few other erythrocytic) mRNAs and specific destruction of all other mRNAs[130–132] A second case of specific mRNA destruction has been described during development of the slime mould *Dictyostelium discoideum* Cells which have aggregated will, if left alone, form a stalk, fruiting bodies and spores This is accomplished with the aid of a set of new RNAs formed after aggregation If the developmental cycle is interrupted after aggregation, the new developmentally regulated mRNAs are specifically destroyed[133]

Control of translation

Differential translation of finished mRNA molecules that are apparently already in the cell cytoplasm is recognized early in embryonic development, both for the average rate of protein synthesis per ribosome and for specific protein species Unfertilized sea urchin eggs become at least 50-fold more active in protein synthesis from the same number of mRNAs after fertilization than before[4] By contrast, in clam eggs the total rate of protein synthesis is unchanged after fertilization, however two-dimensional gel analysis of proteins newly formed *in vitro* compared with translation *in vitro* reveals certain proteins are formed specifically only pre- or post-fertilization[135] although the mRNAs are present

Major shifts in total protein synthesis have also been recognized in non-embryonic cells Cultured mammalian cells[136,137] and insect cells[138] decrease total protein synthesis after a heat shock while the translation of certain 'heat-shock' proteins is probably enhanced Cultured mammalian cells undergo a three-fold decrease in protein synthesis during each mitosis[139], and in virus-infected cells the synthesis of host proteins can be interrupted in several different ways although the mRNA is still present[140–142] It is also possible[143], though unproved, that tissue-specific favouritism for the translation of specific mRNAs or classes of mRNA occurs

Control after translation

Several types of post-translational control can be envisioned that would affect the final concentration of particular proteins in given cells For example, as polypeptides exist that can be cut by proteases into different, overlapping polypeptides with different activities, control of proteolysis represents a possible level of gene control This apparently occurs in the posterior pituitary where cells can produce either adrenocorticotropin or β-lipotropin presumably from the same primary translation product[144,145]

Different fates for the same polypeptide, such as differential protein turnover or differential prosthetic group additions, could obviously alter the enzymatic profile of a particular cell Whether such differential post-translational events occur or are common remains to be explored

Conclusion

The evidence summarized in this article demonstrates that a variety of mechanisms determine the abundance of specific mRNAs in eukaryotic cells, with the major level of control usually being transcription in the cell nucleus Although the mechanism of the specific increases or decreases in transcription is not the subject of this review, it is widely believed that site-specific binding proteins either change chromatin structure or directly facilitate or prevent RNA polymerase attachment at specific sites on the DNA[21] Only a few cases of supposed transcriptionally active proteins are known in vertebrate cells or virus-infected cells but quite a number of regulatory loci in lower eukaryotes, for example yeast, are now identified genetically (see, for example, refs 146–148) As yeasts have mRNAs with short half lives[149], most regulation of their rates of protein synthesis is probably due to controlled rates of transcription Progress in the isolation of specific, transcriptionally active proteins in yeasts can be expected soon

In addition to transcriptional initiation, a change in termination has apparently been identified in one adenovirus transcription unit It is unknown whether differential termination will be a common mechanism for regulation of transcription, although evidence of frequent premature terminations[33,34] is tantalizing in this regard Note that transcriptional control for a particular gene does not preclude other levels of control

The second level of nuclear gene control is processing It is now clear that differential poly(A) choices and differential splicing can occur, but if a transcription unit has only one poly(A) site and only one possible spliced mRNA, then differential processing of the primary transcripts cannot occur Of great importance is the possibility of process versus discard control (Cloning of poly(A)$^-$ primary transcripts from one cell source will be necessary to determine whether such transcripts ever become poly(A)$^+$ transcripts in other cells)

Differential mRNA turnover seems fairly common as even at this early stage in the study of specific cell mRNAs, several clear-cut cases of differential turnover are known

Although multiple levels of gene control seem to exist, we are almost completely ignorant of the logic of gene control systems in eukaryotic cells or even whether most genes are ever subject to specific control Regulation at transcription would appear for many genes to be quite strict, regulation of mRNA turnover, in contrast, is probably much less strict What might distinguish genes that are tightly regulated from those that are not remains unknown Finally the mechanisms and molecules that execute the various types of control remain unknown Perhaps only by examining these regulatory molecules will the molecular logic of eukaryotic gene regulation become clear

Implications for trace gases and aerosols of large negative ion clusters in the stratosphere

F. Arnold, A. A. Viggiano & H. Schlager

Max-Planck-Institut fur Kernphysik, Heidelberg, FRG

Stratospheric ions are of considerable interest because they not only control atmospheric electrical properties but also may influence stratospheric trace gases and aerosols The first detailed in situ *composition measurements of the stratospheric heavy negative ion clusters are now reported, these measurements have interesting implications for trace gases and aerosols*

IN SITU composition measurements of stratospheric ions became technically possible only during recent years As found from the first *in situ* negative ion composition measurements[1,2], stratospheric sulphuric acid vapour has a strong influence on stratospheric negative ions Thus, because H_2SO_4 vapour is the most important condensable vapour in the stratosphere, and influences the formation of the stratospheric aerosol layer[3], negative ion composition measurements can also yield information on aerosols In particular $HSO_4^-(H_2SO_4)_b(HNO_3)_c$ ions have been found[4] to be abundant at altitudes above ~27 km, whereas $NO_3^-(HNO_3)_a$ ions are dominant below this height It has been proposed[1] that the former ions are formed from the latter ones by reactions involving H_2SO_4 vapour followed by H_2SO_4-association This suggestion has received strong support

0028-0836/82/220371—06$01 00

from studies of relevant ion reactions conducted by Viggiano *et al*[5] Attention has also been drawn[6] to the possibility of inferring stratospheric H_2SO_4-vapour concentrations from *in situ* negative ion composition measurements

Recent *in situ* negative ion composition measurements conducted by the Heidelberg[7–9] and Bruxelles[10] groups confirmed the original suggestions, but also provided strong evidence for the presence of very massive negative ion clusters in the region above 27 km In fact, it appears that most negative ions fall outside the mass range ($\leq$320 AMU), accessible to previous *in situ* ion composition measurements in which mass resolving modes of operation were used The so called 'total throughput modes' allowed detection of heavy negative ion clusters without yielding detailed mass information We have investigated large negative ion clusters in the stratosphere and their bearing on aerosol formation[11,12] Our detailed *in situ* measurements are given below

Negative ion composition measurements

The principle of the balloon-borne ion mass spectrometer used in the present studies has been discussed in detail elsewhere[1,4,12] and therefore will not be reviewed here Note, however, that the present instrument has an extended mass range covering 0–612 AMU, which was achieved by reducing the frequency of the R F -generator of the quadrupole mass filter from 2 0 to 1 4 MHz

The improved instrument was flown on a balloon during daytime on 17 October 1981 over southwestern France (geographical coordinates of the measuring site 44° N, 0° W) and reached a maximum altitude of 34 km The composition measurements of heavy negative ions were made between 32 and 34 km during the ascent and float portions of the balloon flight between 09 24 and 09 47 LT

Typical negative ion mass spectra obtained in this height region are shown in Fig 1 The mass resolution used was only

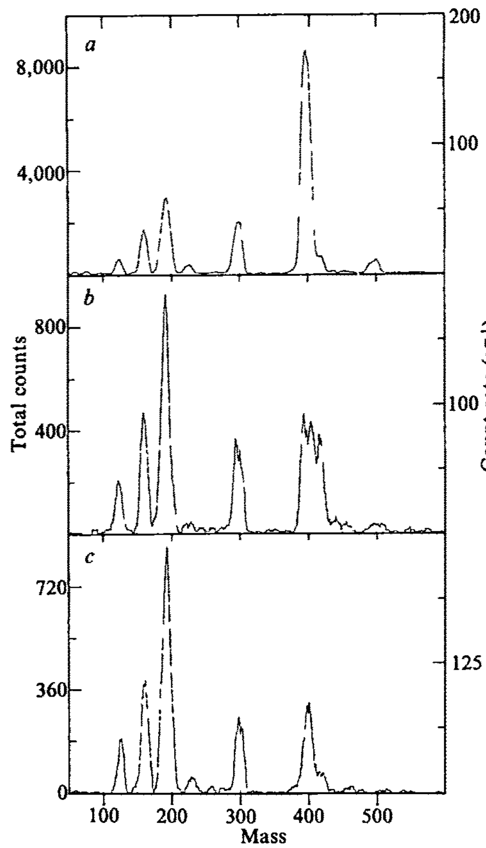

Fig 1 Negative ion mass spectra measured at altitudes of 34 (*a*), 32 9 (*b*) and 32 4 (*c*) km Total integration times were 1,000, 140 and 100 s A running window of 51 channels was used to improve statistics

moderate (average peak width at half maximum equal to about 14 AMU) to achieve a high sensitivity for ion detection, particularly at large masses Due to the large peak width, masking of small peaks may have occurred The estimated uncertainty for mass identification is about ±1 AMU large peaks and ±2 or 3 AMU for smaller peaks depending on the ion pulse statistics, which, in turn, depend on the integration time Due to a much larger integration time, the peaks of the spectrum obtained at 34 km (float altitude) have much better defined shapes

Results for the spectral region 0–320 AMU are rather similar to those obtained previously[1,2,4,7,10] Therefore, we will focus on the mass region 320–612 amu, which was not previously accessible

Clearly, this region contains major peaks, which is particularly striking in Fig 1*a*, where the dominant mass peak is 391±1 A compilation of the observed peaks is given in Table 1 together with fractional count rates and tentative ion identifications No attempt has been made to convert ion count rates to ion abundances as this conversion is complicated by cluster ion break-up that occurs during ion sampling As has been discussed previously[4], break-up should not drastically alter the ion composition at these heights However, cluster ions may have lost one weakly bonded ligand molecule during sampling

Negative ion chemistry

Table 1 reveals that the major heavy ions have HSO_4^- cores containing mainly H_2SO_4 ligands Size distributions for these ions are shown in Fig 2 The distributions are relatively flat up to $b=3$ (b is the number of ligands) and fall off steeply for larger b Most likely, these ions are formed by

$$NO_3^-(HNO_3)_a + H_2SO_4 \rightarrow HSO_4^-(HNO_3)_a + HNO_3 \quad (1)$$

followed by further displacement of HNO_3 by H_2SO_4 and finally H_2SO_4 association As b increases the thermal dissociation process

$$HSO_4^-(H_2SO_4)_b + M \rightarrow HSO_4^-(H_2SO_4)_{b-1} + H_2SO_4 + M \quad (2)$$

becomes important and leads to the observed fall-off of the size distribution

The predicted size distribution can be obtained from a steady-state treatment yielding

$$\frac{[HSO_4^-(H_2SO_4)_{b+1}]}{[HSO_4^-(H_2SO_4)_b]} = \left(1+\frac{\alpha n_+}{k_+[M][H_2SO_4]}+\frac{k[M]}{k_+[M][H_2SO_4]}\right]^{-1} \quad (3)$$

where k_+, k and α are the rate coefficients for ternary H_2SO_4-association, thermal dissociation and ion–ion recombination, respectively The quantities $[M]$ and n_+ are the total gas and positive ion concentrations Taking the phenomenological binary rate coefficient, $k_2=k_+[M]$, for H_2SO_4-association equal to 10^{-9} cm^3 s^{-1} (saturated ternary process) and a sulphuric acid vapour concentration $[H_2SO_4]=3\times10^6$ cm^{-3} (derived from the abundance ratio of measured HSO_4^- and NO_3^--ion clusters using the method described in ref 6) one finds that the second term on the right-hand side of equation (3) becomes $\ll 1$ Consequently, if H_2SO_4-association proceeds close to the collision rate, as expected, the ion abundance ratio (3) becomes $\simeq 1$ when thermal dissociation is negligible As seen from Fig 2, this seems approximately to be the case for b up to 2–3 When thermal dissociation becomes very efficient, the third term on the right-hand side of equation (3) becomes dominant and the predicted ion abundance ratio becomes $\ll 1$ This seems to be the case for $b \geq 3$

From Table 1, one sees that there are less abundant heavy ions containing HNO_3, H_2O and probably HSO_3 ligands While H_2O and HNO_3 ligands were expected, the presence of HSO_3 ligands comes as a surprise H_2O, HNO_3 and HSO_3 probably associate to the negative ion clusters and are lost by thermal dissociation, displacement by more strongly bonded ligands or

Table 1 Mass numbers of major negative ions as measured at 32 5, 32 9 and 34 0 km altitude

Mass	Fraction 006	Ion
62±2	0 006	NO_3^-
125±1	0 065	NO_3^- HNO_3
143±2	0 009	NO_3^- HNO_3 H_2O

178±2	0 020	HSO_4^- HNO_3 H_2O
188±1	0 190	$NO_3^-(HNO_3)_2$
195±3	0 100	HSO_4^- H_2SO_4
223±1	0 018	$HSO_4^-(HNO_3)_2$
251±2	0 003	$NO_3^-(HNO_3)_3$
276±3	0 010	$HSO_4^-H_2SO_4$ HSO_3
293±1	0 120	$HSO_4^-(H_2SO_4)_2$
311±3	0 003	$HSO_4^-(H_2SO_4)_2H_2O$
374±3	0 003	$HSO_4^-(H_2SO_4)_2HSO_3$
391±2	0 140	$HSO_4^-(H_2SO_4)_3$
409±3	0 130	$HSO_4^-(H_2SO_4)_3H_2O$
427±3	0 022	$HSO_4^-(H_2SO_4)_3(H_2O)_2$
454±2	0 015	$HSO_4^-(H_2SO_4)_3HNO_3$
472±3	0 004	$HSO_4^-(H_2SO_4)_3HSO_3$
489±3	0 012	$HSO_4^-(H_2SO_4)_4$
507±3	0 015	$HSO_4^-(H_2SO_4)_4H_2O$
587±3	0 004	$HSO_4^-(H_2SO_4)_5$

Tentative ion identifications and fractional ion count rates for the 32 9 km spectrum are given

possibly by reactions The mass identity of the ligand we identify as HSO_3, however, does not exclude other possibilities For example, the mass of an HNO_3 and H_2O molecule added together (81 AMU) is the same as that of HSO_3 The relative abundances of the ions $HSO_4^-(H_2SO_4)_nH_2O$, $HSO_4^-(H_2SO_4)_nHNO_3$ and $HSO_4^-(H_2SO_4)_n$ 81, however, leads one to believe that mass 81 corresponds to only one ligand HSO_3 is then the most likely candidate for this ligand because it is the only acid of this mass to be expected in the atmosphere and acids are the preferred negative ion ligands[1,2 4]

Because both, H_2O and HNO_3 are relatively abundant stratospheric trace gases (approximate number densities are 10^{12} cm^{-3} and 10^8 cm^{-3}, respectively, at 30 km altitude), they associate rapidly to the negative ion clusters However, both molecular species probably do not bond very strongly to the larger ion clusters and, therefore, may undergo rapid thermal detachment or displacement by more strongly bonded ligands, such as H_2SO_4 The ligand bond strength seems to increase in the sequence H_2O, HNO_3, H_2SO_4 for the cluster ion sizes considered here

Measured abundance ratios for hydrate ions to their corresponding unhydrated forms are given in Table 2 Generally, the ratios decrease as the size of the unhydrated ion increases, in qualitative harmony with a simple charge–dipole interaction model However, for $HSO_4^-(H_2SO_4)_b$ clusters, the ratios increase as b becomes >2 This behaviour, which as yet has not been observed for cluster ions, probably indicates strong cooperative bonding In other words, ligand–ligand interaction seems to become important In view of the large heat of mixing for bulk phase H_2SO_4–H_2O mixtures, this finding may qualitatively be expected Quantitatively, however, it is surprising that cooperative effects become important already for relatively small ion cluster sizes

The probable detection of HSO_3-ligands indicates that HSO_3-vapour is present in the stratosphere and associates to the negative ion clusters

This view is supported by recent high pressure ion source studies made at our laboratory[13] It was found that besides $HSO_4^-(H_2SO_4)_b$, clusters of the type $HSO_4^-(H_2SO_4)_b$ HSO_3 were most abundant in a gas mixture of SO_2 and room air (mostly N_2, O_2, and H_2O) ionized by a gas discharge The HSO_3-ligand evidently bonds relatively strongly to $HSO_4^-(H_2SO_4)_b$ ion clusters This is also supported by collision-induced fragmentation studies of $HSO_4^-(H_2SO_4)_bHSO_3$ ions

The fate of stratospheric HSO_3-ligands is, however, uncertain They may detach thermally, become displaced by H_2SO_4, or undergo chemical reactions The latter processes may involve reactions with OH-radicals

$$HSO_4^-(H_2SO_4)_bHSO_3 + OH \rightarrow HSO_4^-(H_2SO_4)_b + SO_3 + H_2O \quad (4a)$$

$$\rightarrow HSO_4^-(H_2SO_4)_b \; H_2O + SO_3 \quad (4b)$$

$$\rightarrow HSO_4^-(H_2SO_4)_b + H_2SO_4 \quad (4c)$$

$$\rightarrow HSO_4^-(H_2SO_4)_{b+1} \quad (4d)$$

In process (4*d*) another ligand, for example H_2O, also contained in the precursor ion complex may become 'boiled off' carrying away the chemical energy released

Processes (4*a*–*d*) would represent 'ion catalysed reactions'[17]

Inferred HSO₃-abundance

Although the HSO_3-radical has not yet been detected in the stratosphere, its presence is expected It is thought[3 14,15] that HSO_3 arises from

$$SO_2 + OH + M \rightarrow HSO_3 + M \quad (5)$$

and is lost preferentially by

$$HSO_3 + OH \rightarrow SO_3 + M \quad (6)$$

whose rate coefficient is not known The SO_3 radical is then presumed to react with H_2O to form H_2SO_4 Within the framework of their complex photochemical–diffusive model, Turco *et al* have calculated the stratospheric HSO_3 abundance, yielding ~10^5 cm^{-3} at 30 km altitude

From the ion composition data reported above, a lower limit to the HSO_3 abundance can be inferred Assuming that $HSO_4^-(H_2SO_4)_bHSO_3$ ions are formed by HSO_3-association proceeding at the collision rate and that they are lost only by ion–ion recombination a steady-state treatment yields a lower limit of $[HSO_3] = (2–10) \times 10^4$ cm^{-3} When compared with this inferred value, the model calculation of Turco *et al* are in approximate agreement

As the model assumed reaction (6) to proceed at the collision rate (rate coefficient 10^{-11} cm^2 s^{-1}) the above agreement may imply that reaction (6) is in fact fast The HSO_3-lifetime compared with attachment to negative ions is ~10 times larger than the lifetime compared with reaction (6) if upper limits to the corresponding rate coefficients are used (ref 16, and personal communications from D Smith, N G Adams and E Alge, and P J Crutzen) Consequently, the HSO_3 abundance would be of the order of 10^6 cm^{-3} at 30 km if reaction (6) was unimportant and if the HSO_3-loss would proceed by ion attachment

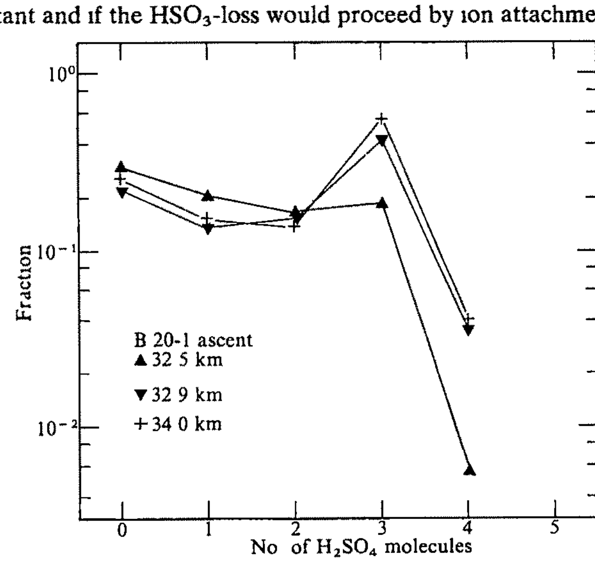

Fig. 2 Measured distributions of HSO_4^- clusters containing 0–5 H_2SO_4-ligands Count rates were normalized to the total count rates for HSO_4^- clusters

At lower altitudes, however, where the OH-abundance is lower and where the total ion concentration is larger, a significant fraction of HSO_3 may be lost by ion reactions Because, at these heights, $NO_3^-(HNO_3)_a$ ions are most abundant, another ion process involving HSO_3 may be considered It involves

$$NO_3^-(HNO_3)_a + HSO_3 \rightarrow HSO_4^-(HNO_3)_a + NO_2 \quad (7)$$

followed by recombination of $HSO_4^-(HNO_3)_a$ with a positive ion, mostly $H^+(CH_3CN)_l(H_2O)_m$ and $H^+(H_2O)_n$ possibly leading to the formation of an H_2SO_4 molecule Reaction (7) is exothermic[5 18 19] by ~40–50 kcal mol^{-1}

An important implication concerning analytical applications of *in situ* composition measurements of stratospheric negative ions is that the detection of HSO_4^- cores would not allow us unambiguously to infer H_2SO_4 abundances, thus the previously derived[6 8 9] H_2SO_4 abundances should be reported as H_2SO_4 and HSO_3 abundances below ~27 km Above this height, however, H_2SO_4 should be much more abundant than HSO_3 and the derived quantity should refer only to H_2SO_4 This conclusion is supported by the fact that above 27 km the negative ion clusters also contain H_2SO_4 ligands

Thermodynamic properties of ion clusters

The present ion composition data can also be used to infer unknown thermodynamic properties of large negative ion clusters

For this purpose, the concentrations of the clustering gas phase molecular species, H_2SO_4, HNO_3, HSO_3 and H_2O as well as the gas temperature have to be known Sulphuric acid concentrations were inferred independently from the negative ion composition (see above) whereas HNO_3-, HSO_3- and H_2O-concentrations were taken from model calculations The actual values used are $[H_2SO_4] = 3\times10^6\ cm^{-3}$, $[HNO_3] = 1\times10^8\ cm^{-3}$, $[HSO_3] = 1\times10^5\ cm^{-3}$, $[H_2O] = 1\times10^{12}\ cm^{-3}$ The gas temperature was measured by various radiosonde stations (CNES Meteorological Service, personal communication) in the vicinity of the balloon launch site on the day of our experiment In addition, the gas temperature can be inferred from the simultaneously measured positive ion composition with relatively high accuracy The resulting temperature for 32–34 km was consistently 233 K

The above concentrations, with the exception of $[HSO_3]$, are sufficiently large to allow for clustering time scales less than the ion–ion recombination lifetime (2,000 s) Consequently, quasi-equilibria for ion-clustering of these species should be established For HSO_3 clustering, this is not the case and therefore only lower limits to bond strengths can be inferred

First, we will examine H_2SO_4-clustering to $HSO_4^-(H_2SO_4)_b$ ions ($b = 2, 3, 4$) Equilibrium constants, K, can easily be inferred from the measured ion abundance ratios and the derived H_2SO_4 abundance The free energy difference, $\Delta G = -RT \ln K$, can then be evaluated using the measured gas temperature The resulting ΔG values are listed in Table 3 along with free enthalpy differences, $\Delta H = \Delta G + T\Delta S$, estimated by assuming a typical common entropy difference[20], ΔS, of 25 cal $mol^{-1}\ K^{-1}$

The inferred ΔG-values for H_2SO_4-clustering to $HSO_4^-(H_2SO_4)_b$ clusters with $b = 3$–4 are both about 13 kcal mol^{-1} which is comparable to the heat of vaporization for bulk phase H_2SO_4 (ref 21) (12 6 kcal mol^{-1} at 233 K) The inferred ΔG represents only a lower limit, because thermal dissociation of $HSO_4^-(H_2SO_4)_3$ does not seem to be sufficiently fast to allow for an equilibrium between $b = 2$ and 3 to be established (see Fig 2)

This result suggests that the properties of the observed heavy $HSO_4^-(H_2SO_4)_b$ clusters ($b = 4$ and 5) already exhibit a trend towards bulk phase properties Qualitatively, this may be expected as this trend is well known from laboratory studies[20 22 23] of cluster ion equilibria such as $H^+(H_2O)_n$, $NO_3^-(H_2O)_n$ and $Cl^-(SO_2)_n$ It was found that ΔH-values for clustering of a molecular species to ion approach the heat of vaporization of the molecular species as the number of ligands contained in the ion cluster increases Usually, only a few ligands (3–5) are needed to make the agreement better than 1 kcal mol^{-1}

Table 2 Ratios of measured hydrate ion abundances to their unhydrated precursors

Unhydrated species	Ratio
$NO_3^-(HNO_3)_1$	0 14
$HSO_4^-(HNO_3)_1$	0 14
$HSO_4^-(H_2SO_4)_2$	0 03
$HSO_4^-(H_2SO_4)_3$	0 92
$HSO_4^-(H_2SO_4)_4$	1 25
$HSO_4^-(H_2SO_4)_3H_2O$	0 17

Assuming that HSO_3 is indeed observed as a ligand, only lower limits to $-\Delta G$ can be inferred from the stratospheric ion composition data, as equilibrium abundances may not be reached and the concentration of HSO_3 is not easily derived These lower limits (Table 2) are comparable to the corresponding values for H_2SO_4-clustering, which suggests that the HSO_3-radical bonds strongly to HSO_4^- clusters In turn, this implies that the heat of vaporization of HSO_3 from an H_2SO_4–HSO_3 mixture should be >18 kcal mol^{-1}

Now we consider H_2O-clustering to negative ions Measured hydrate-ion distributions are given in Table 2 and corresponding ΔG and ΔH values are listed in Table 3 The extent of hydration first seems to decrease as the cluster size increases and that it increases for $HSO_4^-(H_2SO_4)_b$ clusters when $b \geq 2$ The former behaviour is known from laboratory studies[20 24] of negative ion hydrates containing H_2O-ligands only Unfortunately, no studies of mixed clusters containing H_2O- and H_2SO_4-ligands are available Qualitatively, a decrease of H_2O-bond energies with increasing cluster size should also be expected from a simple charge–dipole interaction model

Evidently, if the observed increase of ΔH for $b > 2$ is real, it reflects the occurrence of strong cooperative bonding between H_2O- and H_2SO_4-ligands When compared with the heat of vaporization for bulk phase H_2O (10 4 kcal mol^{-1}), our inferred ΔH-values for $HSO_4^-(H_2SO_4)_3(H_2O)_d$ ($d = 1, 2$) are markedly larger Qualitatively, this may be expected from bulk phase considerations, as the H_2SO_4–H_2O system has a large heat of mixing

Our inferred values for ΔH of 13–14 kcal mol^{-1} are much closer to the heat of vaporization of water from a bulk phase solution of 75% H_2SO_4 and 25% H_2O (13 kcal mol^{-1}), which is thought to be the composition of the stratospheric aerosol Additional strong support for the above interpretation comes from recent studies of negative ion hydration in our laboratory[13] where it was found that ΔG values for the hydration of the ion series $HSO_4^-(H_2SO_4)_b$, in fact, increase as b becomes >2

However, due to their small bond energies, negative ion hydrates may undergo substantial collisional dissociation while being sampled into the mass spectrometer This is supported by simulation experiments[13] in which it was found that in conditions similar to those for flight electric field-induced detachment of the weakly bonded H_2O molecules can be important But this effect should at most raise the $-\Delta G$ values by 1 kcal mol^{-1} (90% dissociation) and otherwise not significantly affect our interpretations

We now turn to HNO_3-clustering Here direct comparison with laboratory ΔH-data[20 25] can be made, at least for $NO_3^-(HNO_3)_2$ and $NO_3^-(HNO_3)_3$ and good agreement is found This supports our approach and suggests that no significant dissociation of these cluster ions occurs at the altitudes considered This does not conflict with the above remarks on H_2O dissociation because HNO_3 bonds more strongly to negative ions than does H_2O This conclusion is also supported by the observed large abundance of $H^+(H_2O)_4$ ions (bond energy

17 kcal mol^{-1}) which excludes significant dissociation of this ion Thus, for ligands with bond strengths >17 kcal mol^{-1} no significant dissociation seems to occur

Again, in the case of HNO_3 an increase in ΔG seems to occur at large cluster sizes ($HSO_4^-(H_2SO_4)_3HNO_3$) This may suggest that the heat of vaporization of HNO_3 from bulk phase H_2SO_4–HNO_3 is much higher than that for bulk phase HNO_3 which is only ~8 kcal mol^{-1} It seems, therefore, that the observed heavy HSO_4^--clusters exhibit properties which are similar to those of the bulk phase

Implications for aerosols

Our *in situ* composition measurements of stratospheric negative ions have important implications for stratospheric aerosols, concerning both their nature and their formation mechanism Because thermodynamic properties of large ion clusters seem to approach those of the corresponding bulk phase, information on the composition of aerosols may be obtained from studies of large ion clusters existing in the same environment The ion clusters studied in the present *in situ* measurements, however, are not very large and, therefore, their properties may still depart from those of the bulk phase Thus, the following discussion should be treated with caution

The largest negative ion clusters measured contain mostly H_2SO_4 and H_2O, and thus, they contain exactly the same molecular species which are thought to make up most of the stratospheric aerosol mass However, the ligand shell of the ion cluster $HSO_4^-(H_2SO_4)_3(H_2O)$, for example, contains much less water (up to about 8% by mass) than the aerosol solution droplets (about 25%) This discrepancy may be partly due to cluster ion fragmentation occurring during the measurement, but most of the discrepancy appears real

The detection of HSO_3 and the discovery that it bonds strongly to the large negative ion clusters suggests that the as yet unknown heat of vaporization of the HSO_3 radical is large, possibly comparable with that of H_2SO_4, which would imply that HSO_3 also undergoes efficient attachment to stratospheric aerosols

If HSO_3 is, indeed, a precursor of stratospheric H_2SO_4, this may imply that HSO_3 attaches to aerosol solution droplets and is then converted to H_2SO_4 by chemical reactions in the liquid phase Subsequently, H_2SO_4 may evaporate from the droplets and a condensation–evaporation equilibrium should be established according to temperature[29]

Thus, stratospheric aerosols may grow mostly by condensation of the HSO_3 radical and its hydrates rather than by H_2SO_4-condensation The possibility of HSO_3-nucleation and -condensation was originally discussed by Friend *et al*[26] their "radical nucleation" hypothesis being based on their laboratory studies of the SO_2-photooxidation

In view of the large estimated aerosol surface area density at heights below ~30 km gas phase HSO_3-radicals may therefore preferably attach to aerosols rather than attaching to ions or reacting with OH

At 20 km, for example, the estimated HSO_3-lifetimes against these processes are about 2×10^4 s, 7×10^4 s and 10^5 s At higher altitudes where the aerosol abundance decreases and where OH becomes more abundant, gas phase HSO_3 may preferably react with OH

Another implication of the present ion composition measurements concerns polyion nucleation It has been proposed[11] that the coagulation of large positive and negative ion clusters may lead to polyions or multi-ion complexes, which, in turn, may grow to the size of condensation nuclei The first step in polyion-formation is the formation of a stable ion pair by recombination of a negative and a positive cluster ion To prevent spontaneous neutralization and thereby destruction of the ion pair, the following criterion has to be fulfilled

$$S > IP - EA + E_C \qquad (8)$$

Table 3 Free energy- and enthalpy differences for ion clustering as inferred from stratospheric ion composition data (32 9 km altitude)

Ion	Ligands	$-\Delta G°$	$-\Delta H°$	$-\Delta_{lab}^{\circ}$
$HSO_4^-(H_2SO_4)_2$–H_2SO_4	3	14	19 8	
$HSO_4^-(H_2SO_4)_3$–H_2SO_4	4	13	18 5	
$HSO_4^-(H_2SO_4)_4$–H_2SO_4	5	13	18 9	
$HSO_4^-(H_2SO_4)_2$–HSO_3	3	>12	>18 0	
$NO_3^-HNO_3$–H_2O	2	7 1	12 9	
HSO_4^-–HNO_3–H_2O	2	7 2	13 0	
$HSO_4^-(H_2SO_4)_2$–H_2O	3	6 3	12 1	
$HSO_4^-(H_2SO_4)_3$–H_2O	4	8 0	13 8	
$HSO_4^-(H_2SO_4)_4$–H_2O	5	8 1	13 9	
$HSO_4^-(H_2SO_4)_3H_2O$–H_2O	5	7 2	13 0	
$NO_3^-HNO_3 - HNO_3$	2	12 6	18 4	18 3
$NO_3^-(HNO_3)_2$–HNO_3	3	10 2	16 0	16 1
$HSO_4^-HNO_3$–HNO_3	2	11 2	17 0	
$HSO_4^-(H_2SO_4)_2$–HNO_3	3	10 3	15 9	
$HSO_4^-(H_2SO_4)_3$–HNO_3	4	11 1	16 9	

Values are given in units of kcal mol^{-1} Laboratory data, if available, are also given for comparison For the derivation of ΔH as common ΔS of 25 cal mol^{-1} K^{-1} was assumed

where *IP* and *EA* are the ionization potential of the precursor neutral of the positive ion core and the electron affinity of the precursor neutral of the negative ion core E_C is the energy released on formation of a chemical bond, and S is the total solvation energy or, in other words, the total energy for all bonds between ligand molecules and the core ions

For $HSO_4^-(H_2SO_4)_b$, $H^+(H_2O)_n$ and $H^+(CH_3CN)_l(H_2O)_m$ ions, the most prominent ions around 32–34 km, the inequality (8) becomes

$$S > 13\ 6\ \text{eV} \qquad (9)$$

assuming that $H^+(CH_3CN)_l(H_2O)_m$ solvation energies are similar to those of $H^+(H_2O)_n$ This is supported by recent laboratory measurements[27] of the competitive solvation of a proton by CH_3CN and H_2O Here, a lower limit to $EA(HSO_4)$ = 4 5 eV as measured by Viggiano *et al*[5] is assumed E_0 has been set equal to the H–HSO_4 bond strength[19] While the total solvation energy for $H^+(H_2O)_n$ is known, that for $HSO_4^-(H_2SO_4)_b$ ions is not known for b equal to 1, 2, and 3 Assuming $\Delta H = 1, 2, 3$ to be the same as that deduced from the present data for $b = 4, 5$ (~20 kcal mol^{-1}) upper limits to the critical sizes of cluster ions having the potential to form stable ion pairs can be estimated The resulting minimum (n, b) pairs for critical clusters are $(2, 6)$, $(3, 5)$, $(4, 4)$, $(5, 3)$ and $(7, 2)$ Because ΔH values for $HSO_4^-(H_2SO_4)_b$ ($b = 1, 2, 3$) were underestimated and a lower limit to the electron affinity of HSO_4^- was used, the actual critical values may be smaller by about one ligand molecule

In view of the fact that $H^+(H_2O)_4$ and $H^+(H_2O)_5$ are the most abundant proton hydrates around 32–34 km, it seems that ion–ion recombination of the newly observed large HSO_4^--clusters may mainly lead to stable ion pair formation Taking fractional ion abundances equal to measured fractional count rates, the fraction of ion–ion recombinations able to form stable ion-pairs is estimated to be about 0 1–0 7 around 32–34 km

Thus, at the altitudes considered, the abundant negative ion clusters seem to grow just large enough to allow for stable ion-pair formation on mutual recombination with the dominant positive ion clusters

At still lower altitudes, $NO_3^-(HNO_3)_a$ and positive ion clusters may again ultimately become large enough to allow for high polyion formation rates However, in this region, small polyions, due to the large aerosol surface area density, may rapidly attach to aerosols before they reach nuclei sizes

Because negative ion clusters are largest around 30–35 km and because the size of positive ion clusters decreases as height increases the region around 30 km seems to be particularly favourable for polyion formation Around this altitude, there may exist a layer of seed particles, which on mixing into the region below 30 km, where HSO_3 or H_2SO_4 become highly supersaturated, may initiate nuclei formation

Conclusions

We have shown that *in situ* composition measurements of stratospheric ions can provide valuable information on thermodynamic properties of large ion clusters and aerosols In addition, they yield new information on condensable vapours like H_2SO_4 and possibly also HSO_3 Thus, *in situ* ion composition measurements strongly contribute to our understanding of stratospheric trace gas and aerosol processes.

Substantial progress in the new field of stratospheric ion composition measurements can be expected when it becomes possible to lower ion detection limits and to reduce collisional dissociation occurring during ion sampling Thus, it may be possible to detect even larger ion clusters having low abundances and bond energies

We thank R Turco, J Friend, P Crutzen and D Ehhalt for helpful discussions We also thank the technical staff of the Cosmophysics Department of the Max-Planck-Institute for Nuclear Physics, particularly K Oberfrank, W Thron, D Dorflinger, H Sauer, B Preissler and K Bechberger for their encouragement without which this project would not have been possible Part of the project was funded by the Bundesministerium für Forschung und Technologie through Gesellschaft fur Strahlen- und Umweltforschung

A computational model of binocular depth perception

J. E. W. Mayhew* & H. C. Longuet-Higgins†

* Department of Psychology, University of Sheffield, Sheffield S10 2TN, UK
† Laboratory of Experimental Psychology, University of Sussex, Brighton, Sussex BN1 9QG, UK

We point out that the horizontal disparities between a pair of retinal images are inadequate for computing the three-dimensional structure of a scene unless supplemented by independent information about the distance and direction of the fixation point We suggest that this supplementary information is derived not from non-visual sources, but from the vertical disparities of a few non-meridional image points This hypothesis is shown to account quantitatively for Ogle's induced effect—the marked distortion of a scene by a vertically magnifying lens placed in front of one eye

THE binocular perception of depth may be regarded as proceeding in two stages the establishment of a point-by-point correspondence between the left and right retinal images to extract disparity information, and the interpretation of the disparities to yield a three-dimensional percept The position of an image point on the left retina can be represented by its plane projective coordinates (x, y), if (x', y') are the coordinates of the corresponding image point on the right retina, then the difference $x'-x$ is described as the horizontal disparity between the two image points, and $y'-y$ as the vertical disparity The 'correspondence problem'—that of computing the disparities—has been fully discussed in the literature[1-5] and we shall not consider it further Our present concern is the 'interpretation problem'—that of using the disparities for computing the three-dimensional structure of the scene.

As vertical disparities produced by local depth variations (in contrast to those produced by asymmetrical convergence) are commonly much smaller than horizontal ones[1,8]—and necessarily vanish on the horizontal meridian—it is often supposed that only the horizontal disparities are relevant to the binocular perception of depth There are two difficulties with this hypothesis First, the horizontal disparities supply insufficient information, even in principle, for computing the absolute distances and directions of a set of visible points, they must be supplemented by independent information about the distance and direction of the fixation point, but non-visual estimates of these 'viewing parameters' are notoriously unreliable There is, however, a more serious difficulty the binocular perception of a three-dimensional scene is profoundly altered by distorting one of the retinal images in the *vertical* dimension If a cylindrical lens which induces a small vertical magnification is placed in front of one eye, then a visually textured surface in the fronto-parallel plane will acquire a pronounced tilt, as if it had been rotated about a vertical axis, although the horizontal disparities and the non-visual cues to fixation distance and direction are quite unaffected by the introduction of the lens

0028-0836/82/220376—03$01 00

The question therefore arises could the vertical disparities supply the information about the viewing parameters that is required for deriving the structure of the scene from the horizontal disparities? The answer, as we shall see, is in the affirmative, and the hypothesis that the viewing parameters are derived from the vertical disparities rather than from non-visual information sources accounts quantitatively for the above phenomenon, which Ogle has described as the 'induced effect'[1]

It has recently been pointed out[6,7] that a binocular system which takes account of the vertical as well as the horizontal image coordinates can in principle solve the interpretation problem without recourse to extra-retinal sources of information, and also[8] that there exists a remarkably simple approximate method of deriving the position and orientation of a visually textured plane from the horizontal and vertical disparities of a small number of texture elements lying in the plane Figure 1 illustrates the geometry of this situation O and O′ are the nodal points of the two eyes, and the observer is looking—not quite straight ahead—at the plane $Z = PX + QY + R$, where the Z axis joins the mid-point of O O′ to the fixation point $(0, 0, R)$ and makes an angle g with the forward direction The capital letters refer to a coordinate system with the origin at the midpoint of the line joining the optical centres of the eyes If the fixation distance R is large enough compared with the interocular distance I, then one can neglect, in the disparities, terms of the second order in I/R It then becomes possible to use the algebra that Longuet-Higgins and Prazdny[14] used in their analysis of the visual perception of motion, the problem being isomorphous with that presented by the stereoscopic viewing of an object at a moderate distance If $\sin(g) = s$ and $\cos(g) = c$, one obtains, in this way,

$$H(x, y) = x' - x = [(Pc + s)x + Qcy + (c - Ps)x^2 - Qsxy]I/R \quad (1)$$

$$V(x, y) = y' - y = [sy + (c - Ps)xy - Qsy^2]I/R \quad (2)$$

These equations simplify if g is small enough for s and c to be replaced by g and 1 respectively, and for Pg and Qg to be neglected, in these conditions

$$H(x, y) = x' - x = [(P + g)x + Qy + x^2]I/R \quad (3)$$

$$V(x, y) = y' - y = (gy + xy)I/R \quad (4)$$

These equations immediately suggest a way of computing the unknown parameters P, Q, R and g The equation for V implies that a plot of V/y against x gives a line of slope I/R and intercept gI/R, so that the values of R and g can be obtained from the vertical disparities of just two non-meridional points with different x coordinates (that is, points with $y \neq 0$ and $x_1 \neq x_2$) Explicitly

$$R = I/V_{xy} \qquad g = V_y/V_{xy} \quad (5)$$

where V_y and V_{xy} denote the coefficients of y and xy in the expression for V Likewise, if H_x and H_y denote the coefficients of x and y in H, it follows from equation (3) that

$$P + g = H_x R/I, \qquad Q = H_y R/I \quad (6)$$

Substituting from equation (5) into equation (6), we infer that

$$P = (H_x - V_y)/V_{xy}, \qquad Q = H_y/V_{xy} \quad (7)$$

In short, the viewing parameters R and g can be directly computed from the vertical disparities alone, once they are known the geometrical parameters P and Q may be computed from either equation (6) or equation (7), in which the viewing parameters do not appear explicitly A computer simulation implementing equations (5) and (7) has shown that the small-angle approximations underlying these equations are indeed adequate for a wide range of reasonable surface orientations, viewing distances and angles of gaze

When a vertically magnifying lens is placed in front of one eye, the two retinal images become mutually incompatible, in the sense of ceasing to admit of a consistent three-dimensional interpretation It is therefore quite surprising that the observer should obtain a clear three-dimensional percept, albeit a distorted one The induced effect therefore offers a challenge to theories of stereopsis Would a 'seeing machine' which was based on a particular theory be subject to the induced effect, or would it arrive at a different interpretation of the two images, or fail to reach any interpretation at all? For example, machines based on the theories described in refs 6 and 7 would not be subject to the induced effect and therefore may be excluded as models of the human visual process Similarly, a full implementation of equations (1) and (2) would not in general show the induced effect, whereas a machine implementing the approximate solutions [equations (3) and (4)] apparently interprets the two images in a similar way to that reported by human subjects We shall now show that a system which computes P and Q directly from equation (7) will be subject to an induced effect of exactly the same nature and magnitude as that investigated by Ogle

Suppose that a lens of horizontal magnification λ and vertical magnification μ is placed over the right eye Then the new retinal coordinates for that eye will be

$$\hat{x} = \lambda x', \qquad \hat{y} = \mu y' \quad (8)$$

so that the horizontal and vertical disparities will be

$$\hat{H} = \hat{x} - x = \lambda[(P + g)x + Qy + x^2]I/R + (\lambda - 1)x \quad (9)$$

$$\hat{Y} = \hat{y} - y = \mu(gy + xy)I/R + (\mu - 1)y \quad (10)$$

The new values of V_x and V_{xy} will therefore be

$$\hat{V}_x = \mu gI/R + (\mu - 1) = \mu(V_y + 1) - 1 \quad (11)$$

$$\hat{V}_{xy} = \mu I/R = \mu Y_{xy} \quad (12)$$

and the new values of H_x and H_y will be

$$\hat{H}_x = \lambda(P + g)I/R + (\lambda - 1) = \lambda(H_x + 1) - 1 \quad (13)$$

$$\hat{H}_y = \lambda QI/R = \lambda H_y \quad (14)$$

The apparent values of P, Q and R will therefore be

$$\hat{P} = (\hat{H}_x - \hat{V}_y)/\hat{V}_{xy} = [\lambda(H_x + 1) - \mu(V_y + 1)]/\mu V_{xy} \quad (15)$$

$$\hat{Q} = \hat{H}_y/V_{xy} = \lambda H_y/\mu V_{xy} = \lambda Q/\mu \quad (16)$$

$$\hat{R} = I/\hat{V}_{xy} = I/\mu V_{xy} = R/\mu \quad (17)$$

If λ and μ are both $\simeq 1$, the values of Q and R are not much affected, but with P it is an entirely different matter To see

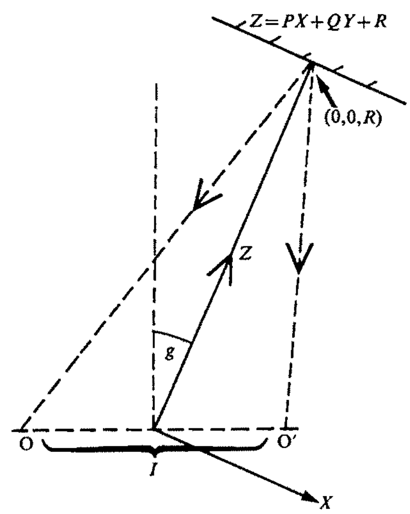

Fig. 1 The coordinate system has origin at the midpoint of the line joining the optical centres of the eyes (O and O′) The line joining this point to the point of fixation $(0, 0, R)$ defines the Z axis, the X axis lies in the plane containing the line OO′ and fixation point, and the line normal to this plane is the Y axis The angle of gaze g, is the angle OO′ makes with the X axis The analysis assumes that the eyes are free to rotate around their X and Y axes but not their Z axes

this, suppose that P is actually zero, as it will be for a fronto-parallel plane Then, according to equation (7), H_x and V_y must be equal, and so the apparent value of P, given by equation (15), will be

$$\hat{P} = (\lambda - \mu)(1 - V_y)/\mu V_{xy} \tag{18}$$

As V_y is of order I/R, and λ and μ are close to 1, we may neglect V_y in the numerator and infer that

$$\hat{P} \simeq (\lambda - \mu)/V_{xy} = (\lambda - \mu)R/I \tag{19}$$

Equation (19), with μ set equal to 1, becomes Ogle's own expression for the apparent tilt produced by a horizontally magnifying lens—an effect which can be understood in purely geometrical terms and which he therefore named the 'geometric effect' Various predictions follow, and all are confirmed by Ogle's observations

(i) The apparent tilt is proportional to the difference between the horizontal and vertical magnification, so that for a given value of R a vertical magnification induces an apparent tilt equal and opposite to that produced by an equivalent horizontal magnification (The induced effect actually falls off at high magnification, this is not predicted by equation (19), but is presumably connected with the fact that $\hat{V}_y/\hat{V}_{xy}$ then implies an implausibly large value for the angle of gaze)

(ii) An ordinary spherical lens, with $\lambda = \mu$, induces no tilt

(iii) When $\mu = 1$ and λ near 1 the induced tilt is proportional both to $\lambda - 1$ and to R At a viewing distance $R = 40$ cm, Ogle found that the angle of tilt increased by 3–3 5° for every 1% increase in magnification With an interocular distance $I =$ 6 5 cm, equation (19) predicts a value for this ratio of

$$(180/\pi) \times (40/6\ 5) \times (1/100) = 3\ 53° \text{ per \% magnification}$$

In his experiments, Ogle actually used a null method of estimating the induced tilt of a vertical plane the subject had to tilt he plane himself (in the opposite direction) until the apparent slope P became zero, that is, until $\hat{H}_x = \hat{V}_y$ This relationship entails that

$$\lambda(H_x + 1) = \mu(V_y + 1) \tag{20}$$

or

$$(\lambda - \mu) = \lambda H_x - \mu V_y = [\lambda(P + g) - \mu g]I/R \tag{21}$$

Remembering that $\lambda = 1$ and $\mu = 1$, we get

$$\mu - \lambda \simeq PI/R \tag{22}$$

showing that the actual value of P required to make $P = 0$ is

$$P = (\mu - \lambda)R/I \tag{23}$$

This is, indeed, equal and opposite to the apparent tilt of a fronto-parallel plane under identical viewing conditions

Discussion

It has commonly been believed (see ref 9 for a review) that only the horizontal disparities convey useful information about the distances of objects, and only qualitative information at that Vertical disparities, which arise when an object is nearer one eye than the other, have been regarded merely as something that the visual system must be capable of allowing for in fusing the two images into a unitary percept Our approach to the problem, from an artificial intelligence standpoint, has led to a computational solution of the interpretation problem which accounts quantitatively for the induced effect Various explanations of this effect have been proposed, both by Ogle and by others[1,2 9–12], but none, we feel, follows so naturally from a theory of normal stereoscopic depth perception as the explanation proposed above (the limitations of a recent theory[12] which attempts to explain the induced effect without using vertical disparities have been criticised elsewhere[11]) Ogle's explanation, like ours, agrees quantitatively with the psychophysical magnitude of the induced effect, but requires the use of the vertical disparities on the vertical meridian to compute the compensatory rotation of the Veith–Muller circle necessary to maintain the correct egocentric localization (this corresponds to the direction of gaze in our expressions) However, Ogle's theory fails to exploit the vertical disparity information at other retinal locations and thus does not solve for the other viewing parameter, distance, which remains as an unknown scaling variable in his expression Note that the retinal eccentricity of the location at which the disparity information is measured is of fundamental importance in our expressions relating horizontal and vertical disparity to the viewing and scene parameters [equations (1)–(4)] Without the terms derived solely from the retinal eccentricity, the system of equations would be homogeneous and without a unique solution The emphasis on a coordinate system derived from concern with corresponding points—the horopter and the Veith–Muller circle—may have masked the importance of these terms from Ogle's consideration, and may explain why, when he was so close to a complete solution, he failed to find it

As our theory is formally complete, it predicts that the induced effect will result from any stimulus which supplies misleading cues about the viewing parameters—the distance and direction of the fixation point Although the vertical disparities from any two retinal locations could be used to solve for the viewing parameters, and thus the computation could be essentially local to a particular region of retina, the results of the computation have global implications which can provide powerful constraints and checks on its consistency In contrast to the interpretation of horizontal disparities where the results in one region of the retina exert little constraint on the interpretation at another region, the interpretation of the vertical disparities should give the same result everywhere There are obvious advantages in making viewing system parameters globally available, and so one might expect that the induced effect would act on the whole visual field even though vertical disparity information could only be derived from a particular region of it Ogle[1] reports an experiment confirming this expectation Vertical disparities from one part of the visual field changed the apparent depths of vertical rods (which of course cannot provide vertical disparity information) in accord with the predictions of the induced effect If the stimulus situation presents incompatible vertical disparity information at different parts of the visual field or, alternatively, vertical disparity information whose interpretation results in grossly implausible viewing system parameters, one might expect some difficulty in perceiving the induced effect This may explain why there may be some difficulty in producing the induced effect without the aid of a cylindrical lens[12 13]

Finally, it is of interest that Ogle reports excellent agreement in estimates of stereoacuity derived from experiments investigating the induced effect and other psychophysical procedures, which correspond to a sensitivity of about 0 2% magnification between the two eyes' images The constraints that this degree of resolution imposes on the implementation of the processes described above are currently the subject of computational and psychophysical experimentation

LETTERS TO NATURE

Could primordial black holes be the source of the cosmic ray antiprotons?

Michael S. Turner

Astronomy and Astrophysics Center, The University of Chicago, Chicago, Illinois 60637, USA

Antiprotons ($\bar{p}$) are expected to be found in the cosmic rays at the level of $\sim 10^{-4}$ relative to protons (p) as they should be produced by cosmic-ray proton collisions with the interstellar medium[1-3]. The recent observations of Buffington *et al*[4]. are puzzling, however, because the total $\bar{p}$ flux observed is ~ 10 times larger than predicted, and the shape of the $\bar{p}$ spectrum differs greatly from that predicted. We explore here the possibility that primordial black holes (PBHs) of mass $\sim 10^{13}$–10^{15} g which evaporated after decoupling ($t \gtrsim 10^{14}$ s) are the primary source of the cosmic ray $\bar{p}$s. The PBH scenario predicts a universal $\bar{p}$/p ratio of $\sim 10^{-4}$–10^{-8}.

Cosmic-ray protons are generally believed to traverse ~ 5 g cm^{-2} during their life in the Galaxy Cosmic-ray proton collisions with the interstellar gas are therefore predicted to produce an $\bar{p}$ flux of $\bar{p}/p \simeq 2\times 10^{-4}$ for $\bar{p}$ kinetic energies above a few GeVs The predicted $\bar{p}$/p ratio falls very steeply for $\bar{p}$ energies below about 1 GeV (refs 1–3) The recent measurements of Buffington *et al*[2] in the energy range 130–320 MeV indicate a $\bar{p}$ flux of $\sim 2\times 10^{-5}$ cm^{-2} sr^{-1} s^{-1} GeV^{-1}, which is several orders of magnitude larger than the flux expected if the $\bar{p}$s are cosmic ray secondaries The three measurements made so far span the energy range from ~ 100 MeV to ~ 10 GeV, and are consistent with a constant $\bar{p}$/p ratio of $\sim 3\times 10^{-4}$ The integrated $\bar{p}$ flux is about a factor of 10 larger than is predicted

There are three possible explanations of the discrepancy (1) The measurements are wrong The results for the energy range of a few to 10 GeV are only a factor of two to three higher than the predicted flux[5,6] Buffington *et al*'s[4] measurement shows greater divergence (2) The $\bar{p}$s observed are indeed secondary particles, but the standard picture of cosmic ray propagation must be modified For example, some of the cosmic ray protons would have to traverse significantly more grammage than ~ 5 g cm^{-2} thus producing more $\bar{p}$s[7-9], and a stochastic mechanism[11] to decelerate the $\bar{p}$s would be required to explain the high flux of low-energy $\bar{p}$s Buffington *et al*[4] observe (3) The $\bar{p}$s detected are primary particles originating from the big bang, or from regions of antimatter If their origin is the big bang, then there is the problem of storing them so that they escape annihilation[12], and then subsequently injecting them into the Galaxy If the observed $\bar{p}$s originate from antigalaxies[13], then it is difficult to understand why the $^4\overline{\rm He}/^4$He ratio is $<2\ 2\times 10^{-5}$ (95% confidence, ref 4), rather than being equal to the $\bar{p}$/p ratio $\simeq 3\times 10^{-4}$

Here I discuss three models in which evaporating PBHs of mass $\sim 10^{13}$–10^{15} g radiate $\bar{p}$s sufficiently late in the history of the Universe that the $\bar{p}$s avoid annihilation, leading to a universal abundance of $\bar{p}/p \sim 10^{-4}$–10^{-8} The initial spectrum of PBHs required to explain the observations is consistent with previous constraints on the spectrum of PBHs[14], and could also lead to the production of a significant baryon asymmetry[15] (much earlier in the history of the Universe, $t\sim 10^{-35}$ s) Because the PBHs must have a temperature of $\gtrsim 1$ GeV when they produce the $\bar{p}$s, antinuclei will not be produced in the process, thus explaining the absence of antinuclei

First, consider the question of producing $\bar{p}$s that do annihilate with the ambient protons in the Universe The $\bar{p}$ annihilation rate $\Gamma_{\rm ann}$ is given by

$$A6\Gamma_{\rm ann} = n_{\rm p}(\sigma v)_{\rm ann} \qquad (1)$$

The number density of protons, $n_{\rm p}$, is just $(n_{\rm p}/n_\gamma)\times n_\gamma \simeq (3\times 10^{-10})\times(2\zeta(3)T^3/\pi^2)$, where $n_{\rm p}/n_\gamma \simeq (3\text{–}5)\times 10^{-10}$ (J Yang *et al*, in preparation) and the second factor is the number density of photons at temperature T, $\zeta(3)\simeq 1\ 202$ The annihilation cross-section times the relative velocity $(\sigma v)_{\rm ann} \simeq m_\pi^{-2}$ Annihilations will not occur at a significant rate if $\Gamma_{\rm ann} < H \equiv \dot{R}/R = 1\ 66\ g_*^{1/2}T^2/m_{\rm pl}$ (the expansion rate) Here $\hbar = c = k_{\rm B} = 1$, $m_{\rm pl} = G^{-1/2} \simeq 10^{19}$ GeV and g_* is the total number of effective degrees of freedom of all the relativistic species at a temperature T The condition $\Gamma_{\rm ann} < H$ requires

$$T \lesssim 10^{10}(\pi^2/2\zeta(3))m_\pi^2/m_{\rm pl} \sim 0\ 1\ {\rm eV} \qquad (2)$$

This temperature roughly corresponds to that of decoupling ($T\sim 1{,}000$K), and to a time $t\sim 10^{14}$ s Essentially all the $\bar{p}$s produced after $t\sim 10^{14}$ s will avoid subsequent annihilation, while $\bar{p}$s produced earlier will be annihilated (If $n_{\rm p}/n_\gamma \gtrsim (3-5)\times 10^{-10}$, then the Universe will be matter-dominated when the annihilations cease and the analysis above must be modified If, however, the Universe is nucleon-dominated now, then the time at which annihilations cease is independent of $n_{\rm p}/n_\gamma$ If the Universe is not nucleon-dominated and $\Omega h^2 \simeq 1$, $t\simeq 3\times 10^{12}$ s)

Hawking[16] showed that a black hole of mass m should radiate like a blackbody with temperature

$$T \simeq 0\ 1 m_{\rm p1}(m_{\rm p1}/m) \qquad (3)$$

and evaporate in a time[17]

$$\tau \simeq m_{\rm p1}^{-1}(m/m_{\rm p1})^3\,(100/g_*) \qquad (4)$$

where g_* is the number of species with mass less than T Of course, this process is only important for black holes of mass $m \ll 1M_\odot$ Such black holes must be primordial (produced from density perturbations in the early Universe, see, for example, ref 13), as known astrophysical processes can only produce black holes of mass $M \gtrsim$ few $M_\odot$

Equation (4) shows that PBHs are ideal candidates for producing $\bar{p}$s after $t\sim 10^{14}$s, as they have a built-in clock PBHs of mass $m \gtrsim 10^{18}m_{\rm p1} \sim 10^{13}$ g will evaporate after $t\sim 10^{14}$ s A PBH of mass $m\sim 10^{18}\ m_{\rm p1}$ has a temperature of ~ 1 GeV As it radiates, its mass decreases and its temperature increases If we assume that for $T \gtrsim 1$ GeV about one-tenth of the particles the PBH radiates are $\bar{p}$s[14], and the typical $\bar{p}$ momentum is $\sim T$, then the spectrum of $\bar{p}$s produced is

$$dn_{\bar{p}} \simeq 2\times 10^{36}p^{-3}\,dp \qquad (5)$$

where the momentum p is measured in GeV A PBH more massive than $10^{18}\ m_{\rm p1}$ will not emit $\bar{p}$s until its mass becomes less than $\sim 10^{18}\ m_{\rm p1}$, and then it will emit the same spectrum as a PBH of that mass, given by equation (5)

Following Carr[14], we parameterize the initial PBH spectrum as

$$\frac{dn(m)}{n_\gamma} = \zeta\left(\frac{m}{m_{\rm p1}}\right)^{-\alpha}\frac{dm}{m_{\rm p1}} \qquad (6)$$

where $dn(m)/n_\gamma$ is the number of PBHs per photon in the mass interval $m\to m+dm$, ζ is the normalization ($\simeq$fraction of the mass density of the universe in PBHs at $t_{\rm p1}\sim 10^{-43}$ s) and α is the index of the spectrum The most stringent constraint on ζ and α results from the insistence that PBHs of mass $\sim 10^{15}$ g do not contribute excessively to the diffuse γ-ray background[14],

$$\zeta \lesssim 10^{20\alpha - 75} \qquad (7)$$

Of course, ζ must also be <1 [In equations (6) and (7) it is assumed that the number of PBHs per photon has remained constant (neglecting evaporation) This relies on the assumption that the expansion of the Universe has been approximately isentropic, so that the number of photons in the Universe has not increased significantly]

0028–0836/82/220379—03$01 00

Summing the contribution of all PBHs more massive than $\sim 10^{13}$g and taking into account the subsequent cosmological redshift of the $\bar{p}$ momenta, we find that, at present,

$$\frac{dn_{\bar{p}}}{n_\gamma} \simeq 10^{55\ 5-19\ 5\alpha}\zeta \mathrm{KE}^{-3/4-\alpha/4}\, d\,\mathrm{KE} \tag{8}$$

for $\bar{p}$ kinetic energies (measured in GeV) in the range 1 GeV$\geqslant$ KE$\geqslant 10^{-6}$ GeV The lowest-energy $\bar{p}$s are those that were emitted with momentum $\sim$1 GeV by 10^{13} g PBHs just after decoupling, at present they have KE$\sim 10^{-6}$ GeV ($v \sim 10^{-3}c$) For relativistic $\bar{p}$s ($E \gtrsim$ few GeV),

$$\frac{dn_{\bar{p}}}{n_\gamma} \simeq 10^{55\ 5-19\ 5\alpha}\zeta E^{-3}\, dE \tag{9}$$

None of the $\bar{p}$s produced by PBH evaporations would have initially collapsed into galaxies with the baryons, both because the $\bar{p}$s are emitted during the epoch of galaxy formation ($z \leqslant 10^3$) and since they are relativistic when they are emitted they are moving too fast to be captured in galaxies or protogalaxies The entire spectrum, equations (8) and (9), is primarily due to the $\sim 10^{13}$g PBHs which evaporated shortly after decoupling

The universal abundance of $\bar{p}$s relative to photons is obtained by integrating over the spectrum

$$\frac{n_{\bar{p}}}{n_\gamma} \simeq 10^{54\ 5-18\alpha}\zeta \leqslant 10^{-13} \tag{10}$$

and it is dominated by the low-energy $\bar{p}$s ($v \simeq 10^{-3}c$) The upper limit in equation (10) is obtained by using the maximum value of ζ consistent with the limit derived from the diffuse γ-ray background ($\zeta = 1$, $\alpha = 3\ 75$) Equation (10) translates into a universal $\bar{p}$/p ratio $\leqslant 10^{-4}$

Antiprotons are not annihilating rapidly enough now to deplete their abundance significantly, however, the π^0s produced in $\bar{p}$p annihilations contribute to the diffuse γ-ray background when they decay To compute the annihilation rate one must use the nonrelativistic annihilation cross-section, $(\sigma v)_{\mathrm{ann}} \simeq 7\times 10^{-17}\ \mathrm{cm}^3\ \mathrm{s}^{-1}\ (c/v)$ (ref 18) The contribution to the γ-ray background today is

$$I \simeq [(\bar{p}/p)/10^{-4}]3\times 10^{-5}\ \mathrm{cm}^{-2}\ \mathrm{sr}^{-1}\ \mathrm{s}^{-1} \tag{11}$$

The flux observed at $E_\gamma \sim 100$ MeV is about $3\times 10^{-5}\ \mathrm{cm}^{-2}\ \mathrm{sr}^{-1}\ \mathrm{s}^{-1}$ (ref 19) The γ-ray background thus places an upper bound on the universal $\bar{p}$/p ratio of $\sim 10^{-4}$ $(v/10^{-3}c)$, regardless of their source (assuming that they are non-relativistic, see also ref 12)

From the abundance of $\bar{p}$s due to PBH evaporations [equations (8) and (9)], one must calculate the resulting galactic cosmic ray $\bar{p}$ flux For reference, the observed $\bar{p}$ flux corresponds to a local antiproton number density of

$$n_{\bar{p}}|_{\mathrm{galaxy}} \simeq 10^{-14}\ \mathrm{cm}^{-3} \tag{12}$$

essentially all in the energy range 0 1–1 GeV If the Galaxy is taken to be a sphere of radius $\sim$30 kpc, and the $\bar{p}$ number density constant, there are about 10^{55} $\bar{p}$ in the Galaxy today The escape time for cosmic rays of energy greater than several GeV is $\sim 10^7$ yr, however, lower-energy cosmic rays may be trapped for longer In any case, the annihilation time scale for an $\bar{p}$ in the Galaxy is $\sim 10^8$ yr Thus a reasonable estimate for the lifetime of an $\bar{p}$ in the Galaxy is 10^7–10^8 yr, and so $\bar{p}$s of energy 0 1–1 0 GeV must be replenished at the rate of

$$\frac{dN_{\bar{p}}}{dt} \simeq 10^{39}\text{–}10^{40}\ \mathrm{s}^{-1} \tag{13}$$

This is the rate at which the ambient intergalactic $\bar{p}$s must be injected into the Galaxy

There are three possible injection models (1) low-energy ($v \simeq 10^{-3}c$)$\bar{p}$s are captured by the Galaxy and then accelerated up to $\sim$0 1–1 0 GeV, (2) $\bar{p}$s in the energy range 0 1–1 0 GeV are captured by the Galaxy, (3) PBHs of mass $\sim 10^{15}$ g which are in our Galaxy and are evaporating today supply the required flux of $\bar{p}$s All three models are viable, and have associated uncertainties and difficulties

In the case of model (1), the total flux of low-energy $\bar{p}$s ($v \simeq 10^{-3}c$) on the Galaxy is given by

$$\frac{dN_{\bar{p}}}{dt} = 10^{111-18\alpha}\zeta\ \mathrm{s}^{-1} \leqslant 10^{44}\ \mathrm{s}^{-1} \tag{14}$$

To supply the required number of $\bar{p}$s in the energy range 0 1–1 0 GeV, the efficiency of capture and acceleration must be $>10^{-4}$

In model (2), the total flux of $\bar{p}$s in the energy range 0 1–1 0 GeV on the Galaxy is given by

$$\frac{dN_{\bar{p}}}{dt} = 10^{115-19\ 5\alpha}\zeta\ \mathrm{s}^{-1} \leqslant 10^{43}\ \mathrm{s}^{-1} \tag{15}$$

In this case to supply the required numbers of $\bar{p}$s in the range 0 1–1 0 GeV, the probability that a given $\bar{p}$ with energy $\sim$0 1–1 0 GeV incident on the Galaxy enters the galactic magnetosphere must be $\gtrsim 10^{-4}$ In both models (1) and (2) the $\bar{p}$s must scatter off inhomogeneities in the galactic magnetic field in order to become galactic cosmic rays This process is not well understood, and remains the biggest uncertainty in the estimates for models (1) and (2) In both models the $\bar{p}$s come primarily from $\sim 10^{13}$ g PBHs which evaporated at $t \sim 10^{14}$ s

In the case of model (3), although the bulk of the $\bar{p}$s in the intergalactic medium are produced by $\sim 10^{13}$ g PBHs which evaporate just after decoupling, $\sim 10^{15}$ g PBHs which are evaporating now are the primary source of galactic $\bar{p}$s If we assume that these PBHs collapsed with the baryons during galaxy formation, then their local number density is enhanced by a factor of $\sim 10^6$ relative to equation (6) The $\bar{p}$s such PBHs radiate now have energies 0(1 GeV), and are already inside the Galaxy The total flux of $\bar{p}$s from $\sim 10^{15}$ g PBHs in the Galaxy is

$$\frac{dN_{\bar{p}}}{dt} \sim 10^{117-20\alpha}\zeta\ \mathrm{s}^{-1} \leqslant 10^{42}\ \mathrm{s}^{-1} \tag{16}$$

For the maximum value of ζ, the total flux is 10^2–10^3 larger than required Thus one could improve Carr's constraint[14] on ζ slightly, $\zeta \leqslant 10^{-77+20\alpha}$ This model requires the number density of 10^{15} g PBH to be within $\sim 10^2$–10^3 of the maximum allowed number, it has the advantage that the $\bar{p}$s do not have to penetrate the galactic magnetosphere to become cosmic rays, hence avoiding the uncertainties involved with this process

It is therefore possible for the evaporation of $\sim 10^{13}$–10^{15} g PBHs to produce the observed, but unexplained, large flux of $\sim$0 1–1 0 GeV $\bar{p}$s The number density of PBHs must be within a factor of $\sim 10^4$ of the upper limit allowed by the γ-ray background constraint[14] The mass spectrum of PBHs can have an index α in the range 2–3 75 In the first and second models α must be $\sim$3 75 unless the injection of $\bar{p}$s into the Galaxy is very efficient If PBH evaporations are responsible for the cosmic ray $\bar{p}$s, then there should be a universal $\bar{p}$/p ratio of $\sim 10^{-4}$–10^{-8} in the intergalactic medium In two of the models discussed, intergalactic $\bar{p}$s must penetrate the galactic magnetosphere to become cosmic rays In the third model, the cosmic ray $\bar{p}$s are produced by $\sim 10^{15}$ g PBHs within the Galaxy which are evaporating today None of the PBH models is compelling, but they are plausible, and perhaps even intriguing

After completing this paper, I realised that Kiraly *et al*[20] have also suggested PBHs as a source of the cosmic ray antiprotons The model they discuss is similar to my model, in which PBHs evaporating in the Galaxy today are responsible for the cosmic ray $\bar{p}$s

I thank Tom Gaisser for introducing me to this problem and for beneficial discussions, and Gary Steigman for useful comments This work was supported in part by the DOE (ACO2-80ER10773) at University of Chicago and by NSF grant PHY 77-27084 at University of California, Santa Barbara

Isotopically distinguishable carbon phases in the Allende meteorite

P. K. Swart, M. M. Grady & C. T. Pillinger

Planetary Sciences Unit, Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK

The stepwise oxidation of the Allende meteorite reported here has shown that there are at least three isotopically distinct carbon phases, each combustible over different temperature ranges. The temperature of combustion is dependent both on grain size of the fragments studied and/or on the nature of the carbonaceous material and its availability to the oxygen. Thus we attempt here to correlate the isotopic signatures recognized with phases whose existence has been postulated to explain noble gas systematics[1,2] and to provide some insight into the nature and location of these phases. Most of the carbon ($\delta^{13}C$= −20‰), possibly a highly cross-linked polymer, exists predominantly in the matrix and has been reported by others[3] to be the host of most of the normal planetary noble gases. Carbon protected in mineral grains may be isotopically heavier at −13 to −7‰, but is still more easily oxidized than graphite when exposed by HF/HCl demineralization. A very easily oxidized phase, as yet unidentified, has a $\delta^{13}C$ value typically ~−23 to −27‰.

Carbon isotopic analyses of carbon-rich meteorites (CI, CM2, C3 and type 3 unequilibrated ordinary chondrites), apart from H_3PO_4-released fractions[4], have revealed a very uninspiring range of values In fact, after removal of obviously separable minor components, such as carbonate and soluble organics, some of which may be contaminants, bulk carbon usually has an isotopic composition of between −5 and −28‰ and shows no coherent trend relative to meteorite group or petrological type[5] The bulk of the carbon in chondrites is largely uncharacterized and only operationally defined Thus, being insoluble in mineral acids and organic solvents, it can only be some allotrope or polymer of carbon The root cause of the unprepossessing isotopic compositions may be that bulk carbon is an unresolved mixture in such meteorites With material of several different isotopic compositions present in varying proportions, bulk values would be at best confused Recognition of several carbonaceous noble gas host-phases within a single meteorite[1,2] apparently endorses such an interpretation Obviously a method capable of further resolving mixtures within the bulk carbon would possibly allow isotope signatures to be recognized

The Allende C3V meteorite has a reported carbon isotope value of between −16 4 and −19 5‰ (refs 6–8) Much effort has been made recently to separate carbon-rich phases, thought to be among the hosts of anomalous noble gases, from the meteorite[1,2] In one such study, a separate (AMII)[9] was combusted and carbon isotopic analyses of the CO_2 produced reported by Ott *et al*[2] The data showed increasing heavy isotope abundance with temperature At the time, this change was thought to be a result of kinetic isotope effects and hence dismissed as of no significance[2] Recently, however, we have obtained evidence which suggests that such an interpretation may have been premature We performed a series of stepwise oxidations using various bulk sieve fractions of the Allende meteorite (>50μm, <50μm and <25μm) as well as a sample from which silicate had been partially removed by HF/HCl treatment, in an effort to bridge the gap between fully demineralized and bulk samples The method involved is similar to that used by others[2,3] for stepwise oxidations and involves the combustion of each sample for 30 min in an atmosphere of O_2(>20 mbar) derived from the decomposition of CuO Gases evolved are frozen into a variable temperature cryogenic trap and excess O_2 adsorbed onto a CuO/Cu furnace Carbon dioxide produced is separated from SO_2 and measured with a capacitance manometer Isotopic measurements were performed using a VG Micromass 602-E and data reported in ‰ relative to PDB To evaluate the extent of kinetic isotope effects during stepwise combustion, several carbonaceous substances were analysed using the same method

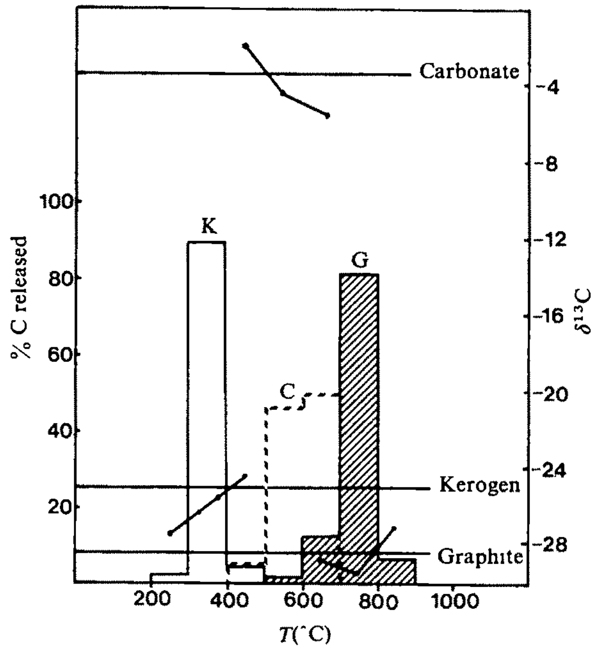

Fig. 1 Stepwise oxidation of three standard carbonaceous substances Kerogen (type I kerogen extracted from Upper Jurassic Kimmeridge Clay), PSU-1 carbonate (sparry calcite standard), and graphite (NBS-21) The $\delta^{13}C$ values obtained by a one-step total extraction are shown as horizontal lines

Stepwise carbon release patterns and isotopic compositions for the standard and meteorite samples are shown in Figs 1 and 2 For the <50 μm fraction, carbon yield and isotopic values, calculated by summing the individual temperature steps, agree well with measurements made during conventional extraction procedures, bulk measurements have not been made on the other fractions Unfortunately, the higher temperature extractions of the HF/HCl-treated sample were contaminated with fluorinated species and no isotopic data were obtained However, on the basis of previous results[2], we assume that the 500–800 °C fractions would have contained slightly heavier carbon We discount the interpretation that an increase in heavy isotope abundance with temperature of oxidation, seen in all cases, merely reflects kinetic isotope fractionation for several reasons (1) None of the standard materials exhibited a variation >±1 5‰ about their mean $\delta^{13}C$ values, although weighted averages of the $\delta^{13}C$ obtained in a stepwise fashion are comparable with that derived from a single step combustion (2) The spread of Allende isotopic measurements is 15–20‰ irrespective of grain size and is independent of whether any silicate has been removed from the sample The release pattern of the

0028–0836/82/220381—03$01 00

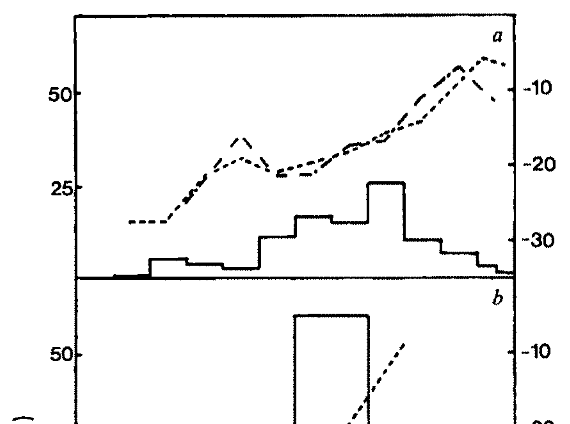

Fig. 2 Per cent carbon release and $\delta^{13}C$ composition from various size fractions and treatments of Allende *a*, >50 μm bulk duplicate analysis, $\Sigma\delta^{13}C = -17.2$, -17.1‰, $\Sigma C = 0.21\%$, only one carbon release profile is shown, *b*, <50 μm bulk, $\Sigma\delta^{13}C = -18.8$‰, $\Sigma C = 0.27\%$, *c* <25 μm bulk, $\Sigma\delta^{13}C = -18.9$‰, $\Sigma C = 0.37\%$, *d*, partially demineralized by HF/HCl, $\Sigma\delta^{13}C = -17.4$‰, $\Sigma C = 1.89\%$

carbon from the sample is, however, governed by the physical condition of the sample, being easier to combust in the absence of minerals and much more difficult to release from the >50 μm fraction The opportunity for kinetic isotope effects in the latter sample, which was analysed in duplicate, is obviously greater but clearly not excessively manifest (3) None of the undemineralized meteorite samples show a regular and continuous increase in $\delta^{13}C$ with temperature In the samples of >50 μm and <50 μm, troughs occur in the isotope release pattern over the 500–700 °C interval The <25 μm sample exhibited two distinct plateaus corresponding to peaks in the carbon release (4) Stepwise combustion applied to other meteorite samples gives rise to complex release profiles which cannot be explained by simple kinetic fractionation[10]

We suggest that for Allende, different forms of carbon are being oxidized or decomposed as temperature increases Undoubtedly, some kinetic isotopic fractionation occurs, but this is probably within a few per mil, based on evidence from our stepwise combustion of individual carbonaceous substances The profile obtained for the <25 μm fraction provides the best estimate of the isotopic compositions of the carbon phases (Fig 2) We have estimated the isotopic compositions on two criteria first, the carbon shows sharp release profiles and second for the most part these profiles appear to correspond with plateaus in the carbon isotope ratio The initial low temperature release (below 400 °C) shows a rapid increase in isotopic ratio to the first plateau, perhaps as a result of mixing of two or more phases having only slightly different oxidation temperatures The mid-temperature oxidizable phase, which contributes the bulk of the carbon is released over the interval 450–600 °C and has a mean $\delta^{13}C$ of ~−20 3‰ The high temperature carbon in the <25 μm fraction is liberated above 600 °C and has the heaviest carbon encountered in this size fraction and averages out at −13 4‰ Higher $\delta^{13}C$ values may be encountered in coarser size fractions (Fig 2) although these could reflect an enhanced kinetic isotope effect

In the duplicate >50 μm sized fractions of Allende, a reduction in the carbon isotopic ratio between 500 and 600 °C was observed Such a pattern of isotopic release could be explained as the existence of a further, possibly low abundance, carbonaceous phase possessing a very negative isotopic composition During stepwise combustion of <4 μm Allende matrix samples[11], the $\delta^{15}N$ plummets to −53‰ for the 1 28 p p m of nitrogen liberated during the 490 °C step and correlates strongly with the release of a heavy xenon component suggesting the addition of an isotope of nucleosynthetic origin[11] The admix of nearly pure ^{14}N of presolar origin into Solar System materials has previously been discussed by several workers[12–14] There may be no *a priori* significance between compatible release of nuclear components and a possible low $\delta^{13}C$, but the coincidence merits further study

The carbon release and isotope patterns of the various fractions studied allow us to draw some conclusions regarding the nature and location of the phases believed to exist First, we note that the mid-temperature phase (<25 μm nomenclature, Fig 2*c*) which constitutes most of the carbon in the meteorite is of variable temperature release when other fractions are considered Coarse sieve fractions do not release the phase completely until 900 °C, but our partially demineralized sample and the AMII fraction of Ott *et al*[2] suggest that in its free form this material combusts between 300 and 600 °C Such a reaction temperature is above the value found for a type I terrestrial kerogen, but well below that observed for NBS graphite and lends credence to the interpretation that the major carbon phase in Allende is a highly cross-linked, possibly aromatic, polymer, although some allotrope of carbon such as carbyne or amorphous carbon cannot be ruled out We thus concur with the interpretation of Simmonds *et al*[15] that carbon in Allende is in a macromolecular form unlike graphite We are unable to comment on the oxidation properties of "the interwoven ribbon-shaped packets of graphite layer plains" of Smith and Buseck[16] or poorly crystalline graphite[17] Although direct comparisons are difficult because of sample differences, the mid-temperature phase is most probably that discussed extensively by Frick and Pepin in relation to noble gases and nitrogen[9] The mid-temperature carbon phases must be associated with a portion of the meteorite which can be easily crushed and available for oxidation, the evidence seems to point strongly towards the fine-grained olivine matrix which has been shown to have carbonaceous surface deposits[17,18] Second, the high temperature carbon phase of the <25 μm fraction does not show a pronounced temperature variation when other sieved undemineralized fractions are considered Thus the heaviest carbon in the sample probably resides within the silicate minerals and corresponds to the so-called 'protected phase' of Frick and Pepin[3] Once the silicate minerals are partially or completely removed, the carbon becomes oxidizable below 700 °C suggesting that it is neither a highly crystalline nor ordered graphite Third, the very low temperature phase released below 400 °C in all undemineralized samples is clearly available to oxidation Although precautions were taken, it cannot be ruled out that a proportion of terrestrial contamination is involved Finally, we perceive, as previously reported by Chang *et al*[6] an increase in carbon content and a slight shift

towards lighter carbon as particle size decreases. These trends may be accounted for by an additional availability of the low and medium temperature phases and concurrent with their occurrence in fine-grained, easily crushed matrix.

We conclude that stepwise combustion of bulk and demineralized samples provides an easy and relatively contamination-free method of identifying the carbon isotopic composition of phases within Allende. The use of the technique in conjunction with noble gas and other volatile element analyses and its application to model materials should prove highly informative.

We thank the SERC for support, Professor E. Anders for stimulating our interest in stepwise combustion, the members of the Planetary Sciences Unit, Cambridge for helpful discussions and Mr I. Gilmour for the kerogen sample.

The acidity of rain has attracted considerable international interest during the past decade. An area of enhanced rainfall acidity with its focus in the Low Countries of north-west Europe was identified by the European air chemistry study[1] for the period 1955–68, and widespread concern arose as a result of observations that fish populations were decreasing in areas of Scandinavia subject to acid rain[2]. We report here measurements of acidity and related anion concentrations in rain collected at 16 sites in northern Britain during the period 1978–80. Estimates are provided of annual deposition of acidity in rain, the proportion of this acidity attributable to sulphuric and nitric acids, and an example of the influence of local concentrations of pollutant gases on rainfall acidity in cities.

The term 'acid rain' refers to rain more acid than water in equilibrium with atmospheric concentrations of carbon dioxide (~*p*H 5.6, 2.5 μEquiv. $H^+ l^{-1}$). Although several factors are involved, the areas in Scandinavia with significantly altered fish populations are subject to rainfall acidities of 30–60 μEquiv. $H^+ l^{-1}$ (*p*H 4.5–4.2). Fish mortality in acid water is caused mainly by problems with body salt regulation, the increased solubility of aluminium compounds in acid water being strongly implicated in these effects[3]. Evidence for links between acid precipitation and fish mortality is not restricted to Scandinavia, as similar effects have been reported for eastern North America[4] and Scotland[5].

In the United Kingdom there have been few detailed and systematic observations of rain chemistry in recent years, despite early interest in the subject[6]. Gorham, in 1958, showed that areas of north-west England received appreciable inputs of pollutants, including acidity, from industrial areas to the south-east[7]. Ten years later, Stevenson reported concentrations of all the major ions in rain except hydrogen for eight sites in Britain[8]. In 1978 and 1979, Martin and Barber showed that rain in central and eastern England was 'acidic', with annual average hydrogen ion concentrations of 40–80 μEquiv. $H^+ l^{-1}$ (*p*H 4.4–4.1)[9,10].

At each of the 16 sites (Fig. 1) rain was collected using a 20 cm diameter Pyrex glass funnel mounted 2 m above ground, each funnel surrounded by a ring of spikes to discourage birds from perching on the rim. Pyrex glass has been shown to influence concentrations of sodium and potassium ions through leaching, and may underestimate acidity[11] but the surface properties are likely to remain more consistent over prolonged periods in the field than plastic funnels which deteriorate with time. Rain water flowed into darkened polypropylene bottles through a small piece of nylon gauze inserted into the neck of the funnel to prevent the collection of insects and larger debris. Although preservatives were not added, there was only very occasional evidence of algal growth occurring between the monthly collections of samples, which were sent by post to the laboratory where they were stored at 4 °C before being analysed. There remains the possibility of chemical changes occurring in the sample through biological activity during the intervals between collection. However, Galloway and Likens[11] showed that there were no significant changes in concentrations of the major ions, except chloride, over a 7 month storage period at 21 °C for a sample at *p*H 4. A continually exposed funnel rather than an automatic wet-only sampler was used as there were problems of reliability and contamination with the automatic samplers available in 1977. The contribution of dry deposition

to the ionic composition of rainfall collected in our gauges has been independently estimated, and is discussed later.

Measurements of *p*H and the concentrations of sulphate and magnesium ions were made on samples collected during 1978 and 1979; since 1980 the range of analyses has included concentrations of nitrate, chloride, sodium, potassium and ammonium ions (J.N.C. and D.F., work in preparation). *p*H was measured taking the necessary precautions for samples of low ionic strength[12] using standard glass and calomel electrodes. Chloride concentrations were measured using an ion-selective electrode. Sulphate analysis was by the continuous-flow thoron method[13] with aqueous isopropanol as solvent. Measurement of nitrate was by reduction to nitrite followed by complexation with sulphanilamide/*N*-1-naphthylethylenediamine dihydrochloride[14] in a continuous-flow system, and ammonium was measured as ammonia using continuous flow through an ammonia-selective electrode. Magnesium and calcium concentrations were determined by atomic absorption spectroscopy (after addition of lanthanum) and sodium and potassium concentrations by flame emission spectroscopy.

Fig. 2 Annual deposition of hydrogen ions (kg H^+ ha^{-1}) in rain over northern Britain.

Magnesium ion concentrations were used to estimate the sea-salt contribution to total ionic composition. Fifteen of the 16 rain-collecting sites were located in rural areas remote from local sources of air pollutants, with one site located in central Glasgow (Fig. 1). They provided an approximately uniform coverage of northern Britain (Table 1).

The surfaces of rain collectors are contaminated by dry deposition of gaseous SO_2 and NO_2 and particulate sulphate. As a result the deposition of sulphur and hydrogen ions in rain is overestimated, their estimates in southeastern Scotland being exaggerated by ~10% and in northern and western Scotland by 2–5%. The contamination was quantified from funnel washings following dry days and from laboratory experiments in which funnels were washed after exposure to SO_2 (unpublished data). Collectors sited at 2 m above ground, to limit contamination by surface-derived material, capture 5–10% less rain than identical collectors at ground level[15]. However, for estimates of annual deposition this error can be minimized by combining the solute concentrations found in the network with the amounts of rain recorded by the Meteorological Office.

The weighted mean acidity of rain was least in the north-west of northern Britain (20 μEquiv. H^+ l^{-1}, *p*H 4.7) and greatest in the east and south of northern Britain (60 μEquiv. H^+ l^{-1}, *p*H 4.2) (Fig. 1) The regional gradient, which is relatively simple, is best described by the following quadratic relationship between National Grid coordinates and hydrogen ion concentrations:

$$[H^+]\,(\mu\text{Equiv. } l^{-1}) = 3.80\times10^{-6}\,E^2 + 7.05\times10^{-7}\,E.N. - 3.16\times10^{-6}\,N^2 - 1.06\times10^{-2}\,E + 4.32\times10^{-2}\,N - 118 \quad (1)$$

where *N* and *E* are four-figure northings and eastings from Ordnance Survey maps.

This empirical equation accounts for 94% of the variation,

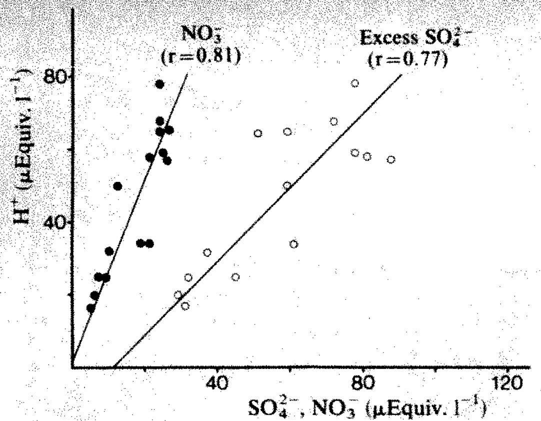

Fig. 3 Relationship between hydrogen ion concentrations in rain collected at 15 rural sites in northern Britain for the period 1978–80, and concentrations of nitrate (●) and non-marine (excess) sulphate (○) ions.

the average uncertainty of the predicted values for the locations marked in Fig. 1 being ±9% (Table 1).

As the regional pattern has been established from collections made in rural locations, it is of interest to consider local variations associated with major industrial and residential areas. To provide an estimate of the 'city influence' the Glasgow site at which the annual average SO_2 concentration is ~80 μg m^{-3} (ref. 16) was included in the study. The regional pattern predicts a rainfall acidity in Glasgow equivalent to 39 μEquiv. $H^+ l^{-1}$ (pH 4.45) whereas an acidity of 55 μEquiv. $H^+ l^{-1}$ (pH 4.26) was actually recorded, indicating that ~30% of the acidity at that site was of local origin. The difference between the predicted regional value and measured local value exceeds the largest difference between predicted and measured values for the rural network sites by a factor of 2 (Table 1). The excess sulphate concentration (that sulphate remaining when sea-derived sulphate has been subtracted from the total) is also large in Glasgow, being approximately twice the regional pattern estimate (92 compared with 43 μEquiv. l^{-1}). This suggests that some of the locally derived sulphate does not contribute to acidity, but seems to be associated with ammonium ions, for which the Glasgow concentration was over twice the average for northern Britain (43 compared with 19 μEquiv. l^{-1}).

When the hydrogen ion concentrations for rain falling at the centre of each 10 km square of the National Grid are combined with the Meteorological Office's 30 yr data for amounts of precipitation, it can be seen that the deposition of hydrogen ions is strongly influenced by height above sea level (Fig. 2), an effect mainly attributable to the relation between amounts of rain and altitude over northern Britain. Rainfall during the period of study exceeded the 30-yr average by ~10%[17]. Rainfall chemistry is not independent of altitude, fine rain often encountered at high altitudes having characteristically larger ionic concentrations[18]. Single rain events show a decrease in concentration with the amount of rain[19–21]. As the combined effect of these two processes is uncertain, average rainfall chemistry has been assumed to be constant with altitude. It is clear from Fig. 2 that rainfall in the west more than compensates for smaller average acidities, so that although most of the region has a hydrogen ion input in rain of ~0.5 kg H^+ ha^{-1} yr^{-1}, there are areas with much larger inputs where annual hydrogen ion deposition may exceed 1 kg ha^{-1} yr^{-1}. For a consideration of effects the degree of acidity is important, but the quantity of acid deposited may be equally important. Henriksen[22] suggested that the effects of the direct inputs of acidity in rain, when acidifying bodies of freshwater, could be likened to a large-scale titration. The deposition pattern shown in Fig. 2 identifies areas of northern Britain where inputs of acidity are large and comparable with areas of Norway where fish populations have decreased markedly[3].

The dominant anions in rain are sulphate, nitrate and chloride. Seawater is a significant source of chloride and sulphate ions in rain, but makes a negligible contribution to nitrate or hydrogen ion concentrations. Our evidence suggests that most chloride has a marine origin, and therefore does not contribute to acidity, although non-marine chloride has been detected at a site in central Scotland close to known sources of gaseous HCl (unpublished data). The proportion of marine sulphate varies from >60% at coastal western sites to 10% in the east. The two major anions associated with acidity are therefore nitrate and excess sulphate, each of which is strongly correlated with hydrogen ion (Fig. 3). Similar correlations have been noted by others[23,24]. There are two extreme interpretations of these correlations. On the one hand, all of the nitrate could be associated with hydrogen ions, in which case 38% of the acidity would be nitric acid, the remaining 62% being sulphuric acid. At the other extreme there is sufficient excess sulphate to account for all of the measured acidity as sulphuric acid. However, because ammonium sulphate is frequently the major component of sub-micrometre aerosols in the United Kingdom[25] and because sulphate concentrations in rain are closely associated with aerosol sulphate concentrations[26], a significant proportion of the excess sulphate in rain is likely to occur as ammonium sulphate. This suggests that at least some of the acidity is associated with nitrate ions and that the second interpretation is unlikely to be tenable. On average an increase in hydrogen ion concentration of 10 μEquiv. l^{-1} was associated with increases in nitrate and sulphate concentrations of 4 and 10 μEquiv. l^{-1} respectively, which suggests an average contribution to acidity of 29% by nitric acid and 71% by sulphuric acid. This is consistent with conclusions reached for the USA[27] and Scandinavia[28].

The acidity of rain falling in the east and south-east of northern Britain is comparable with that in areas of Scandinavia and North America where populations of fish have been severely depleted[3,4]. The regional pattern of acidity shows no correlation with population density nor with the distribution of major sources of sulphur dioxide and nitrogen oxides within the region[29]. Associated studies have shown the acidity to be highly episodic with a complex frequency distribution, and that the most acid episodes (pH<4.0) arise from air masses that have had a trajectory over a major industrial region of the UK or Europe (D.F. and J.N.C., work in preparation). This implies that the scales of transport of the substances which acidify rain are much larger than the scale of northern Britain, and that sources within this region only influence the regional distribution of acidity in rain to a minor extent.

We thank the Forestry Commission, Nature Conservancy Council, Department of Agriculture and Fisheries for Scotland, Hill Farming Research Organisation, Freshwater Biological Association, Glasgow University, Ministry of Agriculture, Fisheries and Food, and Glasgow District Council for assistance with the collection of rain samples, Mr J. N. R. Jeffers and Professor F. T. Last for their helpful comments, and Miss M. McPherson for technical assistance. This work was financed by the NERC, the EEC and the UK Department of the Environment.

Geomagnetic secular variation as a precursor of climatic change

V. Courtillot, J. L. Le Mouel & J. Ducruix

Département des Sciences de la Terre, Université Paris VII and Institut de Physique du Globe, Université Paris VI, 2 Place Jussieu, 75230 Paris Cedex 05, France

A. Cazenave

Groupe de Recherches de Géodésie Spatiale, CNES, Toulouse, France

Long period trends in climate are usually associated with solar disturbance[1]. For example, a close similarity has been demonstrated[2,3] between variations in the length of day (LOD) with periods greater than about 10 yr and trends in several climatic indices over the past 150 yr. We point out here a correlation between variations in the Earth's magnetic field, the Earth's rotation rate and some climatic indicators, thus suggesting a possible long term influence of core motions on climate. We suggest that geomagnetic secular variation can be used to forecast a climatic change in the 1990s.

A good correlation has been established[2,3] between LOD variations and either global temperature θ (correlation coefficient 0.85; θ lagging LOD variations by ~5 yr, see Fig. 1) or the long period atmospheric and oceanic excitation function ψ^T related to near surface winds, changes in the atmospheric mass distribution and eustatic changes in sea level (correlation coefficient 0.75; ψ^T lagging LOD variations by ~15 yr see Fig. 9.6 in ref. 4; ψ^T is computed from ground level

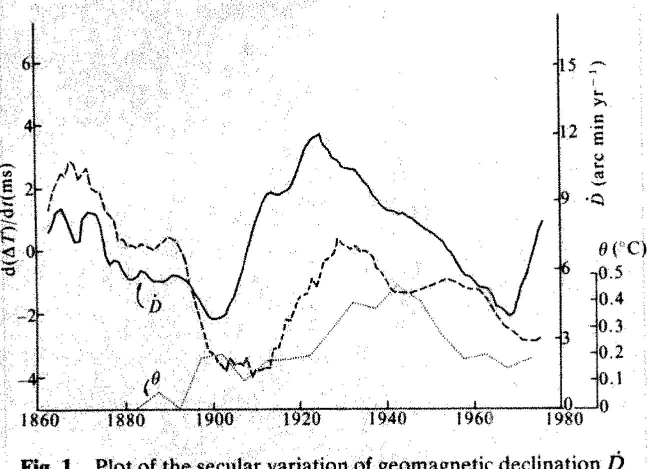

Fig. 1 Plot of the secular variation of geomagnetic declination $\dot{D}$ (solid curve), of the excess length of day $d(\Delta T)/dt$ (dashed curve) and of successive 5 yr averages of the temperature θ over the whole Earth (expressed as departures from the means for 1880–84, after Fig. 18.2 of ref. 1, dotted curve).

pressure sea-level data under the geostrophic assumption). Periods of increasing zonal circulation and increasing global surface temperature are found to correspond to periods of Earth acceleration, while periods of decreasing zonal circulation and decreasing global surface temperature correspond to periods of Earth deceleration. It has been further observed[3] that the excitation function ψ^T represents only about 10% of the amount necessary to explain the LOD variations. This led to the conclusion that it is not possible as yet to establish causal relationships between these phenomena and that one cannot decide whether (1) atmospheric circulation causes the long period changes in LOD, or (2) the fluctuations are both a consequence of a third phenomenon, or (3) the fluctuations in LOD cause the observed variations in the atmospheric circulation.

Although A.C. and Lambeck[3] note the problems related to phase lag between θ (or ψ^T) and LOD and the insufficient amplitude of the excitation function, they tend to reject hypothesis (3) because "the total mechanism for exciting the LOD changes remains to be explained".

More recently, Lambeck[4] has reviewed the long period or decade fluctuations in the Earth's rotation and discussed their geophysical origin. He notes that the role of the core is central, for it is the only sufficiently mobile part of the Earth with sufficient mass to modify the rotation by the observed amounts on that time scale. Out of the mechanisms proposed for core–mantle coupling, pressure or inertial coupling due to the ellipticity of the core boundary, topographic coupling due to bumps on the core–mantle interface and viscous coupling all seem to be inadequate[4,5]. Only electromagnetic core–mantle coupling, as suggested by Bullard *et al.*[6], survives the screening process despite severe uncertainties regarding the conductivity of the lower mantle and the core motions. The key observations required to resolve these uncertainties come from observations of the secular variation, in particular the rate of westward drift, of the geomagnetic field. The magnetic observations available to Lambeck did suggest some kind of correlation between LOD and geomagnetic variations, but the evidence was inconclusive.

The situation has been improved with the observation[7] that the secular variation of the geomagnetic field had undergone sharp accelerations of global extent. The last and best studied such phenomenon which occurred around 1970 is described in refs 8, 9, 14. The secular acceleration can first be used to infer an upper bound on the electrical conductivity of the lower mantle which is found to be of the order of a few hundred $\Omega^{-1}\,m^{-1}$ (refs 10, 11). This parameter is essential in any computation related to electromagnetic core–mantle coupling.

The correlation[7] between secular variation accelerations and extrema in LOD fluctuations has recently been put on a firmer and more systematic basis[12] with the demonstration of a good correlation between LOD variations and the secular variation of declination, observed for instance in European observatories where the longest records are available: the correlation for the period 1865–1975 is far more convincing than any previously reported (Fig. 1). The correlation coefficient is found to be about 0.8, with the magnetic variations leading LOD fluctuations by about 10 yr. J.L. Le M. and V.C.[13] suggest that a model of accelerated westward drift of the upper core based on the original model of Bullard *et al.*[6] accounts both qualitatively and quantitatively for the observations. In this model, the Earth's mantle, an upper core layer and the lower core are all electromagnetically coupled. A sudden torque applied at the time of a secular variation acceleration on a ~100 km thick upper core layer leads to a very fast response of westward drift as observed at the surface, and to a fast response of the lower core in the opposite sense. The lower core finally drags the mantle with a longer time-constant, of the order of 10 yr, as is typically observed in the decade fluctuations of LOD. Thus, these decade fluctuations are probably caused by rearrangements in core motions. Having found a mechanism which can excite LOD changes, it becomes natural to accept the hypothesis that fluctuations in LOD in turn are responsible for changes in atmospheric circulation (although the hypothesis of an indepen-

0028-0836/82/220386—02$01.00

dant common cause cannot be rejected). The observed phase lag between ψ^T and LOD and the amplitude of ψ^T are then at least qualitatively accounted for. There is an attractive causal chain whereby, over the decade period range, angular momentum is transferred from the core to the mantle and finally to the atmosphere (although details of the transfer mechanism remain to be studied).

Lambeck and A.C.[3] point out that LOD variations can be used as an indicator of future climatic trends. Lamb (ref. 1, p. 710) in his review of scientifically based climate forecasts notes that variations are commonly associated with long term variations of solar disturbance. He notes a considerable measure of agreement between the various forecasts, with a trend towards colder climates with weakened general atmospheric circulation which is expected to continue into the twenty-first century, in some cases with a sharp further cooling about 1980 and easier conditions for a time in the first half of the next century. The geomagnetic results referred to here suggest that changes in secular variation can be used as indicators of future LOD fluctuations[12,13] and, with an even longer time lead of 15–25 yr, as indicators of climatic changes, in particular changes in global surface temperature. The clearly established 1970 secular acceleration, which has now been maintained for a decade, suggests a correlated positive acceleration in LOD in the immediate future and the beginning of a period of steady increase in average global temperature around 1990 (±5 yr). K. Brian (personal communication) has recently pointed out a possible correlation between the frequency of geomagnetic reversals and deep ocean temperature over the past 55 Myr, thus suggesting another (very) long term relationship between climate and the Earth's magnetic field.

Spore–pollen evidence for early Oligocene high-latitude cool climatic episode in northern Canada

Geoffrey Norris

Department of Geology, University of Toronto, Toronto, Ontario, Canada M5S 1A1

Climatic cooling in the Eocene leading to markedly lower temperatures in the Oligocene has been documented in oxygen isotope studies in the North Pacific[1,2], New Zealand[3], South Pacific[4] and North Sea[5]. These lower temperatures in the Oligocene correspond to palaeoclimatic interpretations of North American leaf floras[6,7] which suggest a profound cooling occurring towards the end of the Eocene, indicated also in the southeastern United States from studies on mid-Tertiary spores and pollen[8]. Recently, Collinson *et al.*[9] have shown palaeobotanically that in southern England cooling occurred gradually starting in the latest early Eocene leading to two major periods of floristic change before the end of the Eocene. Thick Tertiary sections in the subsurface Mackenzie Delta region, Northwest Territories[10,11] provide well-preserved Palaeogene palynofloras[12] discussed here which indicate a cooler climate in the Oligocene following warm-temperate conditions in the Eocene. This widespread early–middle Oligocene cool episode is thus represented in both high-latitude and lower-latitude floras and seems to have been of global extent, persisting until towards the end of the Oligocene, but its precise dating remains a problem. In northern Canada it is followed by an amelioration of the climate in the late Oligocene which persisted probably until the middle Miocene. The rate of cooling during the Eocene and Oligocene may have varied depending on locality, but once established the cooler Oligocene climate exerted a profound influence on biotic development.

The subsurface Mackenzie Delta region (lat. 69 °N, long. 134 °W) includes a thick Tertiary molasse pile[11,13,14] deposited in the Richards Island Basin, representing several regressive depositional events formed by prograding deltas with marine deposits at the base. A relatively continuous Tertiary section is available here from the Palaeocene through to the Quaternary[11,12,15,16] but a major unconformity removes much of the Palaeogene in the southern part of the basin. The Imperial Nuktak C-22 well in the northern part of the basin has a relatively complete Tertiary section (Fig. 1) down to TD 12,650 ft in the middle Eocene part of the Richards Formation[12], a prodeltaic mudstone unit in excess of 5,000 ft thick which passes laterally southwards into the upper part of the Palaeocene–middle Eocene deltaic Reindeer Formation[11]. The Richards Formation is largely middle to late Eocene on the basis of the *Haplophragmoides* foraminiferal assemblage[11] and the presence near the base[12] of *Pistillipollenites mcgregorii* Rouse and the dinoflagellate cysts *Glaphyrocysta ordinata* (Will., and Dow) Stover and Evitt, *Cordosphaeridium gracile* (Eis.) Dav. and Will., and *Wetzeliella* sp. cf. *W. hampdenensis* Wilson. The precise placement of the Eocene–Oligocene boundary has not been achieved yet because ranges of terrestrial palynomorphs are uncertain at these high latitudes[12,15,17]. It probably occurs almost 1,700 ft below the top of the Richards Formation (Fig. 1) if Rouse[17] is correct in limiting the range of *Integricorpus* sp. (which probably does not occur below 9,500 ft in the Nuktak C-22 well) to the Oligocene. This interpretation is supported by the presence in the upper 1,700 ft of the Richards Formation of spore–pollen species from the putative Lower Oligocene of northeastern China[18].

The terrestrial flora of the middle–late Eocene part of the Richards Formation is diverse and contains taxa which can be

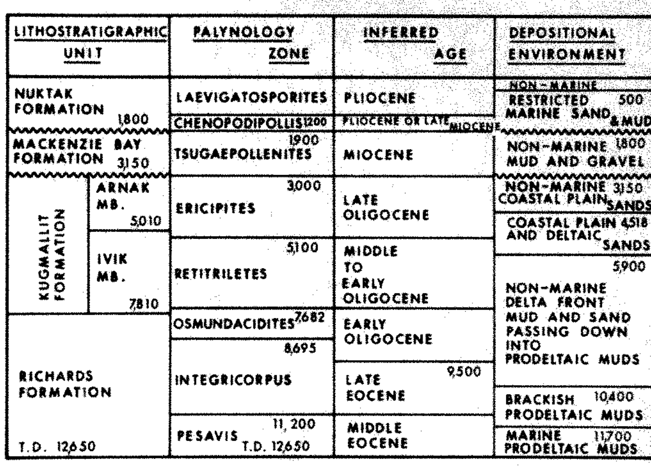

Fig. 1 Tertiary stratigraphy of Imperial Nuktak C-22 well. Palynostratigraphy, zonal names and age according to ref. 12, but Eocene–Oligocene boundary may occur lower (see text for discussion). Lithostratigraphy after Young and McNeil[11]. Numbers give the depth in feet.

0028–0836/82/220387—03$01.00

attributed to the following extant genera as discussed in detail elsewhere[8,12,15,19,20]: *Pinus, Sequoia, Metasequoia, Ulmus, Tilia, Castanea, Quercus, Tsuga, Pterocarya, Picea, Alnus, Betula* and *Sphagnum*. The latter four genera range into cool temperate or boreal regions at the present, but the remaining nine taxa are clearly temperate or warm temperate. This mixed palynoflora may be due to long-distance pollen transport from cooler—perhaps mountainous—regions of the northern Cordillera into warm temperate lowlands prevailing in the Mackenzie Delta region, a possibility supported by the sedimentology[13]. Mixing due to cavings in the cuttings samples may also introduce non-indigenous species into the samples, indicated by the lack of *Picea* and *Betula* in core samples compared with cuttings samples of the Richards Formation. Thus the indigenous palynoflora of the Richards Formation indicates temperate or warm temperate climates in the middle and late Eocene, possibly persisting into the earliest Oligocene. A sharp decrease in diversity of palynofloras and extinction of several species occurs within the prodeltaic mudstones of the early Oligocene part of the Richards Formation between 9,600 and 8,900 ft and is not associated with a major facies change. The Ivik Member of the superadjacent Kugmallit Formation contains a less diverse palynoflora of notably different composition, particularly in the upper part of the member, compared with the Richards Formation. Miospores attributed to extant taxa in the Ivik floras include *Sphagnum, Picea, Pinus, Lycopodium, Osmunda, Tsuga, Alnus, Betula, Carpinus* and *Pterocarya*. However, it is significant that a variety of fungal spores and hyphae, bryophytes and pteridophytes, *Sequoia, Ulmus, Tilia, Quercus, Castanea*, and other thermophylic angiosperms which are common in the Eocene–earliest Oligocene Richards Formation disappear in the lower half of the early–middle Oligocene[12] Ivik Member (below 6,500 ft) but reappear higher in the late Oligocene[11,12] Arnak Member of the Kugmallit Formation accompanied by ericaceous pollen amongst others. The lower Ivik palynofloral changes occur in an interval of rhythmic alterations of mudstone and sandstone in medium-scale coarsening-upward trends typical of progradational deltas. No major facies change occurs in this interval. The lack of thermophylic angiosperm taxa in part of the early and perhaps middle Oligocene indicates a significant cool interval, possibly cooler than the climate of the present Great Lakes region where these taxa terminate their northern ranges in the pollen rain[21]. Their resurgence in the Arnak Member is accompanied by an overall average doubling of terrestrial species numbers. This cannot be attributed entirely to a change to alluvial or deltaic conditions from the delta-front conditions of the Ivik Member because other similar progradational cycles in the Richards Island Basin[11] are not characterized by such a change in palynofloral diversity (unpublished data). The increased diversity, however, may be related to an amelioration of climate as warm temperate conditions were re-established.

The reasons for this early to middle Oligocene cool interval are not clear. An explanation in terms of a change in obliquity of the ecliptic[6,7] is not considered dynamically acceptable[22], nor is it in accord with other floral and faunal evidence of pronounced Palaeogene seasonality indicating significant annual periods of winter darkness at high latitude[23]. However, a cooler interval during the Oligocene appears to be of global extent, affecting oceanic water temperatures in both hemispheres[1-4] affecting the marine biota[22,24], and affecting high and low latitude terrestrial floras for at least 5 Myr. In Central Europe, however, the coolest mid-Tertiary terrestrial floras are late Oligocene[25], in contrast to the early and middle Oligocene cooling indicated in many regions as outlined above. In central British Columbia, Piel[26] reported humid warm temperate to sub-tropical climates for the putative early Oligocene Australian Creek Formation of central British Columbia based on the presence of miospores attributed to *Metasequoia, Picea, Pinus, Podocarpus, Acer, Betula, Carya, Castanea, Engelhardtia, Fagus, Fraxinus, Juglans, Liquidambar, Nyssa, Tilia* and *Ulmus/Zelkova*. Rouse and Mathews[27], however, have interpreted this assemblage to be late early Oligocene representing a mixed mesophytic warm temperate forest, similar to those of southeastern United States or the upper Yangtze River Valley of China. The age of these palynofloras is contentious but may be indicated by the report of associated titanothere teeth (a brontotherine genus, possibly *Megacerops* or *Brontotherium*) said to be late early Oligocene[27]. On the other hand, the presence here of species of *Parviprojectus, Pesavis, Ctenosporites* and *Striadiporites* points to a correlation with the putatively middle and late Eocene *Pesavis* and *Integricorpus* zones in the Richards Island Basin[12] (Fig. 1). Climatic gradient may have strongly affected the differential attenuation of species ranges at different latitudes in the late Palaeocene, thus allowing the extension of arctic Eocene palynomorph species into the early Oligocene at lower latitudes. Until this matter is resolved, however, the possibility exists that the *Integricorpus* zone may be entirely early Oligocene and, therefore, that the climatic cooling indicated by palynofloral data in the upper part of the *Integricorpus* zone and higher in the western Arctic may have occurred later than the Eocene–Oligocene boundary.

This dramatic temperature drop in the Oligocene leads to a paradox[28]. Cooler global air and water temperatures would lead to decreased evaporation rates on a global scale, but, nevertheless, moisture continued to be transported to Antarctica where ice continued to accumulate and reached sea level at the end of the Oligocene. Ice accumulation in the Arctic Ocean did not commence until some time in the Pliocene[29] when the Miocene temperate terrestrial floras were replaced by boreal tundra floras[12], and at which time a major episode of molluscan extinction occurred globally, probably in response to a lethal decline in temperature[30].

The palaeooceanographical changes at the Eocene–Oligocene boundary have been related[24] to cooler air temperatures and floral changes on land. O'Keefe's hypothesis[22] for early Oligocene cooling postulates the development of tektite ring system around the Earth which cast a shadow on the winter hemisphere. This would lead to a temperature drop of ~20 °C and remain stable for several million years. Synchronous global cooling could also result from a variation in the solar output[23]. Progress in understanding the mechanisms will depend in part on increased precision in dating Palaeogene terrestrial deposits. The exact timing of terrestrial floral changes from region to region must be determined and compared with biotic and isotopic changes in the oceans. If the floral and faunal changes are indeed synchronous globally, a pervasive and almost instantaneous mechanism must be sought. If the terrestrial floral changes accompanying cooling prove to be diachronous, a mechanism dependent on local or regional changes in geography, oceanic circulation, or tectonics may be implicated.

This work was supported by an operating grant from the Natural Sciences and Engineering Research Council (NSERC) of Canada, a contract from the Department of Supply and Services, Ottawa and a NSERC strategic energy grant for Basin Analysis at the University of Toronto. Samples and data were provided by the Institute of Sedimentary and Petroleum Geology, Calgary, Austin and Cumming Exploration Consultants, and Imperial Oil Ltd. Dr Glenn Rouse provided valuable information and discussion.

Carbon cycle changes of the Zechstein Sea: isotopic transition zone in the Marl Slate

M. Magaritz

Isotope Department, The Weizmann Institute of Science, Rehovot, Israel

P. Turner

Department of Geological Sciences, The University of Aston, Gosta Green, Birmingham B4 7ET, UK

The carbon isotope composition of carbonate rocks is one parameter used to study the carbon, sulphur and oxygen cycles through geological time[1,2]. The understanding of these interrelated cycles is important in quantitative flux modelling of sedimentary rocks. The carbon isotope composition in the large reservoir of dissolved carbonate in ocean water is a result of mass balance between the amount of carbon in the reduced organic reservoir and the oxidized carbonate reservoir at any given stage. The reduced carbon reservoir preferentially sequesters ^{12}C owing to biological fractionation processes. Any change in the removal ratio of oxidized/reduced carbon will be reflected by the change of the δ^{13}C value of the oceanic carbonate system. Here we present a detailed study of the change in ^{13}C which took place at the base of the Upper Permian Zechstein sequence.

On the basis of measurements of carbon isotopes on rocks of various ages, early models assumed that the mean δ^{13}C (carbonate) values were constant[3–6]. In recent years, however, descriptions of secular variation of δ^{13}C values in carbonate rocks during the Mesozoic[7,8] and Cenozoic[9,10] have become established. These secular variations are explained by large scale burial of organic material and are associated with ocean wide changes such as formation of anoxic conditions and sea-level fluctuation[11].

The same mechanism is used in modelling mass balance chemical and isotopic variation in the C–S–O system between geological periods[1–3]. These mass balance models[2,3] assume that high δ^{13}C values prevail for the whole of the Permian period[12] but, in fact, the detailed evidence indicates that only certain parts of the Permian are characterized by these high values[13]. The ^{13}C maximum in carbonate rocks discussed here starts at the base of the Upper Permian Zechstein sequence and lasts up to the top of the third Zechstein cycle[14] when fully marine conditions terminated. Because such a change also means changes in the amount of oxygen tied to the carbon system then it may be expected to be reflected in the oxygen cycle and the cycles of other elements to which oxygen is related (sulphur and iron).

Some of the carbonate rocks of the Permian period exhibit anomalous enrichment in ^{13}C relative to other Phanerozoic rocks. These high δ^{13}C values are observed even if one mixes all the Permian rocks analysed and compared them with rocks from other periods[12,15]. The fact that some of the Permian carbonate rocks from various parts of the world reach values of up to +7‰ (relative to the normal fluctuation range −1 to +3‰)[16–19] indicates that extreme changes in the C–O–S cycle took place. These changes had also been predicted from the anomalously low values of δ^{34}S in sulphates[1,20]. These two values (δ^{13}C and δ^{34}S) are negatively correlated if one uses mean values for periods. The model showing the relation between the carbon and sulphur cycle based on isotopic data, assuming scales for mixing in the sedimentary cycle of the order of 120–240 Myr, is given by Schidlowski *et al.*[3].

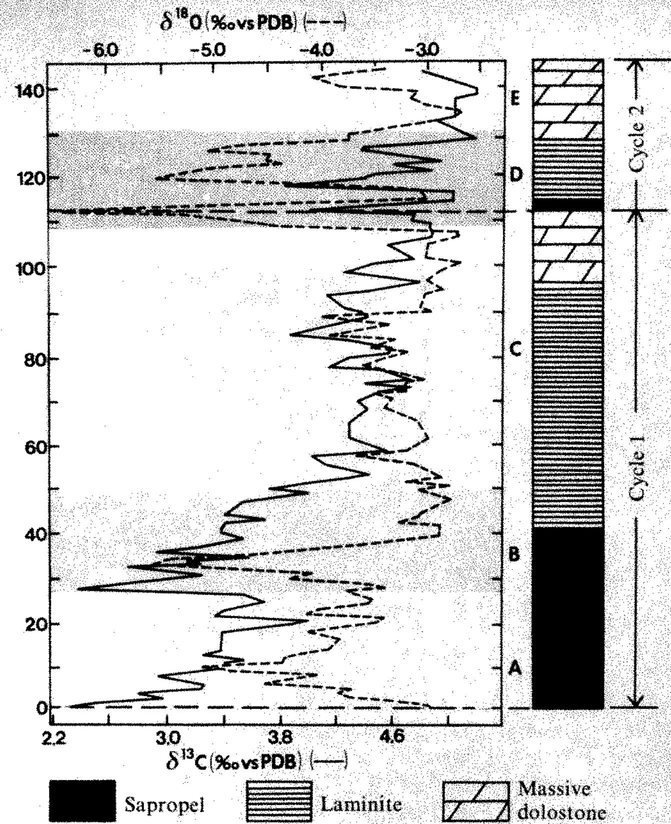

Fig. 1 Carbon and oxygen isotope composition of VT8 core dolomites. Note the spikes of low values of δ^{18}O which occur twice in zone A and zone B representing freshwater reflux of the Zechstein basin. δ^{13}C increases rapidly in zone B and remain constantly high in the upper part of the Marl Slate (zones C–E).

Our understanding of the processes which cause the shift in isotopic ratios will be greatly improved by detailed studies of the transition zone in which the change in ^{13}C is recorded. Magaritz *et al.*[13] noted the presence of the transition zone at the base of the Zechstein sequence in the Marl Slate and its German equivalent the Kupferschiefer. We now discuss the results of a detailed investigation of this isotopic transition zone within the Marl Slate of North-East England.

The Marl Slate represents the earliest extensive marine transgression into the Rotliegend inland drainage basin whose floor lay well below the contemporaneous sea level in Permian times[21]. The preservation of unconsolidated dunes beneath the Marl Slate indicates that the Zechstein transgression was rapid, forming an inland sea up to 250 m deep in places[22]. The Marl Slate is usually less than 1-m thick and mainly comprises organic-rich, dolomitic laminites and closely resembles much younger sapropelic sediments in which lack of bioturbation due to the absence of benthic fauna is a characteristic feature. The present results come from a single core (VT8) drilled by the National Coal Board off the coast of North-East England east of Seaham Harbour (NZ 486 509). This core shows two cycles

0028–0836/82/220389—02$01.00

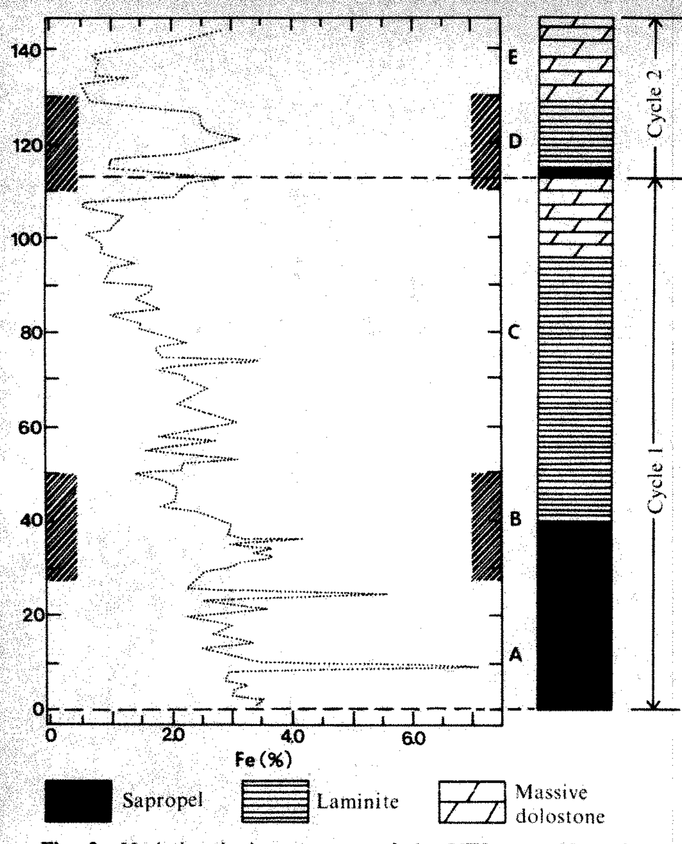

Fig. 2 Variation in iron content of the VT8 core. Note the similarity between the $\delta^{18}O$ curve and iron content.

of sedimentation which include the sequence: sapropel → dolomitic laminite → finely crystalline dolostone (Fig. 1). The core was divided into 144 1-cm thick segments which were used for isotopic and chemical measurements. The carbonate isotopic data (Fig. 1) indicate (1) the lack of correlation between $\delta^{18}O$ and $\delta^{13}C$ values; (2) a gradual enrichment in ^{13}C from the bottom (+2.3‰) to the top (+5.1‰); (3) a $\delta^{18}O$ pattern which exhibits spikes of very low values; (4) a very clear correspondence between the lithological variation and changes in $\delta^{18}O$, a feature which indicates that the isotopic changes are original and not the result of later recrystallization. The preservation of such detailed structure in the isotopic record of the Marl Slate is consistent with its deposition in an anoxic non-bioturbated environment. The organic-rich laminae are interpreted as seasonal phytoplankton blooms and thus enable assessment of the time scale of the events recorded in the core. Oelsner[23] counted the laminae in the Kupferschiefer and arrived at an age of 17,000 yr. Our observations are consistent with this suggesting an overall sedimentation of $\sim 0.08\ \mathrm{mm\ yr^{-1}}$. This value is close to the rate estimated (0.05–$0.07\ \mathrm{mm\ yr^{-1}}$) for the equivalent unit (the Stinkschiefer) in the second Zechstein cycle[24] but greater than the rate of sedimentation of anoxic sediments in the Lower Cretaceous North and South Atlantic ocean which is estimated[25] at $0.01\ \mathrm{mm\ yr^{-1}}$. Our overall estimate of the time represented by the VT8 core is 18,000 yr and the large change in $\delta^{13}C$ values took place within this time interval. The core section can be divided into five macrosegments on the basis of the isotopic variation (Fig. 1), and the main carbon isotope shift occurs in the 22 cm of segment B. This is probably equivalent in time to ~3,000 yr. Even shorter period events are detected in the core in both the oxygen and carbon isotopic record. The shift of more than 1‰ in $\delta^{13}C$ values which occurs within 3 cm (~400 yr) at the bottom of zone A is larger than any shift reported in the Cretaceous[9]. The $\delta^{18}O$ spikes, which are seen in several parts of the core occur within depositional periods of < 5 cm, represent flooding of the basin by freshwater. The period of flooding is similar to that recorded in the Pleistocene sapropelic sediments of the eastern Mediterranean[26]. The low $\delta^{18}O$ values coincide with enrichment of iron (as pyrite) in the sediment (Fig. 2). This correlation indicates that the formation of anoxic conditions was associated with freshwater flooding of the basin. We take this to indicate that in these conditions there was an abundant supply of iron which enhanced iron suphide formation.

The gradual change in $\delta^{13}C$ values in zone B and the early cycle of changes in zone A are considered to represent a change in the dissolved carbonate in the Zechstein Sea. From that point on the $\delta^{13}C$ values of the carbonates in the higher Zechstein cycles remain highly enriched in ^{13}C (refs 13, 14, 19). Such enrichment in ^{13}C is also seen in basins of Permian age other than the Zechstein in various parts of the world[16–18].

We argue that this change in the isotopic composition of the dissolved carbonate in the Zechstein Sea must reflect a similar change on an ocean wide scale. This is because a continuous supply of dissolved salts is needed to account for the succeeding thick carbonate/evaporite sequence. There is no obvious alternative supply of dissolved materials in view of the fact that the other source of dissolved carbonate (freshwater reflux) would result in low $\delta^{13}C$ values. This is evidenced by the less positive $\delta^{13}C$ values seen in the zones of $\delta^{18}O$ minima (Fig. 1).

It is not clear whether all the water column of the Permian ocean (all the oceanic bicarbonate reservoir) changed its carbon isotopic composition (reflecting a large variation in the C–S–N cycle) or whether the change occurred only in the top oceanic layer, because of the lack of a deep oceanic sequence for comparison. The size of the shift in $\delta^{13}C$ values in the Permian period is at least twice the size of any shift in the Cretaceous. Simple mass isotope calculations show that a shift of 3‰ in $\delta^{13}C$ will correspond to almost double the amount of organic material removed from the system at a specific time. Enrichment of 0.7‰ in $\delta^{13}C$ was estimated for the mean dissolved carbonate in the ocean water in a period < 10,000 yr for the Pleistocene glacial/interglacial transition[27]. The shift recorded in the Permian probably took place at a similar rate, but the effect was tripled (~2.3‰).

The $\delta^{34}S$ values of the Zechstein sulphates are all depleted in ^{34}S (ref. 28) which indicates that the accompanying effect in the sulphur cycle had already taken place by the end of the first Zechstein cycle. The very widespread regression ending the Permian Period and the Zechstein Sea was followed by the return to normal $\delta^{13}C$ values in early Triassic carbonates[29].

Hotspots, polar wander, Mesozoic convection and the geoid

Don L. Anderson

Seismological Laboratory, California Institute of Technology, Pasadena, California 91125, USA

The geoid bears little relation to present tectonic features of the Earth other than trenches and hotspots. The Mesozoic supercontinent of Pangea, however, apparently occupied a central position in the Atlantic–African geoid high. This and the equatorial Pacific geoid high contain most of the world's hotspots[1,2]. The plateaus and rises which are now in the western Pacific formed in the Pacific geoid high and this may have been the early Mesozoic–late Palaeozoic position of a large part of Asia and other fragments of the Pacific rim continents. The major global geoid highs were regions of extensive Cretaceous volcanism and may be the former sites of continental aggregations and mantle insulation and, therefore, hotter-than-normal mantle. The pent-up heat causes rifts and hotspots and results in uplift, magmatism, fragmentation and dispersal of the continents and the subsequent formation of plateaus, aseismic ridges and seamount chains which cause a global rise in sea-level. Convection in the upper mantle caused by such lateral temperature gradients is intrinsically episodic. A geoid anomaly of 50 m can be formed in about 100 Myr by continental insulation. We show here that such geoid anomalies are long-lived and may be used to remove the ambiguity in early Mesozoic–late Palaeozoic plate reconstructions. Geoid highs control the rotation axis of the Earth and, in effect, bring long-lived continental aggregations to the Equator. Many aspects of continental geology such as vertical-tectonics and episodicity of magmatism and transgressions can be explained by continental insulation.

The Earth's largest positive geoid height anomalies are associated with subduction zones and hotspots and bear no simple relationship to other present-day tectonic regions such as continents and ridges. When the subduction-related geoid highs are removed from the observed field the residual geoid shows broad highs over the central Pacific and the eastern Atlantic–African regions[1,2]. Like the total geoid, the residual geoid does not reflect the present-day distribution of continents and oceans and shows little trace of the ocean ridge system. Geoid highs, however, correlate with hotspots[1,2] and with regions of anomalously shallow ocean floor and sites of extensive Cretaceous volcanism.

The Atlantic–African geoid high extends from Iceland through the North Atlantic and Africa to the Kerguelen plateau and from the middle of the Atlantic to the Arabian penninsula and western Europe. Most of the Atlantic, Indian Ocean, African and European hotspots are inside this anomaly. Iceland, Trindade, Tristan, Kerguelen, Reunion, Afar, Eiffel and Jan Mayan form the 20-m boundary of the anomaly and seem to control its shape. The Azores, Canaries, New England seamounts, St Helena, Crozet and the African hotspots are interior to the anomaly. This, plus similar evidence in the Pacific, suggests that geoid highs may be associated with hotter-than-normal mantle.

Although the geoid high cuts across present-day ridges and continents there is a remarkable correspondence of the predrift assemblage of continents with the present location of both the geoid anomaly and hotspots (Fig. 1). Reconstruction of the mid-Mesozoic configuration of the continents[3] reveals, in addition, that most of the large shield areas of the world are contained inside the Atlantic–African geoid high. Most of the Phanerozoic platforms are also in this area, the main exceptions being the Siberian and South-East Asian platforms.

The area inside the geoid high is also characterized by higher-than-normal present elevations, for example, in Africa, the North Atlantic[4] and the Indian Ocean south-east of Africa[4]. This also holds true for the axial depth of oceanic ridges[5]. Most of the continental areas were above sea level from the Permo-Carboniferous to the Triassic, at which time there was subsidence in eastern North and South America, central and southern Africa, Europe and Arabia[6]. The widespread uplift, magmatism, breakup and initial dispersal of the Pangean landmass apparently occurred while the continents were centrally located with respect to the present geoid anomaly. The subsequent motions of the Atlantic bordering plates were largely directed away from the anomaly. This suggests that the residual geoid high, hotspots, the distribution of continents during the late Palaeozoic and early Mesozoic and their uplift and subsequent dispersal and subsidence are all related. The shields are regions of abnormally thick lithosphere. The thickest lithosphere is in eastern and central North America, northeastern South America, northwestern and central Africa and northern Siberia[7]. These regions were all within the area of Fig. 1 at 200 Myr.

The area in Fig. 1 also experienced exceptional magmatism during the Mesozoic. The great flood basalts of Siberia and South Africa were formed during the Triassic and Jurassic, possibly at the sites of the Jan Mayen and Crozet hotspots[3]. The plateau basalt provinces of South-east Greenland and Brazil were formed during the Cretaceous and early Cenozoic, possibly at the sites of the Iceland and Tristan hotspots[3]. The Walvis Ridge, the Rio Grande Rise and the plateaus in the western Indian Ocean are mainly on Mesozoic and Palaeocene crust. A large part of the Pacific also experienced extensive on- and off-ridge volcanism in the Cretaceous[8,9]. This extensive ridge and hotspot volcanism may have caused the rapid rise in sea level during the Jurassic and Cretaceous[9]. If sea level[10] can be used as a guide to the volume of the ocean basins then from the end of the Cretaceous to the end of the Oligocene was a period of less intense oceanic volcanism and subsidence of the oceanic and continental crust. Sea-level variations may therefore indicate that the thermal and geoid anomalies formed in the Palaeozoic and have attentuated since the early Mesozoic.

Much of the Pacific rim appears to be terrain which originated in the Pacific[11,12]. The possibility of a continent centrally located in the Pacific has been discussed for some time[13], but its location has been an enigma and its size uncertain. The central Pacific geoid anomaly, like the Atlantic–African anomaly, may mark the early Mesozoic or late Palaeozoic location of a large continental landmass and, later, the site of extensive Cretaceous ridge crest and midplate volcanism.

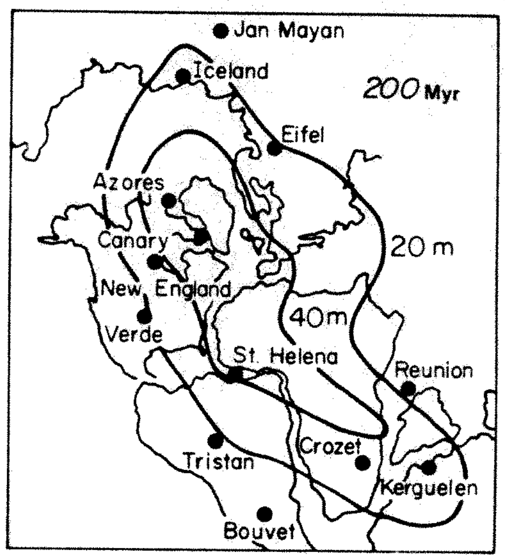

Fig. 1 The Jurassic configuration of the continents, based on Morgan's hotspot-based reconstruction[3], superposed on the Atlantic–African residual geoid high[1,2]. Note that most of the stable shield areas are inside the 20-m contour. Selected hotspots (●) are also shown.

0028-0836/82/220391—03$01.00

Palaeomagnetic data indicate that various blocks of Asia such as Kolyma, Sikhote Alin, Sino-Korea, Yangtze, South-east Asia and Japan have moved northwards by up to 32° since the Permian[11]. It is unlikely that they were in the vicinity of Australia or associated with Gondwana[11] and a central Pacific location is likely. Part or all of Alaska and northwestern North America were also far south of their present positions, relative to North America, in the Permian[12]. The same may be true of California, Mexico, Central America and other accreted terrain in the Pacific rim continents.

The central Pacific residual geoid high (>20 m) extends from Australia to the East Pacific Rise and from Hawaii to New Zealand. It encompasses most of the Pacific hotspots and is approximately antipodal to the Atlantic–African anomaly.

The western Pacific contains numerous plateaus, ridges, rises and seamounts which have been carried far to the north-west from their point of origin. The Ontong–Java plateau for example, presently on the Equator, was formed at 33–40°S in the mid-Cretaceous[14]. The Hess rise, Line Islands ridge and Necker ridge were formed in the Cretaceous on the Pacific, Farallon and Phoenix ridge-crests[8] which were, at the time, in the eastern Pacific in the vicinity of the polynesian seamount province. This ridge-crest volcanism was accompanied by extensive deep-water volcanism[8,9] and, possibly, rapid seafloor spreading[15]. The Caribbean and Bering Seas may have formed at the same location and carried northward on the Farallon and Kula plates. It is significant that the Caribbean and the anomalous regions in the Pacific have similar geophysical and geochemical characteristics[16].

The Pacific geoid high also has anomalously shallow bathymetry[4,5]. This shallow bathymetry, the 'Darwin Rise', extends from the East Pacific Rise to the north-west Pacific in the direction of plate motion, and includes the central and south-west Pacific hotspots. The extensive volcanism in the central western Pacific between ~70 and 120 Myr (refs 8, 9, 16) occurred about 60°–100° to the south-east of its present position, in the hotspot frame. This would place the event in the vicinity of the southeastern Pacific hotspots and the eastern part of the geoid anomaly. This suggests that the anomaly dates back to at least early Cretaceous. A similar thermal event in the Caribbean[17] may mean that it was also in this region in the Cretaceous, particularly since the basalts in the Caribbean are similar to those in the western Pacific[16].

Going back even further are the Triassic basalts in Wrangellia[11] of northwestern North America and the Permian greenstones in Japan[13], both of which formed in equational latitudes and subsequently drifted to the north and north-west respectively. We suggest that they also formed in the Pacific geoid high.

Plate reconstructions based on palaeomagnetism or palaeoclimatology have arbitrary longitudinal relationships between the plates. Figure 2 gives a possible late Palaeozoic reconstruction which places Africa, South America, Antarctica and Europe in the Atlantic–African geoid high and Asia in the Central Pacific geoid high. This is similar to previous reconstructions[6,18] in that North America is adjacent to western South America but Asia is placed much closer to North America. The biogeographic similarities between Asia and western North America are well known[19] and the placement of North America provides the continuity between the major land masses which is suggested by some palaeontological data. With this reconstruction Gondwanaland and Asia were the continental aggregations that caused the geoid anomalies and they brought themselves to the Equator, by the Goldreich–Toomre mechanism[20], before their breakup and dispersal. Parts of Alaska, western North America and West Antarctica may also have migrated away from the Pacific geoid high.

We propose that episodicity in continental drift, polar wander, sea-level variations and magmatism are due to the effect of thick continental lithosphere on convection in the mantle and that supercontinents 'insulated' large parts of the mantle for more than 10^8 yr. The excess heat caused uplift by thermal expansion and partial melting and, eventually, breakup and dispersal of the supercontinents. A large geoid high is generated by this expansion and, if this is the dominant feature of the geoid, the spin axis of the Earth would change so as to centre the high on the Equator[20], much as it is today. The continents stand high while they are within the thermal and geoid high and subside as they drift over cooler mantle.

The association of the Atlantic–Africa geoid high with the former position of the continents and the plateau basalt provinces with currently active hotspots suggests that Mesozoic convection patterns in the mantle still exist, as proposed by Menard.[21]. The mid-Atlantic and Atlantic–Indian ridges and the Atlantic, African and Indian ocean hotspots and the East African rift are regions where heat and material is being efficiently removed from the uppermantle in the Atlantic–African geoid high. The East Pacific rise and the Pacific hotspots are serving the same role in the Pacific geoid high. If geoid anomalies and hotspots are due to a long period of continental insulation and if these regions had higher-than-normal heat flow and magmatism for the past 100 Myr, then we might expect that these features will wane with time.

Global isostatic geoid anomalies can be written[22,23]

$$N \cong \frac{2\pi G}{g}\frac{(l+2)}{(2l+1)}\rho h \delta h$$

where G is the gravitational constant, g is the acceleration of gravity, l is degree of spherical harmonic, ρ is density, h is the depth of the anomalous region and δh is the elevation anomaly associated with the mass anomaly. For a coefficient of thermal expansion of $3\times10^{-5}\,°C^{-1}$, a temperature excess of 70 °C in the upper 500 km of the mantle gives $\delta h = 1$ km and $N = 50$ m for $l = 3$. A similar effect can be achieved by 1% melting. Some combination of heating and melting is likely.

The average heat loss through oceanic areas is $2.4\ \mu cal\ cm^{-2}\ s^{-1}$ (ref. 24). Continental heat flux is about 0.6 of this in spite of the higher radioactivity of continental crust. If we assume that the oceanic heat flux is available everywhere and that there is a balance between heat production and heat loss under oceans the temperature rise under an extended stationary continent is 0.60 °C Myr^{-1} for a 500-km thick column or, alternatively, 6% melting, using a latent heat of 100 cal g^{-1}. Thus, 100 Myr of continental insulation can give the observed geoid and elevation anomalies. The continental aggregations were relatively stable for at least this long[6,18]. True polar wander is likely while the geoid anomalies are developing.

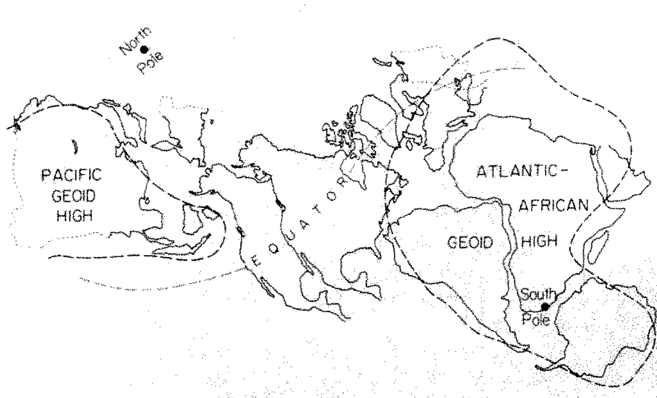

Fig. 2 Possible late Palaeozoic continental configurations relative to the current residual geoid highs and the Palaeoequator. This is similar to previous reconstructions[6,18] except that the Pacific geoid high is used to position eastern Asia. Australia and India are not shown. The dashed lines enclose regions of high elevation (>20 m) of the residual geoid[1,2]. If the geoid highs were generated under Gondwana and Asia they formed in high latitudes and were subsequently brought to the Equator by their affect on the rotation axis of the Earth. The geoid highs are currently centred on the Equator. Parts of western North America may also have been in the Pacific geoid high. This and the eastern migration of North America, relative to South America, during the Palaeozoic are indicated schematically by plotting North America in two positions. Asia is probably also fragmented at this time[11].

After the continents move off the mantle which they have been insulating the thermal and geoid anomalies decay by convection in the mantle and conduction through the newly-formed oceanic lithosphere. The rate of temperature decrease, $\dot{\theta}$, can be written

$$\dot{\theta} = \frac{-\kappa\theta}{h^2}\left(\frac{R}{R_{cr}}\right)^{1/3}$$

where κ is the thermal diffusivity, R is the Rayleigh number and R_{cr} is the critical Rayleigh number. For $R_{cr} = 10^3$, $R = 10^6$, $\kappa = 10^{-2}\ \mathrm{cm^2\ s^{-1}}$, $\theta = 10^3$K and $h = 500$ km

$$\dot{\theta} = -0.12\ \mathrm{°C\ Myr^{-1}}$$

This gives a decrease in elevation of 180 m in 100 Myr. The corresponding geoid height reduction is ~9 m. Thus, geoid anomalies caused by continental insulation are long-lived features.

Horizontal temperature gradients can drive continental drift[25-28]. The velocities decrease as the distance increases away from the heat source and as the thermal anomaly decays. The geoid high also decays. Thick continental lithosphere then insulates a new part of the mantle and the cycle repeats. Periods of rapid polar motion and continental drift follow periods of continental stability and mantle insulation.

The relatively slow motion of the continents[29] or the pole[30], or both, during the Permian and the relative stability of sea level during this period suggest that the geoid anomalies were developing at this time. Continental drift velocities[29] and sea level[10] changed rapidly during the Triassic and Jurassic. This we interpret as the start of extensive rift and hotspot magmatism and the decay of the thermal and geoid anomalies.

The rotation axis was apparently stable from ~200 to 80 Myr (ref. 3) but has shifted with respect to the hotspot reference frame for at least the past 65 Myr (ref. 31). In the framework of our model this shift would represent a growth of the equatorial region of the Atlantic–African high due to continued insulation by Africa, a decay of the South Pacific or North Atlantic portions of the highs due to extensive Cretaceous volcanism, a reconfiguration of the world's subduction zones or some combination.

It is difficult to separate true polar wander and the apparent wander due to continental drift. In the present model they are intimately related. If ridge volcanism is precluded for an extensive period of time, as seems to have been the case in the mantle under Pangea during the early Mesozoic and late Palaeozoic, the mantle will warm up and/or partially melt. In either case a geoid anomaly will develop. This anomaly will affect convection and plate motions in a manner previously suggested[25,32] and will also affect the rotation axis of the Earth[20]. As the thermal anomalies seem to be long-lived and it takes a long time to establish a new thermal regime, major shifts of the rotation axis due to this mechanism will be infrequent and gradual.

Goldreich and Toomre[20] have shown that density inhomogeneities caused by convection in the mantle will control the orientation of the spin axis and that large shifts of the pole, that is, true polar wander, are to be expected in a dynamic Earth. The present orientation of the pole apparently bears no relationship to the present distribution of continents, ridges or trenches[32]. On the other hand, the geoid bears a close relationship to the present distribution of hotspots and to the former distribution of continents and areas of extensive Cretaceous ridge and plateau volcanism.

If our conjecture about the relationship between geoid highs and the former position of continents is correct, then we would conclude that there were two large antipodal continental aggregations in the Permian. The antipodal supercontinents were presumably formed by a previous episode of continental drift which swept buoyant material away from an earlier configuration of thermal and geoid highs. Using sea level as a guide, with high sea-level indicating rifting and extensive sea floor volcanism, the supercontinents were stable from 300 to 150 Myr ago and the previous continental assemblages were dispersing between 500 and 350 Myr. The suggestions that hotspots may be a primary cause of continental breakup[3] and that they affect polar wander[1,2] are not new. What is new is the suggestion that continents cause geoid anomalies and hotspots and, indirectly, control the rotation axis of the Earth.

I thank Brad Hager, Clem Chase, Kevin Burke and Henri Nataf for reviewing the manuscript, and Lynn Sykes for stimulating discussions. Art Boucot gave useful advice on biogeography. Brad Hager showed me how to calculate global isostatic geoid anomalies. This work was supported by NASA grant NSG-7610. Development of earthquake-induced fissures in the Main Ethiopian Rift

Laike M. Asfaw

Geophysical Observatory, Addis Ababa University, PO Box 1176, Addis Ababa, Ethiopia

A series of episodes involving land subsidence along an elongated formation of pits connected by fissures have been observed in various parts of the Main Ethiopian Rift[1-4] over the past 25 yr. Although other workers[1] have proposed a possible relationship between tectonics, subsurface drainage and subsidence no field observations have related earthquakes to such development of fissures. I present here the first observation of the development of fissures following an earthquake swarm with local magnitude, $M_L \leqslant 4$ in the Main Ethiopian Rift north of the Fentale Mountain (Fig. 1) between January and March 1981 (ref. 5). This showed that there could be a variety of developments in the evolution of earthquake-induced fissures depending on geological formation, vegetation cover and drainage; the implication on similar earlier observations is considered.

That the Afar Depression and the Main Ethiopian Rift are regions under tension is well established through geodetic

0028-0836/82/220393—03$01.00

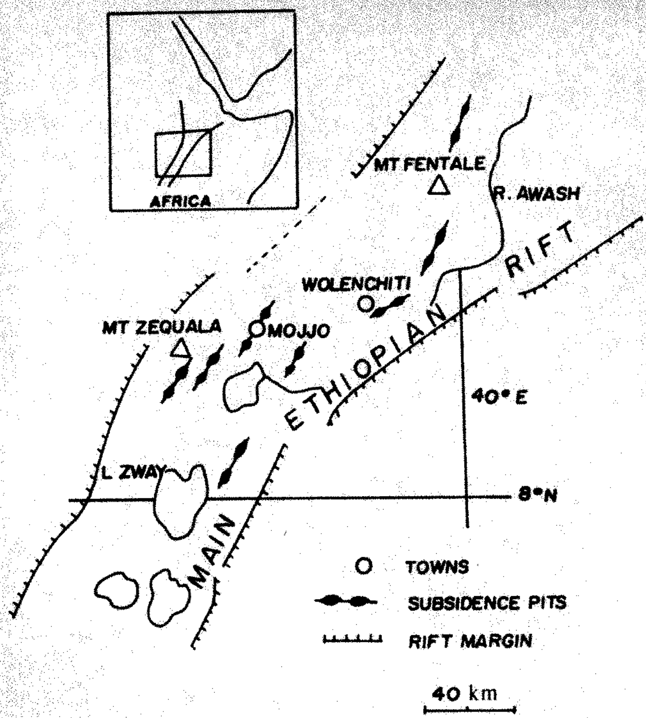

Fig. 1 Sites of subsidence pits associated with fissures in the Main Ethiopian Rift including the event of January–March 1981 north of the Fentale Mountain.

measurements and other surface observations[6,7]. The surface observations consist of tensional fissures and faults along the three major rift trends of the Red Sea, Gulf of Aden and the Main Ethiopian Rift[8,9]. In the Main Ethiopian Rift the Wonji Fault Belt is characterized by fissures and faults[10] and sometimes fissures can be identified by elongated green belts of vegetation in this rift. Here the sediment deposit, rainfall and vegetation make the development of fissures more complicated and varied compared with those in the more arid rifts in the Afar Depression trending in the Red Sea and the Gulf of Aden directions.

Earlier investigators[1-4] had noted subsidence and erosion associated with fissures in the Main Ethiopian Rift. In most of the cases the features observed consist of subsidence pits connected by fissures and oriented either obliquely or parallel to the rift trend, generally indicating a relation to the tectonics of the region. Gouin and Mohr[1] tried to relate earthquakes which occurred a few months earlier in 1966 with such subsidence in the rift floor; they suggested a possible relationship between tectonics, underground drainage and surface subsidence, however, neither a direct relation to earthquakes nor the actual development of the fissures was observed. All reports of subsidences associated with these type of formations were made after the incidences, usually following heavy rains, and therefore the problem of their origin was not solved.

The occurrence of fissures during an earthquake swarm in the Main Ethiopian Rift north of the volcanic centre of Fentale between January and March 1981 and the subsequent erosion provided the first opportunity to follow the development and identify the main features in such a process. In the epicentral area fissures, 2 cm wide, run on sediments and basalt flows for a few kilometres and had a NNE–SSW orientation following the rift trend. After an interval of 6 months, which included a rainy season, the fissures that occurred on sediments on the site were found to have changed considerably while fissures on basalt flows showed very little changes.

Fissures in the sedimentary layer became surface and subsurface drainage channels and the features that developed during a subsequent erosion were determined by the characteristics of sites such as the vegetation cover and the exact nature of geological formations. Depending on the vegetation cover the erosion of fissures on sedimentary formation was either subsurface, where there was deep-rooted vegetation, or gully type, where there was no substantial growth (see Figs 2*b* and 3*c*). In the case of subsurface erosion of fissures the subsidence of the thin sedimentary veneer, which was held together by roots of vegetation, following heavy rains, resulted in the sporadic occurrence of pits connected by fissures (see Figs 2*c* and 3*b*). On the other hand, fissures on sediments with flat topography and therefore with minimum surface drainage were sealed off and did not develop further (see Figs 2*a* and 3*a*). The observed states of erosion following the earthquake swarm between January and March can be classified into three main categories as indicated in Fig. 2.

The features in the third type of development, Fig. 2*c*, bear a strong resemblance to many other observations of subsidences in the Main Ethiopian Rift. The depths of such formations were much larger than their widths and at times full-grown trees had been swallowed in the pits. The great depths attained compared with their widths can be explained by erosion due to subsurface drainage which would mainly be conditioned by the water table there. In such situations both the bottom and lower walls of the fissures would be eroded in an unrelated manner to the overlying walls and cover thereby deepening and widening the lower part disproportionately. Usually the pits occur where there is deep-rooted vegetation. Here the roots would fracture the sediment, facilitating the process of erosion underneath—especially laterally—widening the original fissure into pits. Of course, vegetation would minimize surface erosion and not necessarily subsurface erosion. The sporadic occurrence of pits is partly due to the sporadic nature of the distribution of deep-rooted vegetation and partly due to geological factors.

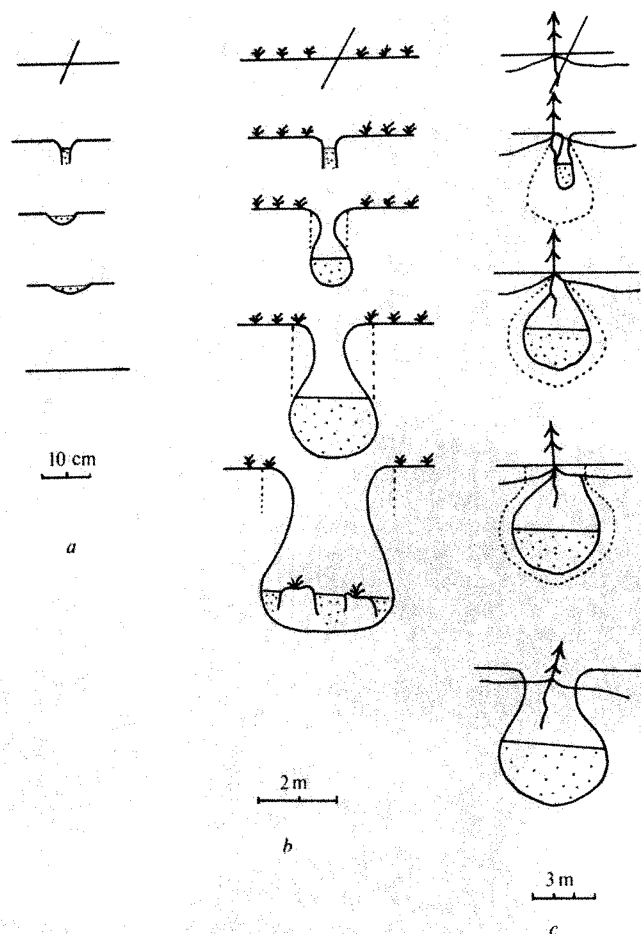

Fig. 2 Types of development of fissures on sediments: *a*, fissures on flat ground with poor drainage; *b* gully type erosion of fissures; *c*, development of subsidence pits. Appropoximate scales do not include vegetation. No vertical exaggeration.

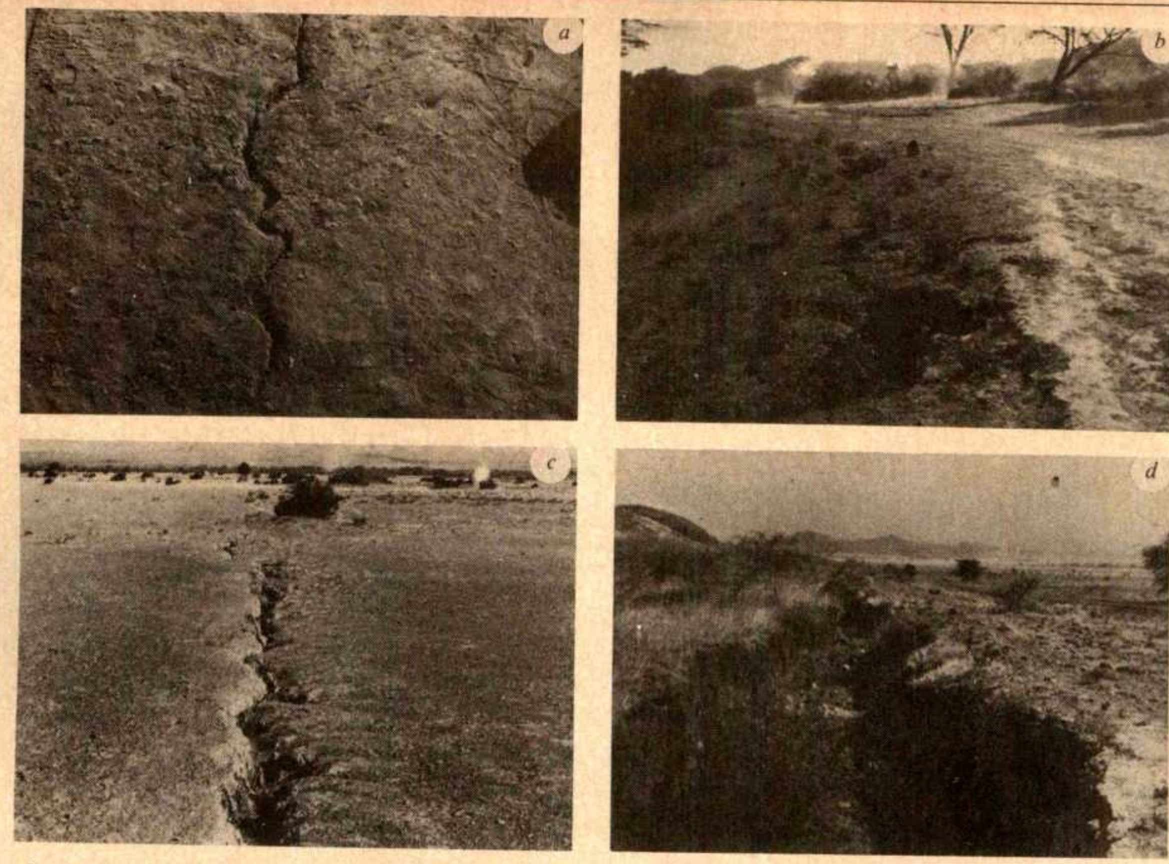

Fig. 3 *a*, Segment of a crack, 2-cm wide, which occurred during the earthquake swarm of January–March 1981 north of Fentale Mountain. This crack was sealed off 6 months later in June 1981. *b*, Subsequent development of pits, about 1 m wide and 50 cm deep, 6 months later, 500 m to the north of Fig. 3*a*. *c*, A small gully type development, 15 cm wide and 10 cm deep, 300 m to the south of Fig. 3*a*. *d*, Gully type erosion of a fissure, 2 m wide and 1.5 m deep, to the west of Fentale Mountain.

The orientation of pits and fissures relative to the rift trend is indicative of their tectonic origin where tension in the region would be associated with fissures oriented generally in the direction of the rift.

The third type of development of fissures, Fig. 3*b*, following the earthquake swarm of 1981, took only 6 months but the main features that characterize subsidence fissures elsewhere had developed. For example, the Mojjo and Wolenchiti fissures and subsidence pits[1–3] could have been considerably older and their rates of development different due to variation in precipitation, subsurface drainage and geological formation. Allowing for age differences the third type of development fully accounts for all the features observed in various parts of the Main Ethiopian Rift. Among other things, the earthquake incidence between January and March 1981 showed that it is possible for earthquake swarms with local magnitude, $M_L \leq 4$ to be associated with fissures. This association is plausible in view of the thin crust there where seismic moments and therefore magnitudes of earthquakes would be small.

On the other hand the segment of the crack shown in Fig. 3*a* was sealed off 6 months later and no trace could be found, while 300 m to the south (Fig. 3*c*) a small gully type development was initiated. These developments correspond to the schemes shown in figs 2*a* and *b* respectively.

Eruption at Le Piton de la Fournaise volcano on 3 February 1981

P. Bachelery, P. A. Blum, J. L. Cheminee, L. Chevallier, R. Gaulon*, N. Girardin*, C. Jaupart†, F. Lalanne, J. L. Le Mouel, J. C. Ruegg* & P. Vincent

Observatoires Volcanologiques, Institut de Physique du Globe de Paris, Tour 14–24, Université Paris VI, 4 Place Jussieu, 75230 Paris Cedex 05, France

Piton de la Fournaise in the island of La Réunion, Indian Ocean, is a young (0.35-Myr old) basaltic shield volcano built on the flank of the extinct Piton des Neiges volcano. It is one of the most active volcanoes in the world (magma output rate of 0.32 $m^3 s^{-1}$)[1,2] and has been under continuous surveillance by the Volcanological Observatory of the Institut de Physique du Globe de Paris since August 1980. The first detailed observations on the volcano reveal a remarkably low level of background seismicity. The 3 February 1981 eruption was preceded by a deep event of volcanic origin at depths of 10–15 km on 2 January; 20 days of quiescence followed this event, until the onset of shallow seismicity close to the eruptive centres on 22 January. The eruption began after 13 days of sustained shallow seismicity and occurred in three phases over 92 days and produced about 10×10^6 m^3 of lava.

A preliminary report of the activity preceding the eruption is given in ref. 3. The seismic network consists of four vertical seismometers and one three-component seismometer (PHR) located around the caldera (Fig. 1*a*). The instruments have a linear response at frequencies of 1–30 Hz with a gain of 10^3. Signals are transmitted by radio to the observatory where they

0028-0836/82/220395—03$01.00

are recorded on strip-chart (2 mm s^{-1} speed). The number of stations was doubled and a new digital recording system set up in January 1982.

Magnitudes were computed using the relationship $M = 2.\log \tau - 0.9$, where τ is the event duration. The detection limit was $M = -1$ and several events of that magnitude may have been missed. Hypocentres were determined using a homogeneous model with a fixed V_P/V_S ratio of 1.7, and by varying the value of V_P between 4 and 7 km s^{-1}. The inter-station distance was typically 5 km and epicentres located in the network interior are considered accurate to 1 km. For those events which were shallow, errors in depth estimates are ~2 km. For epicentres located outside the network, the errors are larger but <3 km for the events reported here. The corresponding errors on hypocentre depths are probably as high as 5 km. A qualitative check on the locations is provided by the distribution of amplitudes.

The Piton de la Fournaise volcano is characterized by frequent volcanic activity with eruptions following each other at 1–2 yr intervals. Yet the seismicity of the island is remarkably low. Researches on local archives dating from 1800 have revealed no accounts of earthquakes of sufficient magnitude to be felt by the inhabitants outside the immediate vicinity of the volcano. During the 5 months which preceded the eruption, <12 events per month were detected by the network (Fig. 2). Events of magnitude >1 seldom occur and the magnitude 2 level was never exceeded. This is in sharp contrast with the level of background seismicity observed at Kilauea in Hawaii, a volcano which belongs to the same category (intra-oceanic).

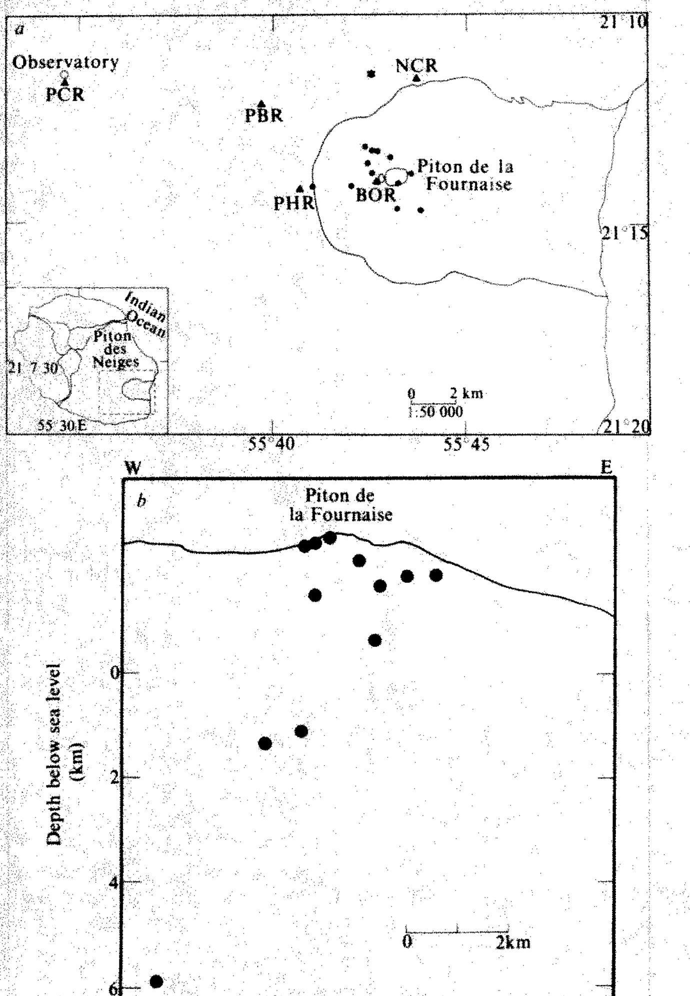

Fig. 1 *a*, Map of the volcano showing the seismic stations (▲) and epicentres of selected events (●). ★, The epicentre of the deep event of 2 January 1981. Locations are accurate to ~1 km in the interior of the network. *b*, Depths of the events shown on *a*. The error is about ±2 km. The deep event at a depth of ~6 km occurred a few hours before the eruption start on 3 February 1981.

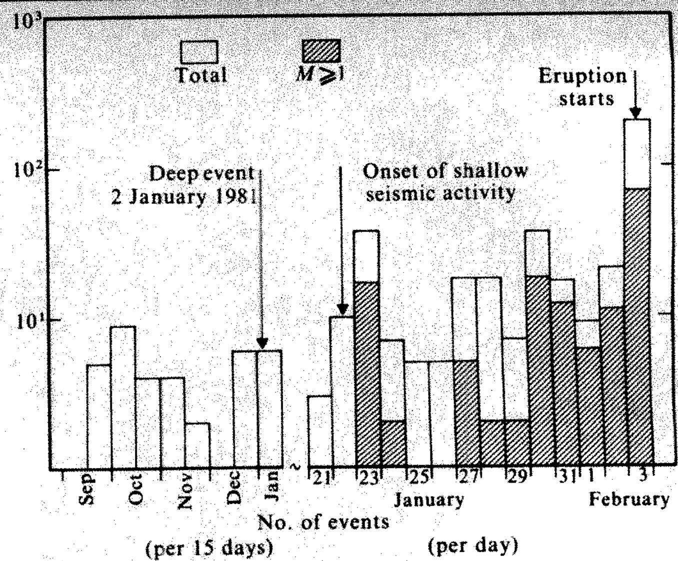

Fig. 2 Seismicity of the Piton de la Fournaise volcano. Note the change of scale on 21 January 1981.

Reports from the Hawaiian Volcano Observatory indicate that the monthly number of events with magnitudes >1 and >3 typically exceed 100 and 10 respectively (see, for example, refs 4, 5).

Premonitory signs of the volcano awakening were first detected on 2 January 1981, when a most unusual event was recorded. It lasted 5 min and was clearly not of tectonic origin (Fig. 3). The S-phase was followed by low frequencies below 0.5 Hz and P-wave polarities varied from station to station. It was a deep event with small-amplitude variations across the network, located 10–15 km below the northern part of the caldera (Fig. 1*a*). It was probably caused by the movement of a light phase (magma or gas) and not by fracturing. No similar event had been observed before and none has occurred since.

No significant increase of seismic activity was noted afterwards (Fig. 2) until 22 January 1981, when 10 events were observed on a single day. On the following day there were 38 events and a warning was issued to the local authorities on 24 January. Seismicity remained at a high level and dramatically increased just before the eruption (Fig. 2). This activity was located around the small Bory crater, close to station BOR (Fig. 1*a*), at depths smaller than 3 km (Fig. 1*b*), with the exception of a deeper event which occurred a few hours before the eruption.

A geodetic network of eight stations was set up around the volcano and the first measurements were carried out on 12 December 1980. The precision in the distance estimates is ~3 cm. Following the onset of seismic activity on 22 January, measurements were conducted on 24 January and 30 January. Only the latter showed a small difference with those of 12 December 1980, barely above the threshold of error, which were interpreted as inflation of the Bory zone[3]. Subsequent measurements made after the eruption start on 12 February 1981 revealed a displacement of 18 ± 2 cm perpendicular to the system of fissures which had opened[3]. No further variations could be detected during February.

Unfortunately no measurements could be made before 12 December 1980. These would have allowed us to see whether

Table 1 Characteristics of the eruptive phases

Eruptive phase	Surface of lava flows (10^6 m^2)	Volume* (10^6 m^3)
1. 3–24 February	0.5	2.5
2. 24 February–31 March	0.7	3.5
3. 1 April–5 May	0.9	4.5

* Computed using a mean thickness of 5 m.

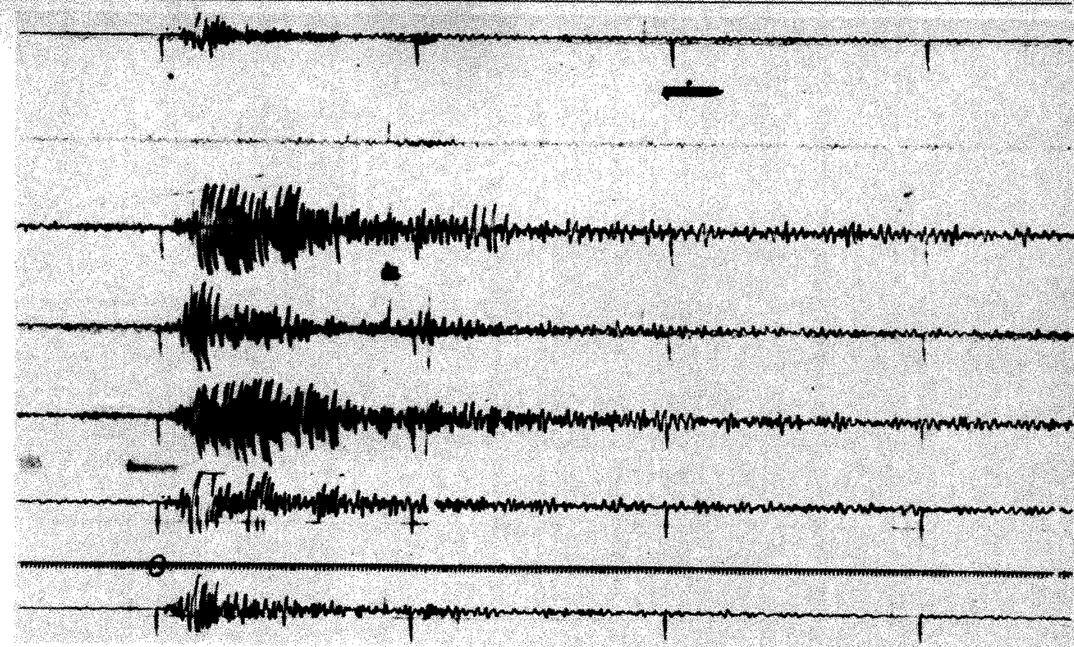

Fig. 3 The 2 Januar event. Large ticks records mark 1 min vals. This event was l at a depth of 10– (from ref. 3).

the inflation detected on 30 January had been going on for a longer time, before the deep volcanic event of 2 January. If such an inflation did occur, however, it was not associated with any significant seismic activity, which would be contrary to what is usually observed at Kilauea[6].

The difference in the seismicity of the two volcanoes may be related to the more complex structure of Kilauea which has several centres of activity. The internal structure of Piton de la Fournaise is not well documented. A detailed study using magnetic data[7] suggests the existence of a small kilometre-sized magma chamber ~1 km beneath the summit area. Shallow seismicity accompanied by inflation is presumably related to the extension of the central dyke complex located immediately below the summit[7].

Eruptive activity occurred in three phases roughly 1 month long (Table 1). Each phase conformed to the same pattern: volcanic tremors for 3–4 h at the start, and virtually no seismicity during the rest of the phase when the greatest volume of lava is erupted. This indicates that tremor activity is due to the initiation of flow.

Tholeiitic lavas came out of fissures which opened along well known NE–SW and NW–SE axes of weakness. They were essentially aphyric[8], contrary to the previous eruptions of April 1977 and July 1979. The three eruptive phases were similar, and characterized by intense degassing with lava fountains reaching heights of 70–100 m. After a couple of days, the activity became limited to a few fissures where spatter cones grew. One or two days later, only one fissure was productive and a volcanic cone was built there. The velocity of lava flow was estimated visually to be close to 4 m s^{-1} at the vent.

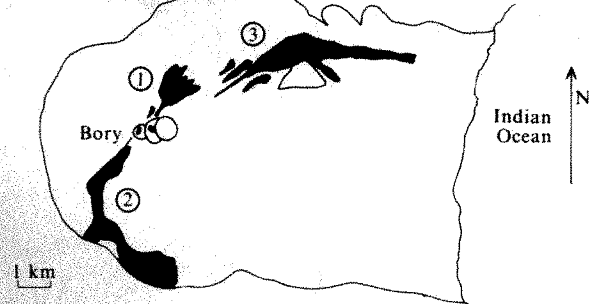

Fig. 4 Map of the lava flows produced by the three eruptive phases.

Lavas produced during this eruption cover large areas (Table 1, Fig. 4) and the total volume is ~10×10^6 m^3, using a mean flow thickness of 5 m. Lava flows were essentially of the aa, gratons and echaudé types which are typical of the island, with some pahoehoe late in each eruptive phase.

Several phreatomagmatic explosions were observed during the first phase, and many during the third, in relation with heavy rainfall.

This is IPGP contribution no. 589.

Prehistoric soil and vegetation development on Bodmin Moor, southwestern England

E. Maltby & C. J. Caseldine

Geography Department, University of Exeter, Exeter, Devon EX4 4RJ, UK

Archaeological excavation of barrows in the St Neot Valley on the southern flanks of Bodmin Moor revealed buried soils developed in the gravelly granitic head typical of the upland block. By comparing these soil profiles with adjacent soils we have obtained evidence for and now describe dramatic prehistoric changes in upland soils and vegetation attributed previously to various combinations of human influences and climatic events. Direct pedological and palaeoecological evidence supports the theory that brown soils existed in pre-Bronze Age times in southwestern England at a site subsequently developing an iron pan (Bf) and accumulating a strongly acid peaty surface.

The barrows CRII and CRIV revealed by the excavation have yielded statistically inseparable radiocarbon dates of 1550–1650 and 1560–1630 b.c. (ref. 1) respectively and occupy opposing valley shoulder positions <500 m apart (Fig. 1). The CRIV complex stands in acid grass–heath moorland characteristic of the uplands of south-west England and in which *Molinia caerulea* and *Calluna vulgaris* are locally prominent. The

0028-0836/82/220397—04$01.00

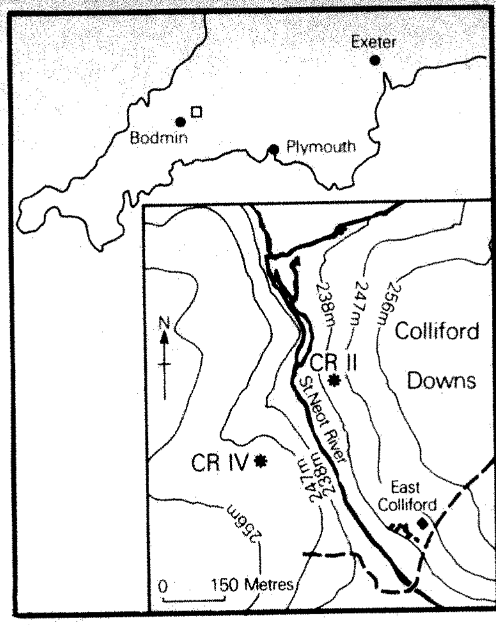

Fig. 1 Location of Bronze Age barrows in the St Neot Valley, Bodmin Moor.

present day soil is a distinctive iron pan stagnopodzol comprising 15–20 cm peaty surface, a variable but stony Ah, grey mottled or pallid E(g) above a thin but wavy and indurated iron pan (Bf) bounding ochreous then brown B_s horizons which merge at 50–60 cm into paler B/C material. CRII occupies a slope enclosed and converted to improved pasture at least since the seventeenth century. Associated soils have a well-mineralized organic surface, commonly lack an E horizon (which has been lost probably by cultivation), but still possess an iron pan (occasionally discontinuous) and strongly developed B_s horizon. It is a cultivated variant of the iron pan stagnopodzol which has been variously mapped and described elsewhere as the Hexworthy Series[2,3].

The profiles beneath two barrow structures of the CRIV complex (CRIVA and CRIVC) are identical to the present day soil except that the original surface peat is attenuated at the old land surface. This is explained by the incorporation of peaty turves into the structure of the barrows. However, a strongly contrasting relationship emerges from the sub-CRII soil. The mineralogenic profile comprises three morphologically distinct horizons above B/C and C(x) material (Fig. 2*a*). Unlike the profile developed within and at the margins of the barrow, under CRIV and associated with the present day surface, there is no organic surface, bleached E_a or E_g horizon or morphological evidence for an iron pan. It seems possible that an original turf layer was removed in the course of barrow construction but otherwise the profile is intact. Horizon notation for the buried profile follows Avery[4] but non-pedogenic nomenclature is preferred for our discussion in view of the potential difficulties in interpretation of buried horizons.

Relatively high values for sodium dithionite extractable iron (Fe_{res}) which are remarkably consistent with depth suggests a strong affinity[5], if not genetic link, between the buried soil and a brown earth type progenitor (Fig. 2*b*). Such crystalline 'aged' Fe only remains in the absence of active biochemical agencies of remineralization usually associated with acid organic surfaces[5] and/or leaf leachates[6,7]. Thus alternatively the pattern of Fe_{res} may be an artefact of burial and protection from fresh sources of complexing or chelating radicals. However, alkaline potassium pyrophosphate extracts (Fe_{ppt}, Fe_{sol}, Al) show particular enrichment of 'active' amorphous Fe in horizon II and confirms general podzolization of the profile. Iron which can be precipitated by NH_3 (Fe_{ppt}) is the dominant fraction in all but the lowest levels sampled. That fraction of the extract remaining soluble (Fe_{sol}) is described by Bascomb as the most active form of Fe linked in 'fresh' organic complexes[5]. Amounts are generally low. This might be expected if the profile were protected substantially from contemporary leaching under the large granite blocks of the barrow but is also a typical feature of brown soils. The proportion of 'active' Fe ($Fe_{ppt}+Fe_{sol}=Fe_{ext}$) to total Fe ($Fe_{ext}+Fe_{res}$) changes with depth in a pattern confirming active enrichment of II and a change to mainly 'aged' iron in underlying B/C material.

A marked peak in active Fe is associated with organic rich infill of a distinct system of channels. The channels are unusual for several reasons: they contain black peaty fill including bleached quartz grains similar to the modern moorland and

	Sand (63-200μ)	Silt (2-63μ)	Clay (< 2μ)	pH S pt. 0·01M $CaCl_2$

Table 1 Dominant and characteristic pollen taxa from the soil horizons of CRII

Horizon	Pollen taxa
I	Dominated by Gramineae and *Plantago* with *Quercus, Alnus, Betula* and *Corylus/Myrica* comprising 30% T.L.P. Variable but high frequencies for *Polypodium* and *Pteridium*.
II	Dominated also by Gramineae and *Plantago* at reduced levels with reduced *Quercus* and *Corylus/Myrica*. Increasing *Calluna* and greater species diversity including Ranunculaceae, *Potentilla* type, Rosaceae, Rubiaceae, *Succisa* and *Rumex*. Highest values for *Polypodium* and *Pteridium*.
III	Dominated by lower values for Gramineae, and *Calluna*. *Plantago*, *Pteridium*, *Polypodium* and all A. P. are reduced. At the lowest sample there is a peak for *Corylus/Myrica*.
Organic pocket	Similar assemblage to surrounding horizon with dominance of Gramineae, *Plantago* and *Calluna* with *Corylus/Myrica*, *Alnus* and *Quercus*.

barrow surface; they exhibit remarkably little variation in internal diameter (mean = 9.84 mm, $s = \pm 1.12$ mm, $v = 12\%$, $n = 25$) except for occasional enlarged pockets; where channels split or bifurcate they often do so in an upward direction; the internal walls are commonly smoothed; they lack smaller lateral systems and macro-remains of recognizable plant debris such as bracken rhizomes. Thin sections reveal the presence of possible earthworm casts within and lining the channels together with evidence in pores of substantial small animal activity (Fig. 2*d*). We propose that these channels are 'fossilized' burrows of lumbricid earthworms with which they compare in permanence, size and depth[8]. Absence of a highly acidic peat or mor humus surface is necessarily implied by their establishment. The population persisted until soil conditions degraded to a point which allowed accumulation of an acid peaty surface as indicated by the character of the fill in the abandoned burrows. Earthworm activity could be responsible for the much finer texture of horizon I (A/Ah?) and also the general homogeneity of the pollen record within this horizon can be explained by active faunal mixing (Fig. 2*c*). Pollen in the channels themselves is better preserved in the more acid and recent fill than generally in the buried profile. An assemblage with up to 15% *Calluna* confirms the idea of infilling occurring when a peaty surface had begun to develop in association with acidophilous heathland communities. Large earthworms died out at least a short time after 1560 b.c. because several channels extend into the barrow structure. Note in this context that at the experimental earthwork on Overton Down, constructed in 1960, earthworm activity rapidly extended well up into the mound from the buried soil surface. By 1964 worm casts are recorded in interstitial spaces throughout the experimental bank[9].

A pollen diagram has been constructed for the buried soil despite problems caused by generally poor pollen preservation (Fig. 3). Changes in the gross character of pollen assemblages between the three horizons are summarized in Table 1. Pollen evidence suggests that the immediate pre-barrow soil developed in a relatively open grassland environment. Increasing *Calluna* down the profile, however, indicates that heather was an important component of the local vegetation before grassland development. It may have comprised the under-storey or gaps in scrubby woodland dominated by hazel or oak already substantially modified by Neolithic human activity. Indiscriminate burning and/or excessive grazing, together with more cultivation could have led to its demise as pressure for land increased into the Bronze Age.

It has been argued that the Hexworthy Series on Dartmoor has developed from an earlier brown earth type under oak forest[10]. Enhanced acidification and leaching have been associated with Neolithic clearance on land generally above 300 m but because of the temporary nature of such clearings and the inferred frequent regeneration of woodland it is by no means universally agreed that there was any long lasting effect on soil development. Pre-Bronze Age podzolization and iron pan development at ~250–300 m elevation is inferred for Dartmoor and certainly pre-dates barrow construction of this period, including that of CRIV elsewhere on the granite uplands of

southwestern England[13,14]. The present study confirms for the area immediately adjacent to CRII, however, that soil changes leading to iron pan formation and accumulation of a peaty surface post-dates this period. Nevertheless, podzolization was already well enough advanced to produce a brown (possibly humic) podzol profile. A wide variety of buried soils ranging from 'unleached' profiles to thin iron pan podzols were described in association with Bronze Age barrows elsewhere in upland Britain and differences explained in terms of very rapid soil changes occurring within this period of prehistoric activity[15]. High rates of differential pedogenesis cannot be dismissed entirely on Bodmin Moor. However, soil changes are not necessarily time-synchronous even over short distances and the effects of slope aspect, subtle differences in elevation, gradient and hydrology together with any differential influences of prehistoric land management should not be ignored as causes of significant time delays in the processes of conversion of brown soils to iron pan stagnopodzols.

Frances Griffith has coordinated the archaeological programme of which this study has been part. We thank Nigel Fenn and Anne Alderton, financed through the MSC Job Creation Programme, for research assistance and Dr Peter Bullock for preparing thin sections and for his helpful interpretation. South West Water are thanked for site access. Figures are by the drawing office and photographic unit, Geography Department, Exeter University.

SO_2 pollution reduces the freezing resistance of ryegrass

Alan W. Davison & Ian F. Bailey

Department of Plant Biology, University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU, UK

Several authors[1-3] have observed that the effects of SO_2 on growth are more severe in winter and Davies[4] has shown that this may be due to low irradiance and the short photoperiod reducing the plants' capacity to detoxify the pollutant. However, in winter plants are also subjected to potentially lethal stresses such as freezing. The important forage grass, *Lolium perenne*, shows only poor resistance to winter temperatures, hence, any effect of pollution on hardiness could be of considerable significance. Here we demonstrate that SO_2 reduces resistance to sub-zero temperatures and that this effect is influenced by mineral nutrition. A reduction in freezing tolerance may contribute to rapid selection of SO_2-resistant genotypes, particularly in newly sown leys.

Three experiments were performed to determine the effects of SO_2 on freezing resistance. In the first, six 1-week-old seedlings of *L. perenne* cv. S23 were planted in each of 90 7-cm plastic pots containing standard garden potting compost and these were fumigated for 3 weeks in wind tunnels. During this phase of the experiment the day length was 18 h, irradiance 32 W m^{-2} and temperature 15 °C. Controls received <15 μg SO_2 per m^3 and treated plants 250 μg per m^3. SO_2 was monitored using a Meloy SA 285 sulphur analyser.

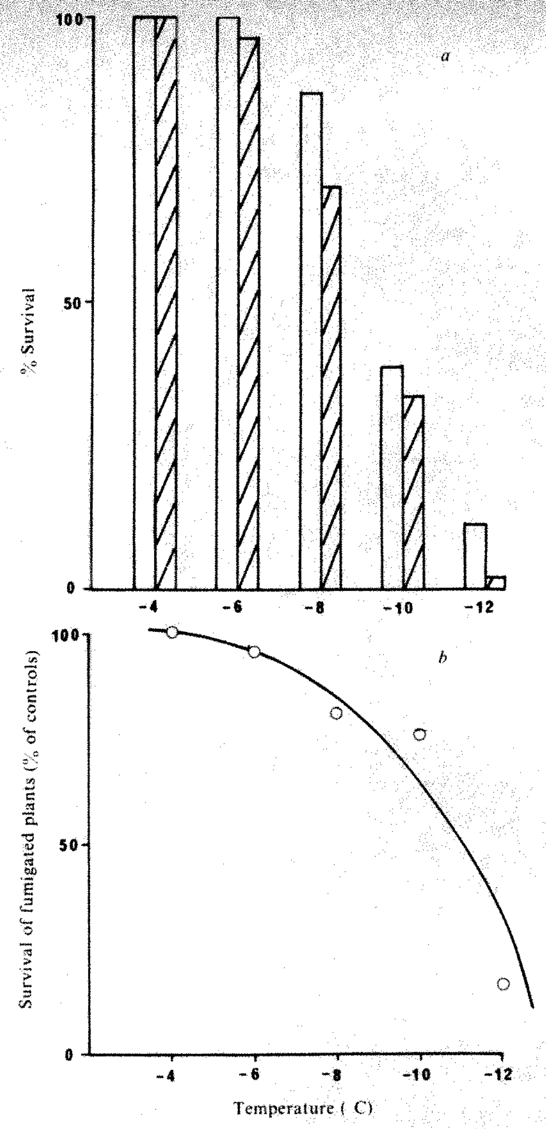

Fig. 1 Survival of *L. perenne* exposed to sub-zero temperatures and SO_2. *a*, Percentage survival of control (open bars, <15 μg SO_2 m^{-3}) and fumigated (cross-hatched bars, 250 μg SO_2 m^{-3}) plants. LT_{50} of controls = -9.7 ± 0.4 °C, that of fumigated plants = -8.8 ± 0.3 °C. *b*, Survival of fumigated plants expressed as a percentage of controls.

After this initial period, fumigation conditions were kept the same except that the temperature was reduced to 2 °C and the daylength to 10 h to 'harden' the plants. After 2 weeks of such treatment, all the plants were removed from the wind tunnels and placed in randomized blocks in a modified deep freeze (daylength, 10 h and irradiance, 55 W m^{-2}). They were not fumigated during this phase. Using a cam-operated temperature control, the plants were held at 0 °C during the first day, followed by exposure during the night to a fall in temperature of 2 °C h^{-1} to a minimum of −4 °C. This minimum was kept constant for 4 h then the temperature was allowed to rise at 2 °C h^{-1} back to the daytime temperature of 0 °C. On subsequent nights the same regime was followed except that the minimum was lowered to give −4, −6, −8, −10 and −12 °C on successive nights. Nine replicate fumigated and control pots were removed at random each day and kept without fumigation at 2 °C in the wind tunnels until all the plants had been removed from the freezer. Then the plants were returned to the same environmental conditions as those during the 3-week pre-hardening period. After 5 weeks of recovery, the plants were scored for survival (post-freezing production of new root, leaf or tiller). The results are shown in Fig. 1.

Survival of the fumigated plants was consistently poorer than controls and probit analysis showed that the LT_{50} values (tem-

peratures at which 50% of the plants were killed) were respectively -8.8 ± 0.3 and -9.7 ± 0.4 °C. Figure 1*b* shows that when survival of fumigated plants was plotted as a percentage of controls the difference between the treatments increased with decreasing temperature.

As the supply of nitrogen and other elements influences[5-9] the effects of SO_2, we performed experiments to determine the effects of soil nitrogen and sulphur on the SO_2–freezing interaction. The first of these experiments was a fumigation–growth study which was used to select contrasting nutrient treatments for use in the second experiment. In the former, newly germinated seedlings of *L. perenne* cv. S23 were sown at a density of 5 per 7-cm plastic pot containing washed, coarse sand. All treatments received deionized water each day and 10 ml of nutrient solution per pot twice a week. Four nutrient treatments were used (Table 1) to give low soil S–low N, low S–high N, high S–low N and high S–high N. All nutrient solutions contained (mg l^{-1}): KH_2PO_4 180, $CaCl_2.2H_2O$ 367, $MgCl.6H_2O$ 313 and trace elements, together with different concentrations of Na_2SO_4 and NH_4NO_3. The low and high sulphur solutions contained 21.3 and 213 mg l^{-1} Na_2SO_4, giving 4.8 and 48 mg S l^{-1}, respectively, while the low and high nitrogen solutions contained 40 and 400 mg l^{-1} NH_4NO_3, giving 14 and 140 mg N l^{-1}, respectively. Twelve replicate pots were used for

LT_{50} of controls = -8.4 ± 0.4 °C, that of fumigated plants = -7.6 ± 0.2 °C. *b*, As for *a*, but plants were given low sulphur–low nitrogen medium. LT_{50} of controls = -8.5 ± 0.4 °C, compared with -8.4 ± 0.3 °C for fumigated plants.

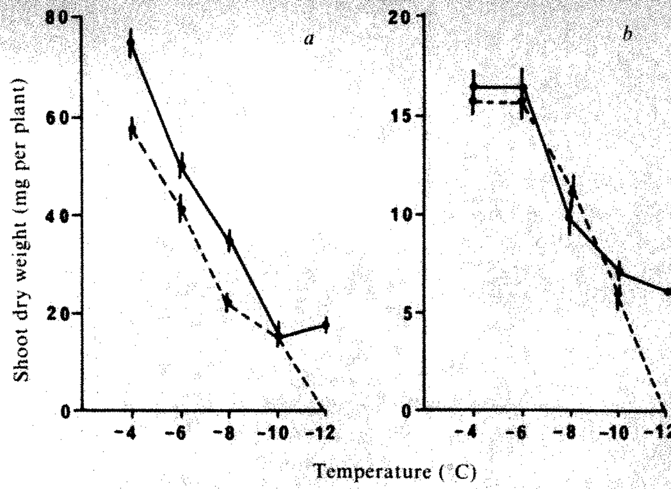

Fig. 3 Dry weight (mg per plant) of *L. perenne* shoots exposed to sub-zero temperatures and SO_2. *a*, Control (—) and fumigated (- - -) plants on high sulphur-high nitrogen medium. *b*, Plants on low sulphur–low nitrogen medium. Vertical bars represent standard errors.

each treatment. Immediately after sowing, the pots were placed in randomized blocks in wind tunnels and exposed to the same environmental conditions as in the pre-hardening period of the first experiment. After 5 weeks of fumigation, the plants were harvested, dried at 105 °C and weighed. The results are shown in Table 1.

In both control and fumigated treatments, an increase in nitrogen concentration significantly increased yield but the effects of soil sulphur were more complex. Increasing the sulphur concentration increased yield only in the presence of high nitrogen concentration in clean air—that is, sulphur was limiting only when the nitrogen concentration was high and SO_2 was low. SO_2 did not appear to compensate for low soil sulphur. With high substrate sulphur and nitrogen, SO_2 caused a significant ($P<0.02$) reduction (18%) in shoot weight. Based on these results, the two extreme nutrient treatments (low S–low N and high S–high N) were used in the final experiment, which examined the interaction of SO_2, substrate sulphur and nitrogen, and freezing injury. Seedlings were grown in sand culture in the same environmental conditions and regime as in the previous experiment. After 5 weeks of recovery from freezing, the plants were scored for survival, harvested, dried and weighed (Figs 2, 3).

The reaction of plants given high substrate sulphur and nitrogen to sub-zero temperatures (Fig. 2*a*) confirmed the results of the first experiment in that SO_2 reduced both survival and the LT_{50} (from -8.4 ± 0.4 °C to -7.6 ± 0.2 °C). However, the difference between control and fumigated plants was greatly reduced (Fig. 2*b*) when they were grown on the low sulphur–low nitrogen medium. The poor winter hardiness of *L. perenne* was reflected not only in the LT_{50} but also in the dry weights. In both nutrient regimes and for both control and fumigated plants, lowering of the temperature caused a progressive decrease in shoot weight but the weight of fumigated plants on the high sulphur–high nitrogen medium was consistently less than controls. On the low sulphur–low nitrogen medium, SO_2 had no effect on shoot weight except at the lowest temperature, where no fumigated plants survived. Root weights showed the same pattern as the shoots (data not shown).

The possibility that pollutants might affect winter hardiness was first mentioned by Bleasdale[10] in 1952 but until now there has been no direct evidence that SO_2 affects any of the attributes that constitute what we call hardiness. A reduction in survival at temperatures that are commonly recorded in British winters has several implications, particularly in relation to efforts to quantify the economic impact of SO_2. Several authors[11-13] have commented on the difficulties involved in extrapolating results obtained in the laboratory to the field situation because of the

effects of variable environmental factors such as light, genetic variation and interactive effects of other pollutants. The finding of an effect of SO_2 on freezing resistance and its modification by mineral nutrition adds to the difficulties and reinforces the view that in order to quantify effects as they occur in the field, experiments must involve exposure of plants at all times of the year and to all the normal range of environmental conditions.

There is good evidence[14-18] that in areas subjected to SO_2 pollution there exists natural selection of tolerant populations. The rate of selection has not been fully established[18] but if SO_2 reduces freezing resistance then this could promote extremely rapid selection, especially in re-seeded leys. It is possible that selection might be so rapid that the effects of SO_2 on the production of re-seeded grasslands might be transient and limited to a short period immediately after sowing.

'*Wasted*', a new mutant of the mouse with abnormalities characteristic of ataxia telangiectasia

L. D. Shultz, H. O. Sweet, M. T. Davisson & D. R. Coman

The Jackson Laboratory, Bar Harbour, Maine 04609, USA

Research into the basic mechanisms underlying the development of complex multi-system diseases has been facilitated by the study of single gene mutations in experimental animals. Ataxia telangiectasia is such a multifaceted genetically determined disease for which no animal model has been described. It occurs in children and is characterized by varying degrees of immunodeficiency, cerebellar ataxia, oculocutaneous telangiectasia, chronic sinopulmonary disease, endocrine abnormalities, chromosomal aberrations, and a high incidence of neoplasms[1-3]. Although the clinical manifestations have been well documented, the cause of the disease is unknown. The pleiotropic nature of the ataxia telangiectasia gene is very complex. Many aspects of this disease, including impairment of tissue differentiation in embryological development are not amenable to direct study, thus an animal model for ataxia telangiectasia would be valuable in elucidating the underlying mechanisms, and in developing effective preventive or therapeutic measures. We have recently found a spontaneous mutation of the mouse called '*wasted*' (*wst*) that shows pathological changes similar to those of ataxia telangiectasia. This mutation can be recognized at 3 weeks of age by neurological abnormalities. We report here that affected animals show pathological changes in the central nervous and lymphoid systems and exhibit a high degree of spontaneous and γ ray-induced chromosomal damage.

The autosomal recessive mutation *wst* occurred spontaneously in 1972 in the inbred HRS/J colony maintained in the Mouse Mutants Stocks Center at the Jackson Laboratory[4]. Homozygotes (*wst*/*wst*) can be recognized at 20 days of age by neurological abnormalities, including tremor and uncoordinated body movements. Affected mice develop progressive paralysis and do not survive beyond 30 days of age. As wasted mice are short-lived, the mutation was crossed to a segregating background (C3HeB/FeJ × C57BL/6J) to increase viability through 'hybrid vigor'. We then studied the effect of the *wasted* mutation on the segregating hybrid background. We are presently backcrossing the *wasted* mutation to the C57BL/6J strain. Although *wst* has not yet been mapped, it does segregate independently of markers on chromosomes 1–11, 13–15, 17 and 19; further linkage tests are in progress. Allelism tests using *ax^J*, *bc*, *cri*, *dw*, *dy*, *mdf*, *med^J*, *myd*, *nr*, *pcd*, *tn*, *twi* and *wl* were all negative. (For a description of these genes, see ref. 5.)

While mice normally show rapid growth and weight gain between 20 and 30 days of age, *wasted* homozygotes show no weight increase after 20 days. Of particular interest was the finding that, by 28 days of age, *wasted* mice have a marked lymphoid hypoplasia with significantly decreased ($P<0.05$, Student's *t*-test) spleen, thymus, and lymph node to body weight ratios (Table 1). Analysis of peripheral blood in 17 pairs of mutant and control mice revealed that 3–4-week-old wasted homozygotes have a threefold decrease in numbers of circulating leukocytes ($2.8\pm0.52\times10^6\ \mathrm{ml}^{-1}$ for *wst*/*wst* mice as opposed to $8.7\pm1.06\times10^6\ \mathrm{ml}^{-1}$ for +/− littermates). To determine whether the *wst* mutation affects development of both Thy-1-bearing cells (T cells) and surface immunoglobulin-bearing cells (B cells), spleen cell suspensions were analysed by indirect immunofluorescence microscopy[6] using monoclonal anti-Thy 1.2 antibody (cell culture supernatant from hybridoma HO-13-4.9)[7] and fluorescein-conjugated goat anti-mouse immunoglobulin. Preliminary analysis of nine pairs of wasted and littermate control mice (20–28 days old) showed no significant effect of the *wst* mutation on percentages of T and B cells (data not shown). Thus, the lymphoid hypoplasia is not restricted to a single major lymphocyte subpopulation. Similarly, in ataxia telangiectasia patients, percentages of circulating B cells are normal while those of T cells are within the lower normal limits[8].

As patients having ataxia telangiectasia show impairment of delayed-type hypersensitivity (DTH), we examined the DTH response of wasted mice to sheep red blood cells (SRBC). Homozygotes (*wst*/*wst*) had significantly decreased DTH responses 4 days after priming compared with +/− littermate controls, as measured by the specific increase in footpad thickness 24 h after injection of an eliciting dose (10^8) of SRBC[9] (data not shown).

Histological examination of tissues from 10 pairs of *wasted* and littermate control mice (22–29 days old) revealed abnormalities in the central nervous and lymphoid systems of mutant mice. The brain showed degeneration of Purkinje cells and focal demyelination in the cerebellar cortex (Fig. 1); focal demyelination was also found in the ventral columns of the spinal cord of wasted mice. Purkinje cell degeneration and focal demyelination have also been described in association with ataxia telangiectasia[1,3,10]. Marked hypoplasia was found in both the thymus-dependent and thymus-independent areas of the lymphoid system. The follicles of the lymph node and spleen

* Right brachial lymph nodes were weighed.

0028–0836/82/220402—03$01.00

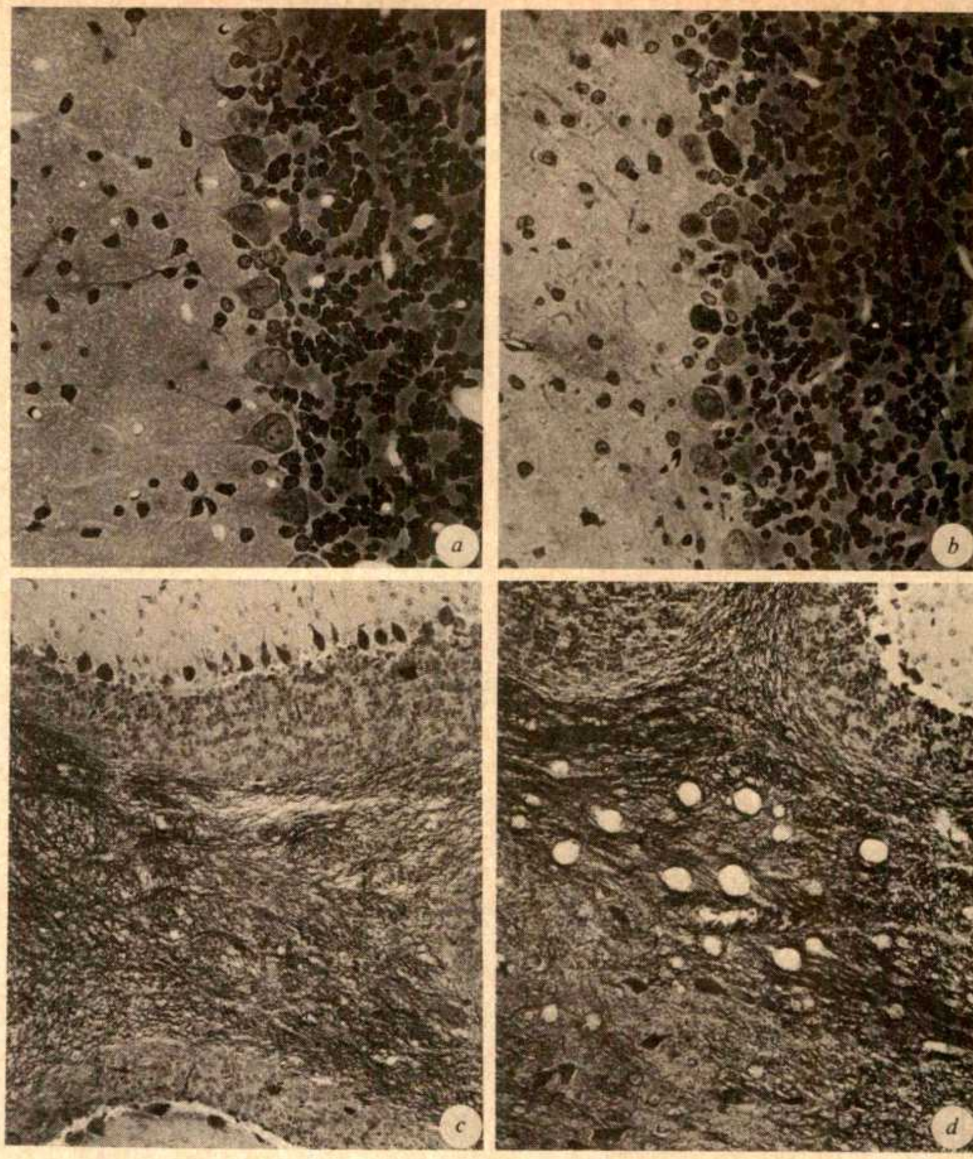

Fig. 1 Sections of brain from 29-day-old wasted and littermate control mice. *a*, Cortex of cerebellum from littermate control showing normal Purkinje cells; aborescent fibrils are evident. *b*, Cortex of cerebellum from *wst/wst* mouse; Purkinje cells appear shrunken and deficient in fibrils (luxol fast blue–cresyl violet, ×140). *c*, Cerebellum from littermate control showing normal myelination. *d*, Cerebellum from *wst/wst* mouse showing advanced myelin loss (luxol fast blue–cresyl violet, ×70).

were poorly developed, Peyer's patches were few and small, and there was a reduction in cellularity of the thymic cortex (Fig. 2). Thymic hypoplasia and lymphocyte depletion in the cortical and paracortical areas of lymph nodes are common features of ataxia telangiectasia[3]. No gross or histological evidence of telangiectases was found in wasted mice, but development of such vascular abnormalities is thought to require exposure to sunlight[11].

As ataxia telangiectasia is characterized by spontaneous and induced chromosomal aberrations, such changes were sought in wasted mice. We examined chromosomes in bone marrow cells collected from nine pairs of *wasted* and littermate control mice (23–28 days old). Cells were not G-banded so that they could be scored for chromosome gaps. At least 50 cells from each mouse were scored blindly for chromosome damage. The *wst/wst* mice showed a fourfold greater incidence of chromosomal damage then their littermate controls ($8.8 \pm 1.69\%$ of cells from *wst/wst* mice compared with $2.2 \pm 0.77\%$ of cells from $+/-$ littermates showed chromosomal damage). The damage included chromosome and chromatid breaks, gaps and fragments, implying either increased chromosome breakage or failure of breaks to rejoin. Preliminary data suggest that wasted mice may also be more susceptible to radiation-induced chromosomal injury. Two *wst/wst* mice and two littermate controls were irradiated with 200R from a Shepard Mark 1 irradiator (^{137}Cs). After 18 h the mice were treated with colchicine, and chromosomes were prepared from bone marrow cell suspensions; 80% of 30 metaphase cells in *wst/wst* mice showed damage of some sort while the controls revealed only minor damage in 30% of the cells scored.

Thus, homozygosity for the wasted mutation results in impaired neurological and immunological development as well as increased levels of spontaneous and γ ray-induced chromosomal damage Whether the chromosomal aberrations in *wasted* mice are associated with defective DNA repair, as has been shown in cell lines isolated from individuals with ataxia telangiectasia[1], has not been determined. Elucidation of the

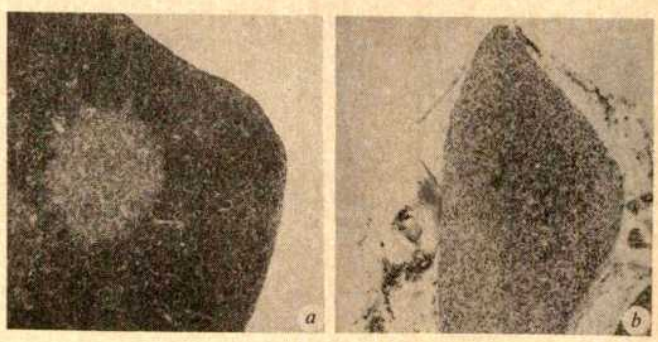

Fig. 2 Thymuses from 29-day-old wasted and littermate control mice. *a*, Littermate control showing normal thymic structure; *b*, 'wasted' thymus showing depletion of cells from cortex (haematoxvlin–eosin, ×25).

mechanism of action of the wasted mutation may further our understanding of ataxia telangiectasia.

We thank Cheryl Bailey for technical assistance. This work was supported by NIH research grants CA20408 and GM27102, NSF grant DEB79-26708, and ACS grant CD-34U.

Note added in proof: Associated with the focal demyelination in the brain and spinal cord of wasted mice are numerous dilated capillaries.

Peripheral pathways are pioneered by an array of central and peripheral neurones in grasshopper embryos

Robert K. Ho & Corey S. Goodman

Department of Biological Sciences, Stanford University, Stanford, California 94305, USA

During embryonic development, neuronal growth cones traverse long distances along stereotyped pathways to arrive at their appropriate targets. Since Harrison's initial observations[1], increasing evidence has supported the notion that axonal pathways are "pioneered" early in development when the distances are short and the terrain relatively simple; thus an axonal scaffold is erected upon which later neurones can navigate. Grasshopper embryos have emerged as an attractive preparation in which to study pathfinding because the nervous system is relatively simple, and the individual identified neurones in the periphery and central nervous system (CNS) of the embryo are large and highly accessible. How are the first axonal pathways established between the periphery and CNS? Bate[2] has described a single pair of cells in the limb buds, and two pairs in the antennae, which were thought to establish the very first peripheral pathways over distances of several hundred micrometres from the periphery to CNS; he called these pairs of cells 'pioneer neurones'. Keshishian[3] confirmed this finding and also described[4] a second pair of pioneers in the limb buds. We report here a further analysis of peripheral pathfinding in the grasshopper embryo using a monoclonal antibody, called I-5, which stains the cells responsible for establishing the first pathways[5,6]. In contrast to the earlier reports, we find a large array of peripheral cells responsible for establishing the first pathways, with both pathfinders and landmark cells spaced at short intervals along the route. Furthermore, growth cones from central motoneurones make important contributions to the first peripheral pathways[6].

Monoclonal antibodies against the grasshopper nervous system have been made with the goal of obtaining cell markers which label specific subsets of cells early in embryogenesis[5,6]. In early embryos, one of these antibodies, called I-5, stains a specific pattern of neurones and mesodermal cells[5,6], including the pairs of peripheral pioneer neurones originally described by Bate[2] and Keshishian[3,4]. Interestingly, the I-5 antibody also reveals an array of previously unseen cells and growth cones that are intimately involved in pioneering the first peripheral axonal pathways. In this paper we have studied these cells using the I-5 monoclonal antibody[5,6], observations with Nomarski optics[7,8], intracellular injections of the fluorescent dye Lucifer Yellow[9], and an anti-Lucifer Yellow antibody (anti-LY)[10].

The I-5 antibody stains the pairs of pioneer neurones in both the antennae[2] and limb buds[2–4] shortly after their final cell division, and before axonogenesis (Fig. 1*a*); the antibody also stains their growth cones and axons (Fig. 1*b*,*c*). In the antenna (Fig. 2), two pairs of neurones [first the ventral pioneers (VP) and then the dorsal pioneers (DP)] appear at the distal tip and extend growth cones towards the CNS, thus pioneering the two axonal pathways within the antenna. At the same time, a single base pioneer (BP) appears at the base of the antenna and its growth cone is the first peripheral process to reach the CNS. Simultaneously, a growth cone from a motoneurone originating in the CNS extends outwards towards the base of the antenna, running parallel, although not fasciculating upon, the BP's axon; the motoneurone growth cone stops at the lateral edge of the antennal base and in time innervates a muscle that develops at this location. Thus, the pathway between the antennal base and the CNS is complete by the time the growth cones from the more distal VP and DP neurones arrive and follow the BP pathway into the CNS. Interestingly, when these cells first appear inside the ectodermal epithelium, they are spaced at

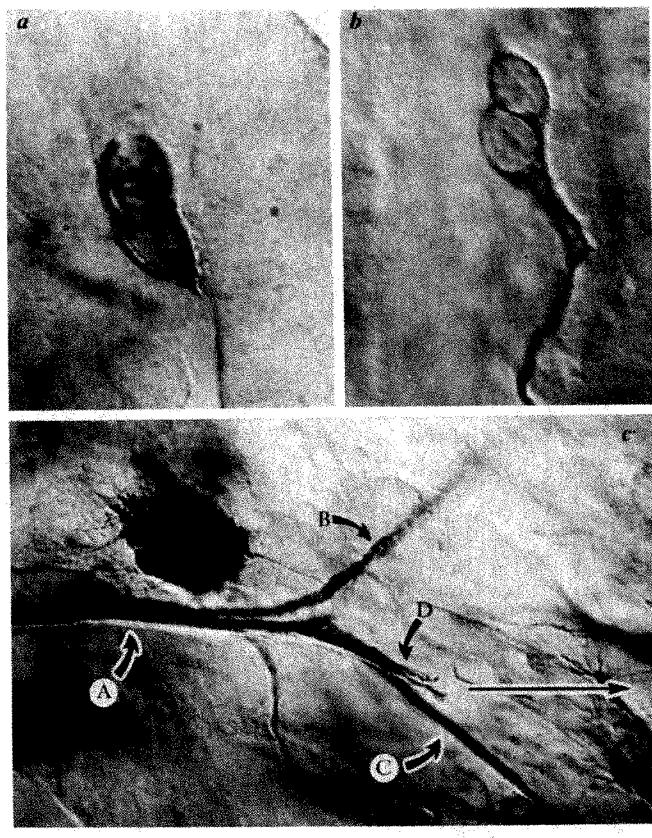

Fig. 1 Photomicrographs of limb buds (A, C) and antennae (B) showing staining of cells with I-5 monoclonal antibody; the growth cones of these cells are involved in pioneering the peripheral axonal pathways in the grasshopper embryo. The embryo is dissected out of the eggshell, lightly fixed in 2% paraformaldehyde, and incubated overnight in I-5 supernatant with 0.2% saponin. The antibody is visualized using an HRP-conjugated second antibody. *a*, Staining of the pair of 1E cells in the limb bud just before they initiate growth cones. The 1E cells are just within the ectodermal epithelium at the tip of the limb bud. *b*, Staining of the ventral pioneers (VP) in the antennae after they have initiated axons. Their growth cones (not shown) have just arrived at the cell body of the base pioneer (BP). *c*, Staining of the limb bud showing the intersection of the A, B, and C pathways (established by the 1A, 1B, and 1C cells, respectively), and the growth cones of the early motoneurones (the β motoneurones) as they grow distally and establish the D pathway (long arrow) (see Figs 3, 4). Large cell above A pathway is a mesodermal cell also stained by the I-5 antibody. Cell body diameters in *a* and *b* are ~15 μm; large mesodermal cell in *c* is ~30 μm in diameter.

0028-0836/82/220404—03$01.00

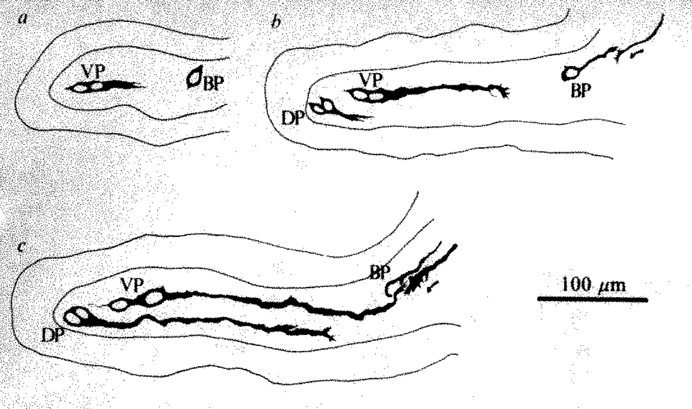

Fig. 2 Drawings of the antennae of the grasshopper embryo at successively older stages of development, showing the pioneering of the peripheral axonal pathways by the growth cones from peripheral and central (arrows) cells. Bar, 100 μm.

relatively short distances from one another; the VP neurones are less than 100 μm from the BP neurone, and the BP neurone is less than 100 μm from the CNS. Lucifer Yellow injections (and visualization with anti-Lucifer Yellow) reveal that the cells before axonogenesis and the growth cones afterwards radiate long, thin filopodia that typically reach over 50 μm and sometimes for up to 100 μm (ref. 10). Thus, the cells may be within filopodial grasp at, or shortly after, axonogenesis.

A similar, albeit more complex, series of events takes place in developing limb buds (Figs 3, 4). The first growth cones in the limb bud arise from the 1B cells (Bate's[2] original 'pioneers'). The 1B growth cones extend proximally towards the CNS along the basement membrane on the inside of the ectodermal epithelium of the limb bud, growing past where the 2B cell appears and towards the 3B cell (the B pathway, Fig. 4). However, the 1B growth cones make a characteristic turn about the time they reach the 3B cell (although they need not reach this cell); they always, however, turn towards the 1A cells which are about 50 μm away and within filopodial grasp (Fig. 3). Upon reaching the 1A cell bodies, the 1B growth cones then continue extending towards the CNS. One source of guidance for the 1B growth cones is likely to be the 1A cells (as 'landmark' cells). In the pro- and mesothoracic limb buds, the 1A cells send growth cones towards the CNS before the 1B growth cones arrive at their cell bodies; thus the 1A cells pioneer the first pathway (the A pathway, Fig. 4) between the base of the limb bud and the CNS (Fig. 3*a*). The timing is different, however, in the metathoracic limb bud. Here the 1A cells do not pioneer the first pathway to the CNS; rather, the 1B cells grow towards them and then continue growing towards the CNS, followed shortly thereafter by the 1A growth cones.

A second pathway is simultaneously made by growth cones of motoneurones originating in the CNS; these growth cones do not fasciculate with the 1A or 1B axons but rather form a separate yet parallel pathway between the base and the CNS. As development proceeds, the A pathway becomes nerve 5 whereas the second parallel pathway becomes nerve 3.

The C pathway is made by the pair of 1C neurones. Much of the D pathway is pioneered by growth cones of motoneurones originating in the CNS which extend out along the A pathway shortly after it is established; instead of growing along the B or C pathways, these motoneurones make a new pathway as they grow distally (Figs 1, 3, 4). These motoneurone growth cones meet those from the 1D cells and thus the D pathway is completed. The E and F pathways are pioneered by pairs of peripheral cells in a similar fashion simultaneous to the pioneering of the D pathway (Figs 3, 4) [the 1E cells are Keshishian's[4] second pair of pioneers]. Just as in the antenna, the distances between the peripheral neurones in the limb bud are relatively short (often 50 to 100 μm) when they first extend growth cones. Here too the cells have extensive filopodia and may be in direct contact at, or shortly after, axonogenesis.

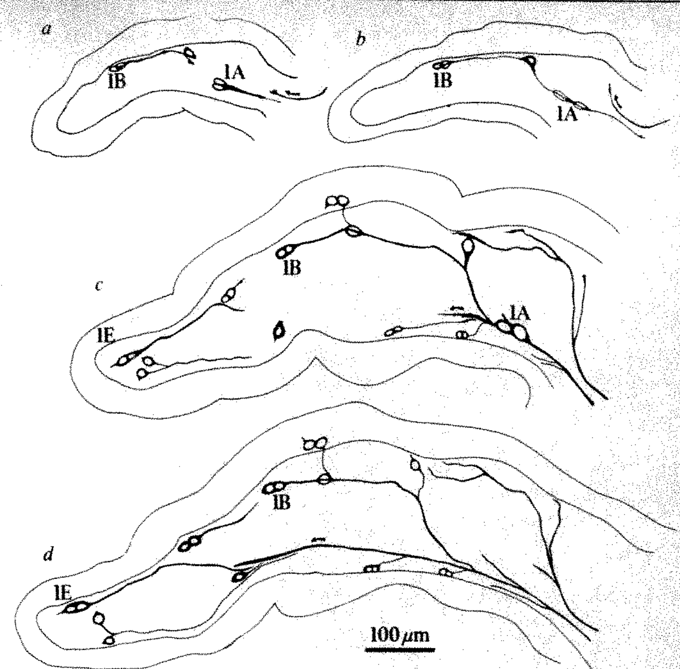

Fig. 3 Drawings of the mesothoracic limb bud of the grasshopper embryo at successively older stages of development, showing the pioneering of the peripheral axonal pathways by the growth cones from peripheral and central (arrows) cells. For clarity, only a few cells are named; the complete identities are shown in Fig. 4.

Four major conclusions are suggested by our results. First, peripheral pathways are pioneered by growth cones from central as well as peripheral neurones. For example, nerve 3 and the D pathway of nerve 5 are pioneered by motoneurones.

Second, there are not just two pairs of cells involved in pioneering the peripheral pathways in limb buds, but rather a large array of cells. In sheer number, this array of cells (Fig. 4) at first glance appears to hopelessly increase the complexity of the problem. Yet their unveiling dramatically simplifies the picture and points us towards specific experiments. The finding that the cells are so close and no one cell must alone traverse a large expanse of axonless territory, shifts our attention from long distance guidance mechanisms (e.g. diffusible gradients) to local interactions between identified cells over short distances. In many cases, cells may be in direct filopodial contact with 'landmark' cells (for example the 1A cells appear to be stepping stones [2] for the 1B growth cones); in other cases, specific mechanical substrates (e.g. the tendon followed by the 1E cells, see below) may take the growth cones to their next neuronal contact. The finding of landmark cells in the periphery is similar to our finding of landmark cells in the CNS[12].

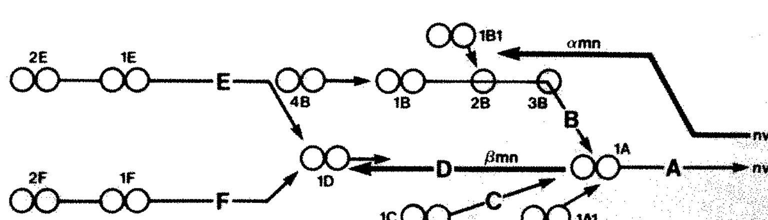

Fig. 4 Schematic diagram showing the identities of cells responsible for pioneering the pathways A to F of nerve 5, and the first pathway of nerve 3 is the pro- and mesothoracic limb buds. In the metathoracic limb bud, the 1A cells do not pioneer the A pathway, but rather the 1B growth cones use the 1A cells as landmarks and then continue growing towards the CNS.

Third, growth cones in the periphery are not simply guided by passive mechanisms. Active guidance mechanisms are suggested because certain growth cones are confronted with several possible choices and make cell-specific decisions of which way to go. For example, the 1E growth cones extend along the epithelium until they near the 4B cell bodies. Rather than climb onto the B pathway, they make a turn and grow along a tendon to the 1D cells, thus completing the E pathway. In a similar way, early motoneurone growth cones are confronted with the B and C pathways, yet choose to grow laterally and pioneer a new D pathway. The finding of specific choices made by growth cones in the periphery is similar to the divergent and specific choices made by identified growth cones in the CNS[11-14].

Finally, we must re-evaluate the concept of 'pioneer neurones'. Bate and Goodman have shown that other peripheral nerves (such as the intersegmental nerve and the median nerve) are pioneered by motoneurone growth cones from neuroblast progeny in the CNS (manuscript in preparation). Furthermore, pathways in the CNS are pioneered by progeny from two different classes of neuronal precursors—the midline precursors and neuroblasts[12,15]. Thus, there is no specialized class of precursor cell which gives rise to cells having the unique role of establishing axonal pathways throughout the grasshopper embryo. Rather, neurones of diverse ectodermal origin appear early in embryogenesis and pioneer pathways when the distances are short and the terrain relatively simple. This finding shifts the emphasis away from the special role played by 'pioneers', and focuses our attention on the questions of what cell-to-cell interactions and substrate features guide the first peripheral growth cones. These questions can be answered by manipulating the pioneer neurones, landmark cells, and ectodermal epithelium in grasshopper embryo cultures. In this way, we hope to establish by what mechanisms these 'pioneering' growth cones are guided across short distances of axon-less territory.

We thank Susannah Chang for the I-5 antibody and Paul Taghert and Michael Bastiani for the anti-LY antibody. This work was supported by grants from the McKnight Foundation, NSF, and Sloan Foundation to C.S.G.

Electrophysiology of mammalian thalamic neurones *in vitro*

Rodolfo Llinás & Henrik Jahnsen

Department of Physiology and Biophysics,
New York University Medical Center,

Although much is known about the morphology and physiology of thalamic neurones[1], no information is available regarding the ionic basis for the electrical excitability of these cells. Furthermore, possible differences in the electrical properties of the principal nerve cells in the various thalamic groups have not been studied in sufficient detail to determine whether the thalamus is, electrophysiologically, a uniform set of neuronal elements. Here we present evidence that thalamic neurones have voltage-sensitive ionic conductances capable of generating two distinct functional states—a repetitive and a burst-firing mode. The neurones are switched from one state to the other by membrane potential changes, each state being dominated by different voltage-dependent ionic conductances. At membrane potentials more positive than −60 mV, the neurones respond to a depolarization with repetitive firing via Na^+-dependent action potentials, whereas at potentials more negative than −65 mV, depolarization of the cell results in short bursts of action potentials via an inactivating all-or-none Ca^{2+}-dependent spike. This property, present in all the neurones comprising the different thalamic nuclei, serves as the basis for their oscillatory properties. Particularly, the inactivating Ca^{2+} conductance represents the ionic basis for the post-anodal exaltation, the mechanism most probably responsible for the alpha rhythm.

The study was performed on 400-μm-thick thalamic slices obtained by coronal section of guinea pig brain using a vibratome cutting device (Oxford G501 Vibratome). Typically, six sections included most of the thalamus. The sections were placed in a special lucite chamber under a flowing mammalian Ringer's solution[2]. Electrophysiological analysis was performed, under direct microscopic observation, on neurones of the anterior, medial and lateral thalamic nuclear groups, including the lateral geniculate nucleus and neurones in the lamina interna. The techniques for sectioning and maintenance of the slice have been described elsewhere[2]. Intracellular recordings were made using potassium citrate-filled micropipettes having a d.c. resistance of 50–90 MΩ. Cells were activated either antidromically or synaptically by means of bipolar stimulating electrodes located on the midline region of the thalamic mass (see arrow in Fig. 1*A*) or directly through the microelectrode using a bridge amplifier. Neurones were identified by their antidromic and synaptic activation, and their thalamic site was determined by direct observation. Although single somata were often not visible, the exact outline of the groups of nuclei could be easily determined (see Fig. 1*A*). Intracellular recordings from these neurones indicated that they could survive well for >8 h after the slicing procedure. The stimulus amplitude required for the antidromic activation of these cells (Fig. 1*B*) was often lower than that for the activation of synaptic inputs (Figs 1*C*, 2*E*, *F*). Considering the thickness of the slices, we suspect that only monosynaptic connectivity can be reliably studied in this material.

The electrical properties of the cells were examined by direct stimulation via the recording electrode. As shown in Fig. 2*A*, thalamic cells may be characterized by two distinct types of electrical response. When the resting potential was more positive than −60 mV, thalamic neurones fired repetitively at increasing frequencies with increasing amplitude of direct depolarization. A plot of the instantaneous adapted firing frequency, f (1 s pulse duration) against current injection (I) is shown in Fig. 2*C*, which illustrates the graded nature of the repetitive firing properties of these cells. However, in contrast to other central neurones[3], no primary firing range was observed: rather, the neurones fired with a typical minimal frequency of ~10 impulses s^{-1} and reached firing frequencies of 165 impulses s^{-1}. At this membrane potential level, we observed no after-depolarization comparable to that seen in motoneurones[4], and Purkinje[2], inferior olivary[5] and hippocampal[6] cells *in vitro*. On the other hand, when the cells had resting potentials more negative than −60 mV, or were hyperpolarized by direct inward current injections, rather than the continuous firing, a single burst of action potentials was observed after a step depolarization (see Fig. 2*A*, *B*). The lower record in Fig. 2*A* demonstrates a passive membrane depolarization produced by a square current pulse that is subthreshold for spike initiation. When, as shown in the upper record in Fig. 2*A*, the same

current pulse was superimposed on a d.c. depolarization, the cell fired repetitively. This is expected if the sum of the two depolarizations reaches the firing level of the cell. However, when the membrane potential was hyperpolarized from rest, another type of electroresponsiveness was observed. Indeed, the excitability of the cell was increased by membrane hyperpolarization. Thus, single burst responses having an abrupt onset and a smooth falling phase were obtained by current pulses as in Fig. 2*A* when the cell was previously hyperpolarized by 7 mV (Fig. 2*B*). Note the marked difference between the firing level for the tonic firing (arrow in Fig. 2*A*) and that of the burst response (arrow in Fig. 2*B*). The burst response had two distinct components: (1) a slowly rising all-or-none depolarization, the amplitude of which is directly related to the level of membrane hyperpolarization; and (2) one or more fast spikes activated from the slow depolarization.

Such a burst was also observed as a rebound response at the break of a hyperpolarizing current pulse (Fig. 2*D*). In these conditions the two components could be easily separated. In fact, with low-amplitude hyperpolarizing pulses only the slow component was observed, emphasizing the graded nature of the amplitude of this response. With larger hyperpolarizations the slow component reached the threshold for fast spike activation. Note that the hyperpolarization had a slow recovery time suggesting the presence of an 'early Na conductance'. The increased excitability that occurred with hyperpolarization was also demonstrated after synaptic activation. Figure 2*E* shows that smoothly graded excitatory synaptic potentials which reached the firing level were obtained in a thalamic neurone having a resting potential of −60 mV after midline thalamic stimulation of increasing amplitude. When the neurone was hyperpolarized by 15 mV (Fig. 2*F*), the same synaptic activation generated all-or-none slow depolarization, which in turn activated fast spikes. Note once again the different firing levels for the activation of the slow response and the fast action potentials.

These two modes of electroresponsiveness were found to have different ionic mechanisms as demonstrated by the addition of specific ionic channel blockers to the bathing solution. The fast action potentials, which seem to arise from the soma and axon areas (judging from the extracellular negativity they generate) can be blocked by tetrodotoxin (TTX) indicating that they are sodium-dependent[8]. As shown in Fig. 2*G*, a step

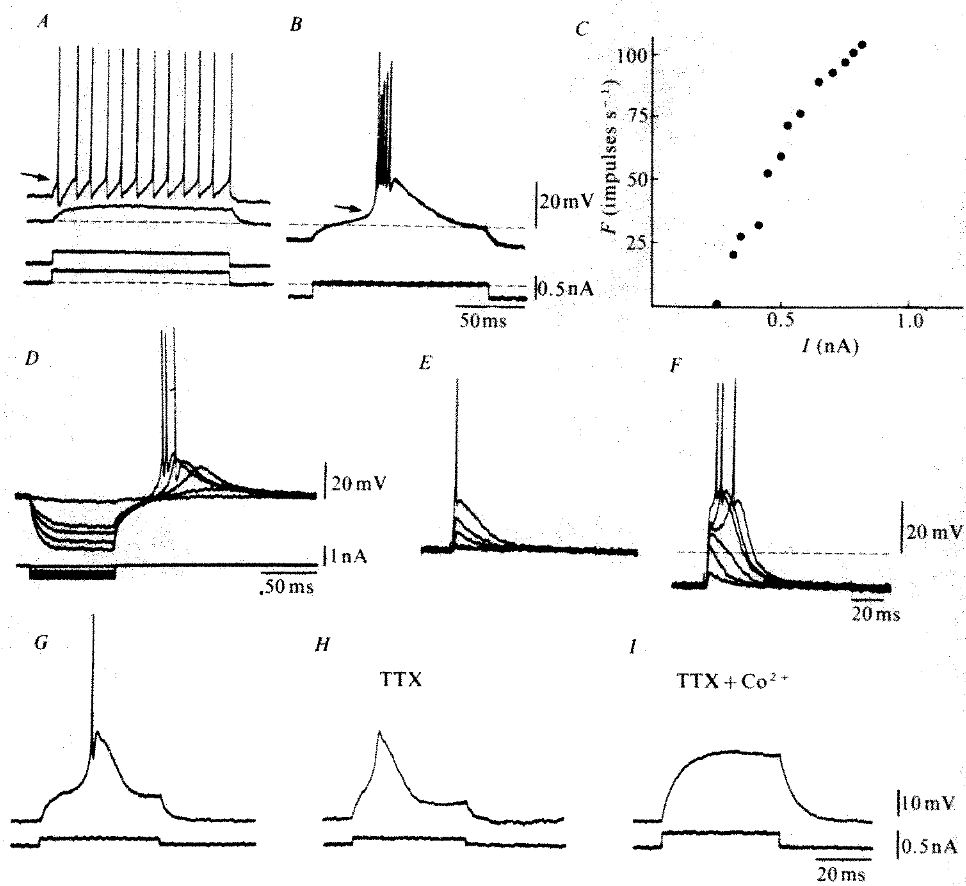

Fig. 2 Electrophysiological and pharmacological properties of thalamic neurones. *A*, a subthreshold depolarization of the cell at resting level (broken line) produces, after a d.c. depolarization, repetitive firing of the cell during the same current pulse. *B*, after d.c. hyperpolarization, similar current pulses as in *A* produce a single high frequency spike burst. *C*, plot of the instantaneous adapted frequency (f) of the repetitive firing of the cells as seen in *A* for different levels of current injection (I). *D*, rebound burst response after hyperpolarizing pulses of different amplitudes. *E*, in another cell, excitatory synaptic potentials obtained from rest show their graded character and the firing level of the neurone. *F*, synaptic potentials of similar amplitude as in *E* produce, following hyperpolarization, long-lasting all-or-none responses on which fast spikes are generated at the same firing level as in *E*. *G*, slow all-or-none response generating fast spike, from a cell slightly hyperpolarized from rest potential. *H*, after blockage of Na^+ conductance with TTX, the fast action potential is blocked but the slow response remains unchanged. *I*, addition of $CoCl_2$ to the bathing solution abolishes completely the slow response seen in *H*, even when the current pulse is increased in amplitude by 2.5 times.

depolarization from a holding level of −65 mV produced a large all-or-none depolarization and a secondary fast spike. Addition of TTX to the bath at 1 μg ml^{-1} completely blocked the fast action potential, leaving the underlying all-or-none slow depolarization unaltered (Fig. 2*H*). By contrast, addition of Ca^{2+}-conductance blockers such as $CoCl_2$ (ref. 9) or $CdCl_2$ (ref. 10) to the bathing solution at a concentration of 1 mM, or substitution of $MnCl_2$ (3.5 mM) for $CaCl_2$, abolished this all-or-none response (Fig. 2*I*). These results indicate that the slow spike is generated by a voltage-dependent change in Ca^{2+} conductance[11]. Furthermore, the nature of this response is similar to the low-threshold Ca^{2+}-dependent spikes described in the inferior olive[5,12].

A more detailed study of the switching between a Ca^{2+}-dominated and a Na^{+}-dominated electroresponsiveness revealed that this change occurs in almost an all-or-none manner. Figure 3 shows that when the excitability of a cell was challenged with a series of brief depolarizing pulses (of sufficient amplitude to fire the cell), and simultaneously the membrane potential was gradually decreased by a slow ramp depolarizing current, the response to the pulse changed from the burst mode to tonic firing. In this case the bursts had a duration of 30–130 ms, and generated a set of fast action potentials at a frequency of 150–320 impulses s^{-1}, depending on the level of membrane hyperpolarization. As the membrane was slowly depolarized, the test pulses produced, rather than the burst, a continuous repetitive spiking for the duration of the pulse (compare *b* and *c* in Fig. 3*B*). The frequency of this repetitive firing was related to the total level of depolarization as indicated in the *f–I* plot in Fig. 2*C*.

The mechanism for the switching between these two excitability states was clarified by further studying the properties of the Ca^{2+}-dependent electroresponsiveness. As shown in Fig. 2*D*, the amplitude and the rate of rise of this Ca^{2+}-dependent response varies with membrane potential in a very steep manner. In addition, as in the case of the inferior olivary cells, these responses completely inactivate at membrane potential levels more positive than −60 mV. This voltage-dependent inactivation explains both the presence of burst responses when the cell is hyperpolarized and the rebound activation of these cells. Furthermore, as observed in inferior olivary neurones[5], these rebound calcium spikes show a long refraction, indicating that the kinetics of recovery from the inactivated state are slow. This slow recovery also explains why such responses are unitary as their activation is followed by a rather prolonged refractory period of 80–150 ms.

In conclusion, these findings indicate that thalamic neurones have special voltage-sensitive ionic conductance properties which allow them to change from a phasic bursting response (followed by neuronal silence) to graded repetitive firing, and this switching is modulated by membrane potential. When the cells have a resting level more negative than −60 mV, a low threshold calcium response is obtained. The other integrative state is characterized by tonic firing brought about by depolarization of the cell to levels more positive than −60 mV. At this membrane potential level, the calcium conductance which generates the slow response is inactivated and the cell fires repetitively. Although the precise distribution of these conductances over the soma-dendritic area of these neurones has not been determined, by analogy with inferior olivary cells[5,12], we suggest that the Ca^{2+}-deinactivated response probably resides at the somatic level, as does the Na^{+}-dependent action potential.

These electrical properties further explain many of the electroresponsive properties observed in thalamic recordings *in vivo* where such switching of tonic to phasic firing has in fact been described[13,14]. Moreover, in conjunction with the recurrent inhibition observed *in vivo*, this newly described Ca^{2+} conductance represents the functional basis of the so-called 'post-anodal exaltation' underlying the recruiting responses[12] at cortical level and most probably the α rhythm[15].

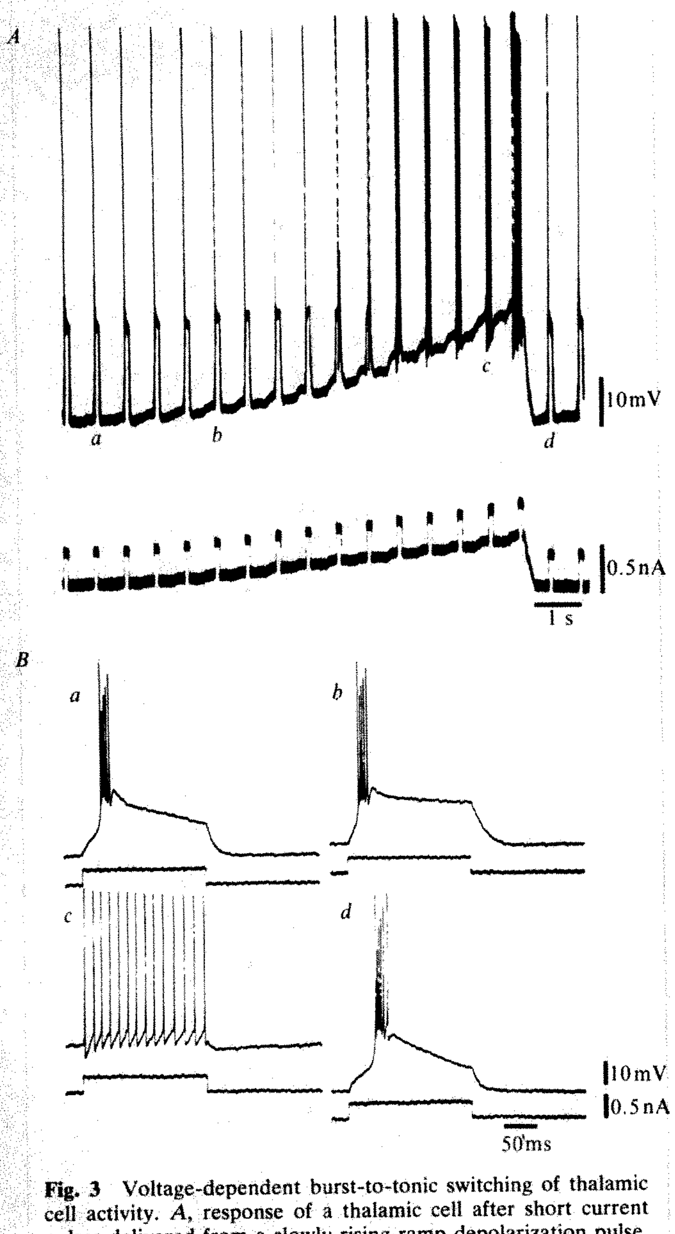

Fig. 3 Voltage-dependent burst-to-tonic switching of thalamic cell activity. *A*, response of a thalamic cell after short current pulses delivered from a slowly rising ramp depolarization pulse. The cell switched abruptly from a burst response to tonic firing as the d.c. potential decreased by ~10 mV from the initial value. *B*, records obtained at a higher sweep speed at the times indicated by *a* to *d* in *A*. Note the transition from burst response (*a* and *b*) to tonic response (*c*), followed by the abrupt return to a burst response (*d*).

Evidence for the presence of S-100 protein in the glial component of the human enteric nervous system

Recently, the complex organization of the enteric nervous system and its independent role in the integrative control of digestive functions have been fully recognized. However, little is known about the non-neuronal elements present in close morphological and, presumably, functional relationship with the enteric neurones. Although 'enteric glial cells' in gut ganglia and Schwann cells accompanying nerve fibres throughout the gastrointestinal wall can easily be recognized by electron microscopy on the basis of their ultrastructural features[1–3], the lack of a suitable common marker for the visualization of these non-neuronal components of the enteric nervous system has hampered investigation. S-100 is a Ca^{2+}-binding protein[4] originally isolated from the brain[5], where it is localized mainly in glia[6,7]. We demonstrate here, using immunohistochemistry and electron immunocytochemistry, that both enteric glial cells and Schwann cells of the human gut contain densely immunoreactive S-100. This protein can therefore be regarded as a common marker for the glial components of the enteric nervous system.

The distribution of the S-100 protein in the enteric nervous system was studied by immunocytochemistry in tissue samples obtained from uninvolved areas of segments of human gut resected for carcinoma (stomach, ileum and colon; $n = 15$). Throughout the entire length of the gastrointestinal tract, S-100-immunoreactivity was detected in the ganglia of both the submucous and the myenteric plexus, in slender cells having numerous projections partially surrounding enteric neurones (Fig. 1*a*), presumably glial cells. In addition, numerous elongated, dendritic cellular elements were immunostained in all non-epithelial layers of the wall (Fig. 2); these were considered to be Schwann cells.

To confirm that in enteric ganglia S-100 is selectively localized in glial cells, we compared the distribution of this antigen with that of neurone-specific enolase (NSE), an isomer of the glycolytic enzyme enolase that is specifically localized in neurones of the central nervous system (CNS)[7,8] and has also been demonstrated in gut neurones[9]. Figure 1 shows that S-100 was localized only in glial cells (*a*), while neurones, identified by NSE immunostaining (*b*), were completely negative.

Ultrastructurally identifiable Schwann cells accompany the bundles of nerve fibres running through all layers of the gut wall, forming an incomplete sheath around them[2]. To confirm that the S-100-immunoreactive elements found outside the enteric ganglia were Schwann cells, we studied their three-dimensional structure and distribution in stretch preparations of either submucosa or lamina propria separated by microdissection, then immunostained and examined whole[10]. In both of these layers, a network of S-100-immunoreactive elements was demonstrated in the internodal strands running between enteric ganglia (Fig. 3*a*), around blood vessels, and in a dense mesh of interconnecting cells both at the level of the muscularis mucosae (Fig. 3*b*) and in the lamina propria up to close contact with the basement membrane of the epithelium. The distribution of S-100-immunoreactivity seems therefore to parallel the general distribution of the enteric innervation.

Glial cells in enteric ganglia have distinctive ultrastructural features resembling those of astrocytes in the CNS[3]. Typical

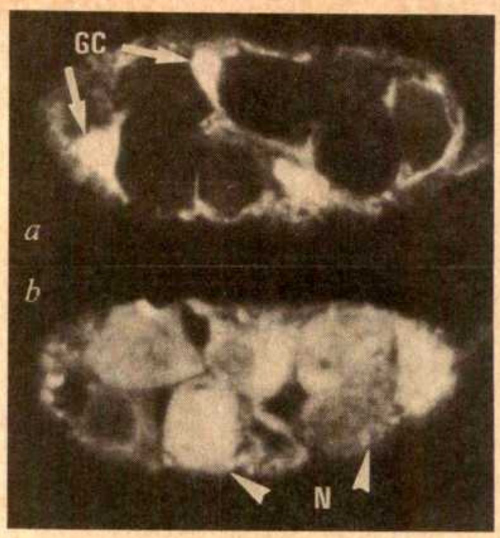

Fig. 1 Immunofluorescent detection of S-100 (*a*) and NSE (*b*) in two serial (4 μm) sections of a submucous ganglion in the human colon. Tissues were fixed in *p*-benzoquinone solution[21] (0.4% in phosphate-buffered saline, PBS) for 2 h, washed overnight in PBS containing 7% sucrose, frozen in melting Arcton and cut with a cryostat. Sections were stained by indirect immunofluorescence using anti-S-100 antiserum diluted 1:500, and anti-NSE antiserum diluted 1:800 in PBS (overnight incubation), followed by fluorescein isothiocyanate-conjugated goat anti-rabbit IgG diluted 1:200 (1 h). Specific rabbit antisera raised against ox S-100[14] and rat NSE[8], fully cross-reacting with the human S-100 and NSE, were used. Controls included the use of antibodies preabsorbed with 20 $\mu g\ ml^{-1}$ of ox S-100 and 5 $nmol\ ml^{-1}$ of rat or human NSE. S-100 immunoreactivity (*a*) was confined to the slender and elongated glial cells (GC) partially surrounding neurones (N), which were completely negative for this antigen and were revealed (*b*) by NSE immunostaining. ×700.

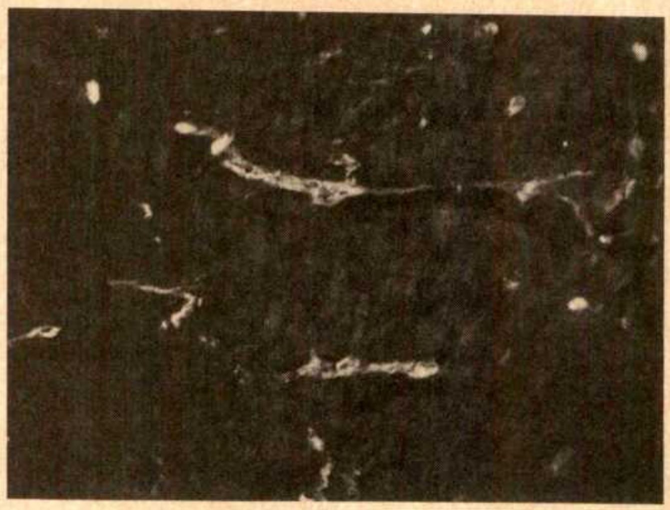

Fig. 2 S-100 immunofluorescence (fixation and immunostaining as described in Fig. 1 legend) in the muscle layer of the human colon. Numerous slender cells having several long, branching processes can be observed. Similar elements, with the morphological appearance of Schwann cells, were demonstrated in all non-epithelial layers of the gut wall (10 μm section, ×120).

0028-0836/82/220409—02$01.00

glial cells identified by electron microscopy in enteric ganglia contain S-100-immunoreactivity, while enteric neurones are negative (Fig. 4*a*). In addition, in all gut layers, positive immunostaining for S-100 was demonstrated in Schwann cells partially surrounding bundles of nerve fibres (Fig. 4*b*). In the present experiments, only the cytoplasmic localization was consistently demonstrated in enteric glia, even though a nuclear localization of this protein has been documented in the CNS[11-13].

Although S-100 has recently been demonstrated in various locations outside the nervous system, including stellate cells in the adenohypophysis[14,15], satellite cells in the adrenal medulla[16], melanocytes and Langerhans cells in the skin[17] and chondrocytes[18], there is general agreement on its prevalent localization in the CNS in glia[6,7]. The presence of this brain protein in the enteric nervous system agrees with the numerous homologies reported between the gut 'mini brain' and the CNS[2].

Another brain protein, the glial fibrillary acidic protein, has recently been demonstrated in enteric glial cells[19]. However, the absence of this protein from Schwann cells[19] precludes its use as a common marker of the non-neuronal components of the enteric nervous system.

In conclusion, our results indicate that the S-100 protein can be reliably used to demonstrate the glial elements of the enteric nervous system in man. This will have immediate relevance to the study of disease conditions affecting the gastrointestinal innervation, especially those in which an abnormal glial proliferation is suggested[20].

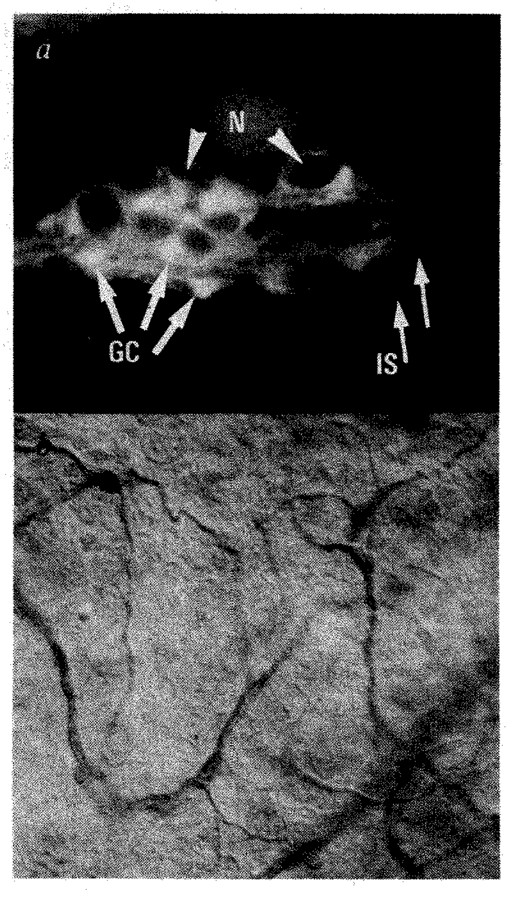

Fig. 3 S-100 immunoreactivity in whole-mount preparations of submucosa[10]. This layer was separated from samples of ileum and colon by microdissection, fixed in *p*-benzoquinone (see Fig. 1 legend), dehydrated through graded alcohols, cleared in xylene, rehydrated and immunostained *in toto* by immunofluorescence or by the peroxidase-antiperoxidase technique[22]. Prolonged incubations (16–36 h) and washings (6–8 h) were used. S-100 immunostaining revealed the general distribution of glial elements in the whole enteric innervation; *a*, in glial cells (GC) partially circumscribing unstained neurones (N) in the ganglia, and in Schwann cells in internodal strands (IS); and *b*, in a rich network of Schwann cells at the level of the muscularis mucosae. (*a*, ×375; *b*, ×280.)

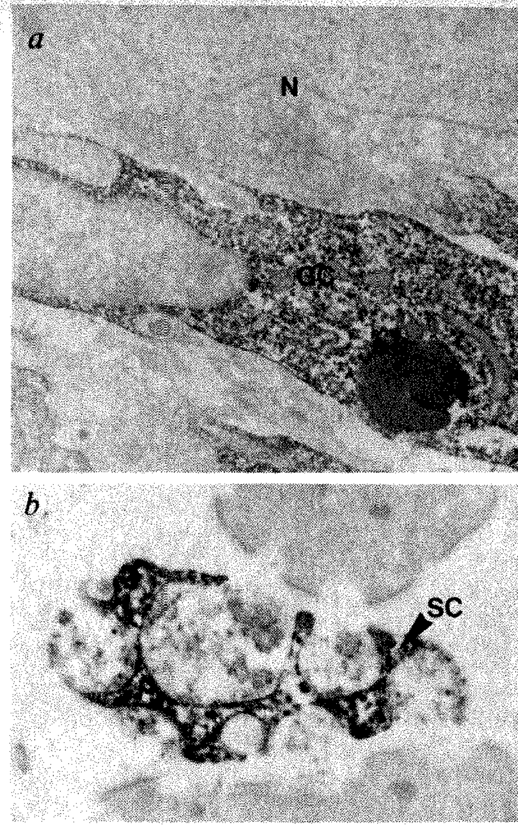

Fig. 4 Electron immunocytochemistry for S-100. Tissues were fixed in 4% paraformaldehyde in 0.1 M phosphate buffer for 3 h, washed overnight in PBS and cut at 100 μm with a vibratome. Sections were stained by the peroxidase–antiperoxidase technique[14,23] (same antibody dilution and controls as described for Fig. 1) using diaminobenzidine acid as coupler, then embedded in Araldite and cut at 60 nm for electron microscopy. In enteric ganglia (*a*), immunoreactivity is demonstrated in the cytoplasm of glial cells (GC), which partially circumscribe neurones that are completely unstained (N). In a nerve bundle in the muscle layer (*b*), projections of Schwann cells (SC) are in close contact with nerve fibres, which are unstained (ileum: *a*, ×10,000; *b*, ×20,000).

Hapten-specific T suppressor factor recognizes both hapten and I–J region products on haptenized spleen cells

M. Zembala*, G. L. Asherson & V. Colizzi*

Division of Immunological Medicine, Clinical Research Centre, Watford Road, Harrow HA1 3UJ, UK

The classical example of genetic restriction is associative recognition, the finding that cytotoxic T-cell killing requires matching between part of the major histocompatibility complex (MHC) of the stimulating cell and the target cell[1,2]. Its analysis would be facilitated by the study of a system in which antigen-specific T suppressor factor (TSF) was genetically restricted in its interaction with haptenized cells. However, only one such system is known[3,4], although there are several systems in which the TSF must be syngeneic with other cells[5–8]. We now describe a genetically restricted TSF which arms an acceptor T cell. This acceptor cell shows some resemblance to the auxiliary T suppressor (Ts) cell, the acceptor T cell and the Ts_3 described elsewhere[5,6,9]. In the presence of antigen (haptenized spleen cells) the armed acceptor cell releases a nonspecific inhibitor of the passive transfer of contact sensitivity (see. Fig. 1). The important finding is that the antigen will only trigger the release of the nonspecific inhibitor when there is matching in the *I–J* region between the TSF and the haptenized cell used as a source of the triggering antigen.

In practice, the T acceptor (T_{acc}) cell is produced by immunization with picryl chloride (pic) or oxazolone. The contact sensitizer used is unimportant because it does not influence the specificity of the system (Table 1). Macrophages are removed by nylon wool filtration as they may act as acceptor cells[10]. The T_{acc} cell population is armed by incubation in anti-pic or anti-oxazolone TSF[11,12]. The cells are then exposed to antigen (picrylated spleen cells) and the nonspecific inhibitor released into the supernatant is tested by its ability to block the transfer of contact sensitivity by immune cells incubated in it. This system is formally analogous to the reaginic system in which the roles of specific IgE, mast cell, soluble antigen and histamine are taken by specific TSF, the acceptor T-cell, haptenized spleen cells and the nonspecific inhibitor (see Fig. 1).

The first experiment investigated the main characteristics of the system. T acceptor cells were produced by immunization with picryl chloride or the unrelated contact sensitizer oxazolone, and were armed with anti-picryl TSF. After washing, picrylated spleen cells were added as a source of antigen and the supernatant was collected after 2 h. Table 1 (lines 3–5) shows that nonspecific inhibitor of the passive transfer of contact sensitivity was produced when the T_{acc} cells were generated by painting with picryl chloride or oxazolone, while normal spleen cells were ineffective, that is, immunization but not specific immunization was required for the generation of T_{acc} cells. Unseparated or nylon wool-purified T spleen cells could be used as a source of antigen (lines 3, 7) and irradiation at 2,000 rad did not affect the ability of picrylated spleen cells to trigger the release of nonspecific inhibitor.

We next investigated the requirement for genetic matching between the anti-picryl TSF and the picrylated cells used as a source of antigen. Immune T cells from CBA or BALB/c mice were used as an acceptor cell population and armed with anti-picryl TSF from CBA or BALB mice. Picrylated CBA or BALB spleen cells were then added as a source of antigen and the supernatant was collected at 2 h. Table 2 (line 3) shows that nonspecific inhibitor of the passive transfer of contact sensitivity was detected when the TSF, the acceptor T cell, the antigen (picrylated spleen cell) and the final test cell were all syngeneic. Lines 7, 9 and 11 of Table 2 show that syngeneity between the TSF and the antigen (picrylated spleen cell) was critical for triggering the release of the nonspecific inhibitor from the acceptor cell.

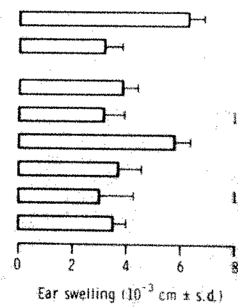
7	″	T_{nyl} pic CBA	″	″	100% ***
8	″	″ †	″	″	98% ***



Anti-picryl TSF was produced by injecting picrylsulphonic acid (PSA) intravenously, painting with picryl chloride on day 6 and culturing lymphoid cells taken on day 7 for 48 h (ref. 12). Nylon wool-purified T spleen cells (T_{nyl}, 1.5×10^8) taken from mice 4 days after painting with picryl chloride (Pic) or oxazolone (Ox) or from normal mice were used as acceptor cells. They were armed with anti-picryl TSF (4 ml) at 37 °C for 1 h, spun down, washed once and antigen added. The standard antigen was picrylated normal spleen cells (3×10^7), prepared by lysis of red cells with Boyle's solution and picrylation with 10 mM PSA for 10 min (ref. 22). The armed acceptor cells and the picrylated spleen cells were centrifuged together and resuspended in 5 ml Eagle's minimal essential medium/Dulbecco's phosphate-buffered saline (MEM/PBS) with 2.5% inactivated foetal calf serum and incubated for 2 h with shaking every 40 min. Finally the nonspecific inhibitor in the supernatant was tested by incubating passive transfer cells (2.5×10^8, 4 day, oxazolone immune lymph node and spleen cells) with nonspecific supernatant (5 ml) for 1 h, washing once and injecting 4.5×10^7 into each of four to five CBA mice[12]. The mice were immediately challenged with 1% oxazolone on both sides of both ears and contact sensitivity was assessed by the ear swelling at 24 h. The horizontal bars show the increase in ear thickness at 24 h in units of 10^{-3} cm ± s.d. The figures show the percent depression of contact sensitivity taking the positive control group incubated in medium as 0% and the negative control group which did not receive any cells as 100%. †The picrylated spleen cells used as antigen were irradiated at 2,000 rad from a cobalt source. The significance of the difference from the positive control by Student's *t*-test was $^*P < 0.05$, $^{**}P < 0.002$ and $^{***}P < 0.001$.

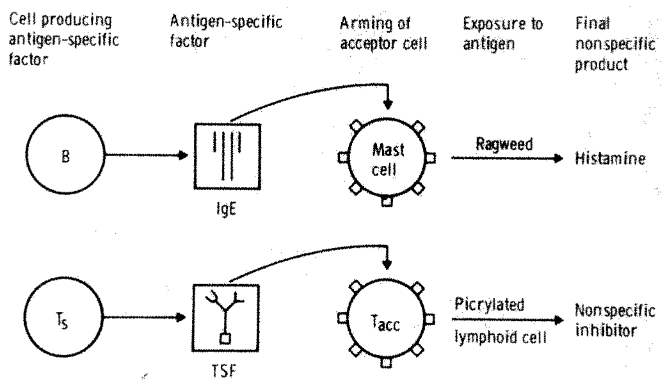


Fig. 1 Analogy between the IgE mast cell system and the T suppressor circuit involving Ts-eff, T suppressor factor and the T acceptor cell. In allergy to ragweed, the B cell makes specific IgE antibody. This is cytophilic and behaves like a mobile receptor which arms the mast cell. On exposure to ragweed the mast cell releases the final nonspecific products such as histamine. Similarly, in the T suppressor system to the picryl group, the T suppressor cell produces an anti-picryl T suppressor factor. This is cytophilic and arms the T acceptor cell. On exposure to antigen (picrylated lymphoid cells with the same *I–J* region as the cells producing the TSF) the T acceptor cell releases the final nonspecific products such as the inhibitor of the transfer of contact sensitivity. The diagram of the T suppressor factor illustrates its binding sites for the attachment to the T acceptor cell (□), the recognition of the picryl hapten (<) and the recognition of the product of the *I–J* locus (⊂).

Pooled lymph node and spleen T cells from mice painted with picryl chloride were used as acceptor cells and armed with anti-picryl TSF. They were exposed to antigen (picrylated spleen cells) and the nonspecific inhibitor was tested on the passive transfer of contact sensitivity to oxazolone in CBA mice. The experiment studied the effect on the generation of nonspecific inhibitor of the genotype (CBA or BALB/c) of the T_{acc} cell source, the TSF and the spleen cells used as a source of picrylated antigen.

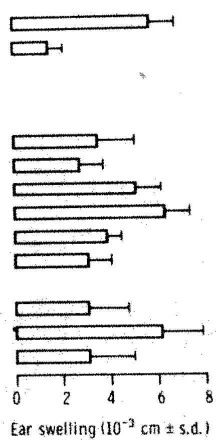
†, Unhaptenized CBA spleen cells (line 4) and ††, unhaptenized BALB cells (line 5) were added (3×10^7) to show that BALB cells did not block the liberation of nonspecific inhibitor through an allogeneic effect.

Congeneic B10.A mice were then used to confirm that the MHC was responsible for the genetic restriction. Anti-picryl TSF was prepared in B10.A and B10.A(3R) mice and used to arm CBA acceptor cells. Various picrylated cells were then used to trigger the release of nonspecific inhibitor. Table 3 shows that syngeneity at *I–J* was both necessary and sufficient.

The question was then asked whether the same molecule in the TSF preparation both had a combining site for antigen and was responsible for the genetic restriction. In a preliminary experiment, TSF purified by absorption onto haptenized microcrystalline cellulose and elution with the corresponding haptenized ε-aminocaproic acid showed genetic restriction. To confirm this result, anti-picryl and anti-oxazolone TSF were purified by binding to the appropriate haptenized microcrystalline cellulose. Dummy elution was then undertaken with the 'wrong' hapten followed by elution with the right hapten. Table 4 shows that the dummy eluates were inactive while the active TSF eluted by the appropriate hapten showed genetic restriction. We concluded that the hapten recognition site and the site which recognized the product(s) of the *I-J* locus of the MHC occurred on the same molecule. The fact that the effect of arming T_{acc} cells with TSF persists after washing suggests that TSF has a binding site for such cells. Stronger evidence is provided by the observation that T_{acc} cells armed with TSF can be purified by adherence (panning) on Petri dishes coated with haptenized albumin[13]. Hence, the TSF has three binding sites—one for attachment to the acceptor T cell, one for recognition of antigen and one for recognition of the products of the *I-J* locus (see model of TSF in Fig. 1). Feldmann[14] has suggested a similar schema. In fact, in the present system, questions about the nature of the combining site(s) involved in associative recognition become structural questions about antigen-specific TSF.

Table 3 Matching in the *I–J* region between anti-picryl T suppressor factor and the triggering antigen (picrylated spleen cells) is required for the release of nonspecific inhibitor

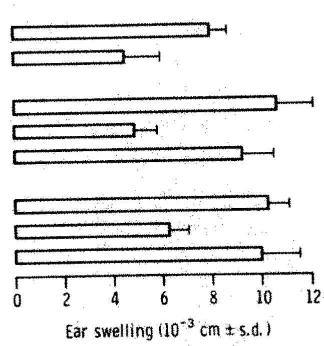
TSF	ag	K	Ia: A	Ia: B	Ia: J	Ia: E	C	D	
	Positive control								
	Negative control								
B10.A	B10.A	+	+	+	+	+	+	+	53%*
	2R	+	+	+	+	+			73%***
	3R					+	+	+	14%
	4R	+	+						0%
	5R				+	+			46%***
	CBA	+	+	+	+	+			64%*
3R	3R	+	+	+	+	+	+	+	64%*
	5R	+	+	+		+	+	+	0%
	4R			+	+				65%*



Anti-picryl TSF was prepared in B10.A and B10.A (3R) mice and used to arm CBA acceptor cells produced by immunization with picryl chloride. Picrylated spleen cells from congeneic mice were used to trigger the release of nonspecific factor and the supernatant was tested for its ability to inhibit the passive transfer of contact sensitivity to oxazolone using CBA cells. The plus signs refer to syngeneity between the TSF and the antigen used for triggering the release of nonspecific inhibitor.

Table 4 Purified anti-picryl and anti-oxazolone T suppressor factors are genetically restricted in their action

TSF	Elution	Antigen	
Positive control			
Negative control			
Pic CBA	Ox-EACA	CBA	0%
	Pic-EACA	CBA	89%***
	Pic-EACA	BALB	0%
Ox CBA	Pic-EACA	CBA	0%
	Ox-EACA	CBA	49%***
	Ox-EACA	BALB	0%



Anti-picryl and anti-oxazolone TSF[12] (15 ml) were absorbed for 2 h with 0.5 ml picrylated or oxazolonated diaminohexane microcrystalline cellulose prepared by haptenizing beads coupled to diaminohexane using sodium periodate and sodium borohydride. They were then eluted with the wrong haptenized ε-aminocaproic acid (3 mg ml^{-1}) for 45 min and then with the appropriate hapten. The eluates were made 0.25% with inactivated newborn calf serum and dialysed against PBS and MEM/PBS. Acceptor cells produced by immunizing CBA mice with picryl chloride were armed with the supernatant. Antigen (CBA or BALB picrylated spleen cells) was then added and the supernatant tested for its ability to inhibit the passive transfer of contact sensitivity to oxazolone using CBA cells.

It is puzzling that the *I-J* locus and the several *I-J* determinants[15] are involved at multiple levels of T suppressor systems. In particular, the TSF is probably made by an I-J^+ cell and TSF, including anti-picryl TSF but not anti-dinitrophenyl TSF[3], carries *I-J* determinants[16–18]. The T_{acc} cell studied here and those reported elsewhere[5,6,9] are I-J^+ and the genetic restriction between the TSF and the triggering antigen in the present system is *I-J*-restricted. An *I*-region restriction between antigen-specific TSF which induces an anti-idiotype Ts_2 and the Ts_3 is also described[16]. Finally in neonatal tolerance *I-J* differences favour unresponsiveness[19] and the presence of allogeneic *I-J* augments the activity of certain immune T suppressor cells[20].

Czitrom, Sunshine and Mitchison[21] proposed that antigen presented in the context of *I-J*, that is, on an *I-J*-positive macrophage or *T* cell[15], selectively stimulates T suppressor cells. This implies that the T_s and the TSF produced by the T_s carry receptors both for antigen and for the *I-J* on the antigen-presenting cell. This hypothesis would explain the requirement for syngeneity between the mouse producing the TSF, in which

antigen was initially presented, and the antigen used to trigger the release of nonspecific inhibitor. An interesting elaboration is that the ability of antigen-specific TSF to give rise to anti-idiotype T suppressor cells[6] might be due to the *I–J* antigen of the TSF (or of the macrophage or T acceptor cell to which it attaches) acting as a signal for the induction of suppressor cells.

M.Z. and V.C. thank the Wellcome Trust and the Lega Nazionale contro i Tumori for financial support, Malcolm Brenner, Miroslav Malkovsky and Liz Simpson for valuable discussion and Valerie Stein and Madelaine Watkins for technical assistance.

Epstein–Barr virus-specific cytotoxic T-cell clones restricted through a single HLA antigen

L. E. Wallace, A. B. Rickinson, M. Rowe & M. A. Epstein

Department of Pathology, University of Bristol Medical School, University Walk, Bristol BS8 1TD, UK

HLA-restriction of antiviral cytotoxic T-cell responses in man, precisely analogous to the H-2-restriction first documented in murine virus infections[1–3], has now been unequivocally demonstrated with influenza virus-specific [4–7] and with Epstein–Barr (EB) virus-specific[8–12] cytotoxic T cells reactivated *in vitro*. If individual effector cells of this kind recognize viral antigen in association with one particular HLA determinant, then it follows that cytotoxic T-cell preparations from HLA-heterozygous donors must be polyclonal with discrete component populations each functionally linked to one of the relevant HLA-A or -B antigens. Clonal expansion of individual cells from such preparations in medium containing T-cell growth factor (TCGF-medium) not only offers a means of testing this hypothesis but should also provide monospecific populations ideal for the analysis of human cytotoxic T-cell function. We describe here the establishment *in vitro* of EB virus-specific human cytotoxic T-cell clones each recognizing the virus-induced lymphocyte-detected membrane antigen (LYDMA) in association with one particular HLA-A or -B determinant.

EB virus-specific cytotoxic T cells can be reactivated *in vitro* by co-culturing peripheral blood mononuclear cells from previously infected (seropositive) individuals with X-ray irradiated cells of the autologous EB virus-transformed B-cell line at particular responder: stimulator ratios[13,14]. Such preparations are preferentially cytotoxic to the autologous stimulating line and kill allogeneic EB virus-transformed cell lines in an HLA-A and -B antigen-restricted fashion[8–14]. Recent work in this laboratory has shown that cytotoxic T cells of this kind can be established as continuously growing TCGF-dependent cell lines without loss of antigen specificity or of HLA-restriction (L.E.W., M.R., A.B.R. and M.A.E., in preparation).

In the present experiments, EB virus-specific cytotoxic T cells prepared by *in vitro* reactivation from seropositive donor SW (HLA-A11, AW24, B7, BW35) were immediately transferred to TCGF-medium with an equal number of X-ray irradiated cells of the autologous EB virus-transformed cell line SW-EB, as feeders. Foci of proliferating cells appeared within 3 days and the resultant T-cell line, maintained thereafter by twice weekly subculture with feeder cells as above, showed a pattern of EB virus-specific HLA-A and -B antigen-restricted cytotoxicity identical to that of the original reactivated preparation. The results in Fig. 1 show that strong killing of the autologous cell line by TCGF-dependent effector cells was not accompanied by any significant reactivity against EB virus genome-negative human leukaemic cell lines HSB2 and K562, included as indicators of natural killer (NK)-like activity[15]. Furthermore, lysis of allogeneic EB virus-transformed cells was particularly strong when associated with either HLA-A11 (target CM) or BW35 (target EG) antigen matching and progressively weaker with matching through B7 (target JT) and through AW24 (target TH). This pattern of HLA antigen 'preferences' has been observed reproducibly in reactivated cytotoxic preparations from donor SW[14].

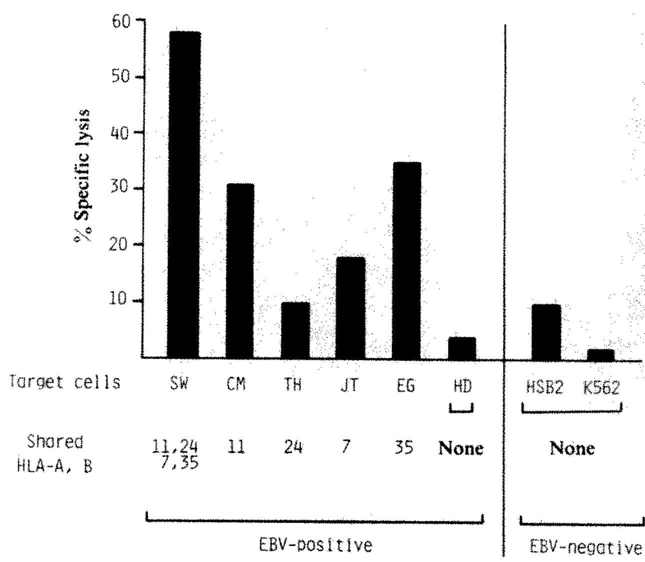

Fig. 1 EB virus-specific, HLA-A and -B antigen-restricted effector function of a TCGF-dependent cytotoxic T-cell line established from donor SW (A11, AW24; B7, BW35). Effector T cells were first obtained by culturing peripheral blood mononuclear cells for 10 days with X-ray irradiated cells of the autologous EB virus-transformed cell line (SW-EB) at a responder:stimulator ratio of 40:1 as described elsewhere[13,14]. Thereafter the T cells were cultured in 2 ml Linbro wells at 2×10^5 cells per well together with 2×10^5 X-ray irradiated SW-EB cells per well in TCGF-medium (RPMI 1640 supplemented with 10% fetal calf serum and 25% TCGF prepared according to the method of Inouyé *et al.*[24]). Cells were collected every 3–4 days and recultured together with fresh stimulator cells in TCGF-medium as above. Thirteen days after their original exposure to TCGF, some of the cells were collected and incubated overnight in TCGF-free medium to remove any residual lectin. Their effector function was tested in a chromium release assay, against the autologous EB virus-transformed cell line, against a range of allogeneic EB virus-transformed cell lines whose degree of HLA-A and -B antigen-matching with the effector cells was as shown, and against EB virus genome-negative cell lines HSB2 and K562 included as indicators of NK-like activity. Results are expressed as percentage specific lysis of ^{51}Cr-labelled target cells in a 5-h assay at an effector: target ratio of 10:1.

Table 1 Effect of the monoclonal antibodies W6/32 and Leu 2a on target cell lysis by clone G9

Monoclonal antibody		% Specific lysis of EB virus-transformed cells from donor: SW (A11, AW24; B7, BW35)	BVR (A11, BW35)	EG (A2, A3; BW35, BW40)	SF (A2 A11; B7, BW44)
—	—	29	68	75	2
W6/32	(ref. 21)	2	15	23	13
Leu 2a	(refs 22, 23)	0	15	16	6

Results of a chromium release assay, conducted as described in Fig. 1, using clone G9 effector cells and EB virus-transformed target cells from donors whose HLA-A and -B antigen type was as shown. Levels of percentage specific lysis seen in the standard assay are compared with those seen when target cells were first pretreated for 20 min at 37 °C in the assay wells with a saturating concentration of W6/32 (1:200 final dilution of a purified immunoglobulin preparation) and with those seen when effector cells were first pretreated, again for 20 min at 37 °C in the assay wells, with a saturating concentration of Leu 2a (1:200 final dilution of serum/ascites).

On day 12 following transfer of the effector cell preparation into TCGF-medium, a sample of the cells was cloned at 0.7 cells per well onto a feeder layer of X-ray irradiated SW-EB cells in U-shaped Microtest plate wells. The cultures were maintained with regular supplements of TCGF-medium and, after 2 weeks, those showing active growth were subcultured into replicate U-wells. Some of these replicate cultures provided effector cells for a preliminary screening assay of cytotoxicity against SW-EB and against HSB2 target cells. Of the 55 clones screened in this way, 22 showed preferential lysis of the autologous cell line, and of these, 4 grew sufficiently well thereafter in TCGF-medium to permit extensive analysis of effector function and the establishment of cloned T-cell lines.

Results obtained with effector cells from clone C2 are illustrated in Fig. 2*a*, showing a representative range of targets only, and strongly suggest specificity for the viral antigen LYDMA in association with HLA-A11. In the tests overall, clone C2 killed 8/8 EB virus-transformed cell lines from donors typed as HLA-A11 but did not kill any of 15 corresponding lines from A11-negative donors even though many of these did possess AW24, B7 or BW35 in common with the effector cell donor SW. Moreover there was no lysis of EB virus genome-negative target cells, whether the NK-sensitive cell lines HSB2 and K562 or mitogen-stimulated lymphoblasts from autologous and from A11-matched donors were used. Two further clones, G13 and H8, gave results very similar to those obtained with clone C2. Another clone, G9, when tested against the same range of target cells, gave a different pattern of reactivity (Fig. 2*b*) suggesting specific recognition of LYDMA in association with HLA-BW35. Overall, clone G9 cells killed 9/10 EB virus-transformed target cell lines from donors typed as HLA-BW35 but none of the 11 corresponding lines tested from BW35-negative donors nor any of the relevant EB virus genome-negative target cells.

Previous studies have shown that EB virus-specific cytotoxic T-cell function can be blocked (1) by pretreatment of the target cells with saturating concentrations of monoclonal antibodies (such as W6/32) which bind to a framework determinant common to all HLA-A, -B and -C antigen molecules[16], and (2) by pretreatment of the effector cells with the cytotoxic/suppressor T-cell-specific monoclonal antibody Leu 2a (L.E.W., M.R., A.B.R. and M.A.E., in preparation). The data in Table 1 clearly show that lysis of EB virus-transformed HLA-BW35-bearing

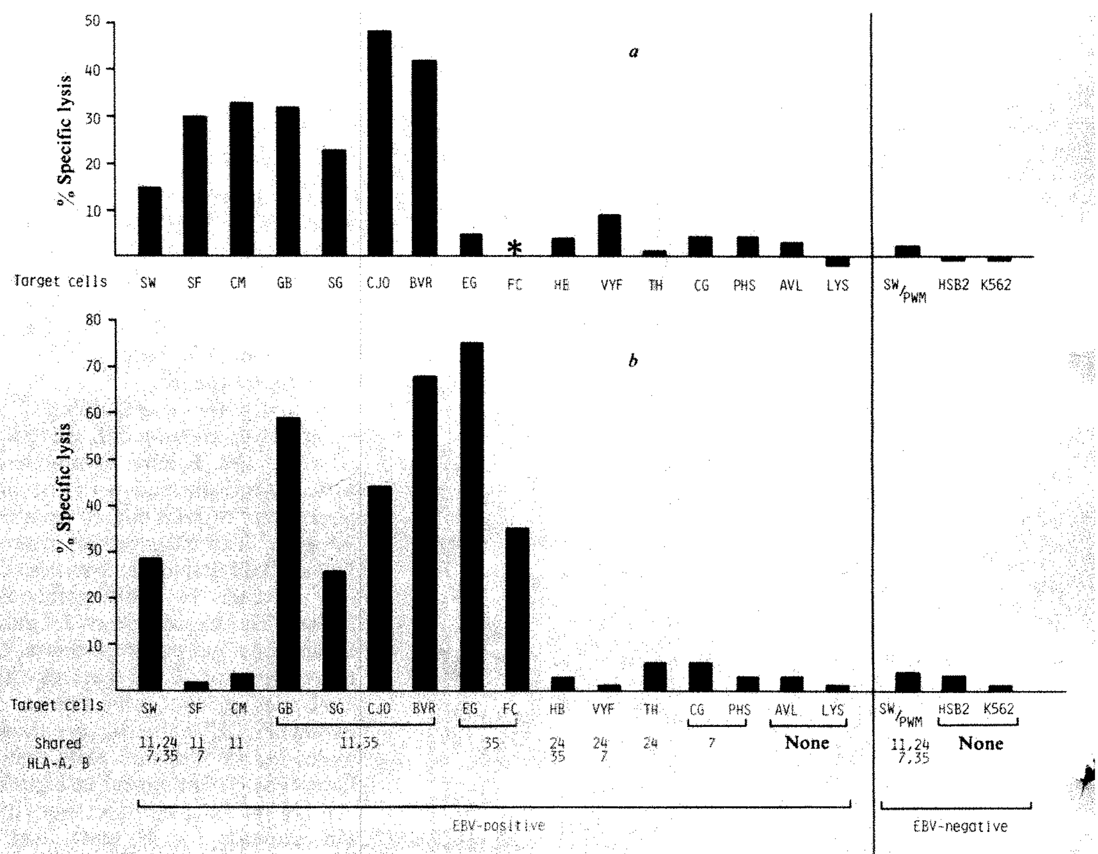

Fig. 2 EB virus-specific effector function of: *a*, clone C2, and *b*, clone G9 derived from the TCGF-dependent cytotoxic T-cell line of donor SW described in Fig. 1. Cloning was performed at an average of 0.7 cells per well seeded into U-shaped Microtest plate wells (Sterilin) containing 2.5×10^3 X-ray irradiated SW-EB cells in TCGF-medium. The cultures were re-fed with fresh TCGF-medium every 3–4 days and those showing active growth were first subcultured after 2 weeks and thereafter expanded into cell lines by regular subculture with X-ray irradiated SW-EB cells in fresh TCGF-medium. The cloned cell lines were tested in chromium release assays, exactly as described in Fig. 1 legend, for cytoxicity against the autologous EB virus-transformed cell line, against a range of allogeneic EB virus-transformed cell lines whose degree of HLA-A and -B antigen-matching with the effector cells was as shown, against autologous pokeweed mitogen (PWM)-stimulated lymphoblasts and against EB virus genome-negative cell lines HSB2 and K562. Results shown for clone C2 are derived from three separate assays performed 35, 38 and 44 days after cloning; results shown for clone G9 are derived from three separate assays performed 31, 50 and 57 days after cloning. * Not tested.

target cells by clone G9 cells is subject to an exactly similar pattern of blocking by these monoclonal antibodies. This adds further support to the view that G9 is indeed a clone of HLA-restricted cytotoxic T cells. In this light, the inability of G9 cells to lyse the cell line from donor HB (HLA-A3, AW24, B14, BW35) is a most interesting result (Fig. 2*b*), particularly as this line did express all four relevant HLA antigens (as defined by serological typing) and was shown in other tests to be sensitive to LYDMA-specific cytolysis by HLA-B14-matched effector T cells (unpublished results). Whilst one could argue that preferential association of LYDMA with HLA-B14 (and possibly with A3 and AW24) on the HB target cell surface might explain the cells' insensitivity to BW35-restricted effector cells, it might alternatively be that donor HB possesses an unusual 'split' of BW35 which effector T cells can distinguish but which is not recognized by current typing sera. Studies with influenza virus-specific human cytotoxic T cells have recently provided examples of this phenomenon within the serologically defined antigens HLA-A2 and A3[17,18].

Clonal analysis of cytotoxic T-cell preparations *in vitro* was first achieved in the H-Y antigen-specific mouse model system[19] and has more recently been investigated using this same antigen-specific system in man[20]. The present report describes the first successful application of this technique in studying the human cytotoxic T-cell response to a natural pathogen. The results show that the response to EB virus is indeed polyclonal with individual reactivities recognizing the viral target antigen in the context of one particular HLA determinant. Since EB virus-specific effector T-cell preparations can be made from most previously infected individuals, it should be possible to establish a library of cytotoxic clones to cover the full range of HLA-A and -B antigen restrictions. Monospecific reagents of this kind could not only facilitate the biochemical analysis of cytotoxic T-cell function but also prove even more valuable as probes for HLA-A and -B antigen polymorphism.

We thank Elizabeth Gough, Ann Green and Jill Sweet for technical help and Dr B. A. Bradley and staff of the UK Transplant Services, SW Regional Transfusion Centre, Bristol, for HLA-A, -B and -C antigen typing of the cell donors. The gifts of monoclonal antibodies W6/32 and Leu 2a from Dr M. J. Crumpton, Imperial Cancer Research Fund Laboratories, and Dr R. B. Evans, Sloan-Kettering Institute for Cancer Research, respectively, are gratefully acknowledged. This work was supported by the MRC (grant G979/1123) and assisted by the Cancer Research Campaign, London, out of funds donated by the Bradbury Investment Corporation of Hong Kong.

Product of a transferred $H\text{-}2L^d$ gene acts as restriction element for LCMV-specific killer T cells

The major histocompatibility complex (MHC) of the mouse, *H-2* on chromosome 17, contains several families of genes encoding cell-surface molecules which have a role in mediating immune responses[1,2]. The class I genes encode a family of homologous membrane proteins including the transplantation antigens K, D and L. These antigens reflect extensive genetic polymorphism which is apparent in the many different class I gene constellations or haplotypes found in mice (for example, BALB/c mice exhibit the $H\text{-}2^d$ haplotype and their class I molecules are denoted K^d, D^D and L^d). Transplantation antigens serve as targets for T-cell killing in allogeneic immune responses such as *in vivo* graft rejection[3] and destruction of allogeneic cells by cytotoxic T cells *in vitro*[4]. However, the physiological role of transplantation antigens may be to serve as restricting elements in virus-mediated T-cell killing of infected self cells. Virus infection of mice generates killer T cells whose receptors must interact with the foreign viral antigen and a class I molecule or restricting element for the cytotoxic effector function to be activated[5,6]. Thus the T-cell receptor recognizes the viral antigen in the context of a class I molecule. To study the interaction between the T-cell receptor and the class I restricting element, we have used the mouse L-cell transformant 8-5 which expresses L^d molecules[7] and the K7-65 transformant expressing K^d molecules (R.S.G. *et al.*, in preparation). Mouse L cells are fibroblasts derived from C3H mice of $H\text{-}2^k$ haplotype and monoclonal antibodies can be used to distinguish $H\text{-}2^d$ molecules from the endogenous $H\text{-}2^k$ products. Recently, we have demonstrated that both L^d (ref. 8) and K^d molecules (unpublished data) expressed on transformed L cells can act as target antigens for alloreactive cytotoxic T lymphocytes. Here we show that the L^d molecule on transformed mouse L cells can serve as a restricting element in lymphocytic choriomeningitis virus (LCMV) infection, whereas its K^d counterpart cannot.

Recently, we described (ref. 7 and R.S.G. *et al.*, in preparation) the production of L-cell transformants expressing L^d and K^d molecules. Briefly, thymidine kinase-negative (tk^-) L cells were co-transformed with the herpesvirus thymidine kinase gene alone or with the *tk* gene together with a cloned L^d or K^d gene. The transformed cells were selected for thymidine kinase (TK) activity and screened for the expression of L^d or K^d molecules by radioimmunoassay with monoclonal antibodies. The expression of L^d and K^d was confirmed by two-dimensional gel electrophoresis. In this manner we generated three types of tk^+ target cell—those expressing K^k and D^k molecules (L-tk^+ cells), those expressing K^k, D^k and K^d molecules (K7-65 cells) and those expressing K^k, D^k and L^d molecules (8-5 clone). Note that mice (or cells) of the $H\text{-}2^k$ haplotype do not appear to express L antigens.

C3H and BALB/c mice were infected with LCMV to generate cytotoxic T cells, and spleen cells from immunized mice were assayed in a 4-h ^{51}Cr-release assay against various target cells (Fig. 1). The cytotoxic T cells generated in C3H mice killed the LCMV-infected target cells from cloned 8-5 cells ($K^kD^kL^d$), L-tk^+ cells (K^kD^k), and K7-65 cells ($K^kD^kK^d$) (Fig. 1*a*). The same cytotoxic T cells killed neither LCMV-infected

0028–0836/82/220415—03$01.00

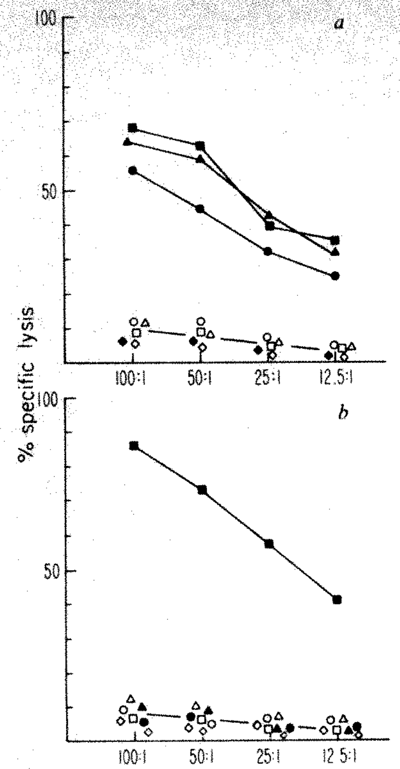

Fig. 1 Killing of LCMV-infected L-cell transformants by spleen cells from LCMV-infected C3H (H–2^k) and BALB/c (H–2^d) mice. Groups of two 6–8-week-old C3H/Bang and BALB/c mice were infected intraperitoneally with 2.5×10^2 plaque-forming units of the Armstrong strain of LCMV 7 days before cytotoxic assay. Spleens were removed and single cell suspensions prepared. L-cell transformants were grown in hypoxanthine–aminopterin–thymidine medium and Nulli-2A teratocarcinoma cells in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum (FCS). The presence of L^d and K^d molecules on the transformants was monitored by radioimmunoassay using monoclonal antibodies as described previously[7]. Target cells were infected with LCMV 40 h before cytotoxicity assay at a multiplicity of infection of 0.5, then trypsinized, washed, and labelled for 1 h at 37 °C with 200 μCi ^{51}Cr in 0.5 ml RPMI supplemented with 10% FCS and 20 mM HEPES. After washing, 10^4 target cells were mixed in triplicates in microtitre plates with varying numbers of effector spleen cells in a total volume of 200 μl. Plates were incubated at 37 °C, 5% CO_2 for 4 h, then centrifuged and 100 μl of the supernatant were removed and counted in a γ-counter. Per cent specific lysis was calculated according to the formula: $\text{c.p.m.}_{\text{exp}} - \text{c.p.m.}_{\text{spon}}/\text{c.p.m.}_{\text{max}} - \text{c.p.m.}_{\text{spon}} \times 100$, where $\text{c.p.m.}_{\text{spon}}$ (spontaneous) and $\text{c.p.m.}_{\text{max}}$ (maximum) were determined in cultures containing medium or detergent, respectively; $\text{c.p.m.}_{\text{exp}}$, c.p.m. (experimental). The s.e.m. never exceeded 5%. The figure shows results for spleen effector cells from *a*, LCMV-infected C3H/Bang mice, and *b*, LCMV-infected BALB/c mice. Target cells: ■, 8-5 (L^d)–LCMV; □, 8-5, uninfected; ▲, L-tk^+–LCMV; △, L-tk^+, uninfected; ●, K7-65 (K^d)–LCMV; ○, K7-65, uninfected; ◆, Nulli-2A–LCMV; ◇, Nulli-2A, uninfected.

Nulli-2A teratocarcinoma cells, which do not express class I molecules[9], nor uninfected target cells. These data demonstrate that LCMV-specific T cells from C3H mice require the viral antigen and a K^k or D^k restricting element. In contrast, LCMV-restricted cytotoxic T cells from BALB/c mice killed LCMV-infected 8-5 cells but not any of the other target cells (Fig. 1*b*). These data demonstrate that BALB/c mice can use the L^d but not the K^d molecule as a T-cell restricting element in response to LCMV. This is consistent with reports on other *H-2*-restricted systems which claim that L^d can act as a restricting element[10–12].

We then raised cytotoxic lymphocytes to LCMV in C-H–2^{dm2} mice. These are mutant mice of the H–2^d haplotype which fail to express an L^d molecule[13,14]. Cytotoxic lymphocytes from the *dm2* mice lysed neither LCMV-infected 8-5 ($K^kD^kL^d$) nor L-tk^+ (K^kD^k) cells (Fig. 2*a*). Control experiments with LCMV-induced cytotoxic T cells in C3H mice again demonstrated lysis of both the 8-5 and L-tk^+ cells as expected (Fig. 2*c*). A similar analysis with LCMV-specific killer T cells raised in B10.Q mice of the H–2^q haplotype lysed neither the 8-5 nor L-tk^+ cells (Fig. 2*d*). This control experiment is interesting because mouse strains of the H–2^q haplotype are known to express an L^q antigen serologically related to the L^d product[15–17]. Thus, the T-cell receptor seems to interact with that portion of the L^d antigen which distinguishes it from its L^q counterpart.

We further tested the specificity of the L^d restricting element in LCMV-infected 8-5 cells by inhibiting the T-cell lysis of these cells with specific antibodies. Two L^d-specific alloantisera were raised by immunizing C3H mice with 8-5 cells as described in detail elsewhere[18], and by immunizing C-H–2^{dm2} mice with BALB/c spleen cells. In addition, we used two monoclonal anti-L^d antibodies (28-14-8S and 4-9.4), a monoclonal anti-D^d antibody (34-2-12), a monoclonal K^d antibody (6-27.10) and normal mouse serum. The results of these experiments are shown in Fig. 3*a*, *b*. All antibodies directed against the L^d molecule inhibited the LCMV-restricted cytotoxic T-cell killing of the L^d-transformed 8-5 cells. In contrast, normal mouse serum as well as monoclonal antibodies to the D^d and K^d antigens, did not inhibit this cytotoxic T-cell reaction. These data again suggest that the L^d molecule serves as a typical restricting element in LCMV-induced T-cell killing.

Thus, the gene transfer procedure results in the expression of class I molecules which are inserted in the membrane of a transformed cell in a normal manner so that they can act as restricting elements for virus-induced cytotoxic T cells. An analysis of various viral infections using the different transplantation antigens should allow us to delineate the roles of the class I molecules in specific virus infections. Moreover, this system, together with *in vitro* mutagenesis, should allow us to elucidate the nature of the interactions between the T-cell receptor and class I molecules. The major advantage of *in vitro* mutagenesis is the ability to generate mutants that carry alterations in specific regions of the class I molecules. In contrast, conventional mutants are selected only for altered T-cell recognition. Thus, our ability to transfer normal and altered class

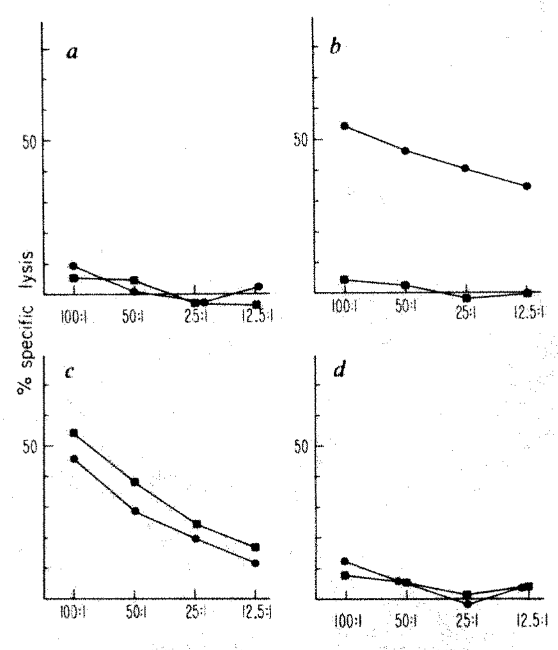

Fig. 2 Killing of LCMV-infected L-cell transformants by spleen cells from different LCMV-infected mouse strains. For experimental details see Fig. 1 legend. Spleen effector cells from LCMV-infected mice: *a*, C-H–2^{dm2} (H–2^d mutant); *b*, BALB/c (H–2^d); *c*, C3H/Bang (H–2^k); *d*, B10.Q (H–2^q). Target cells: ●, 8-5 (L^d)–LCMV; ■, L-tk^+–LCMV. Uninfected target cells never showed >10% lysis.

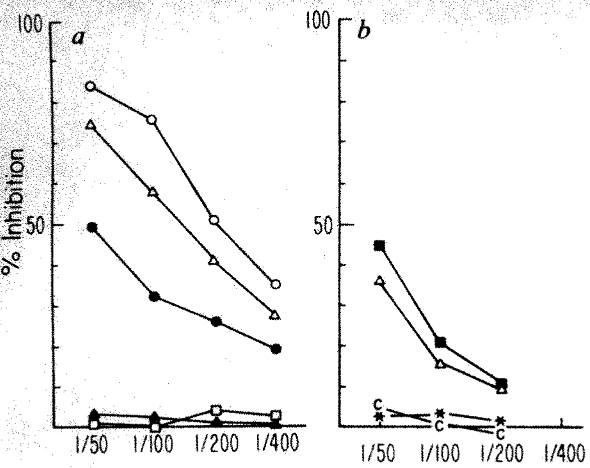

Fig. 3 Inhibition of *H-2*-restricted LCMV-specific cytotoxicity by antibodies directed against different *H-2* antigens. Various antisera or monoclonal reagents were added at the start of the Cr-release assay in the dilutions shown. The cytotoxic reaction inhibited was that of LCMV-infected BALB/c spleen cells against LCMV-infected 8-5 cells. Per cent inhibition was calculated as follows:

$$1 - \frac{\%\ \text{specific lysis in the presence of antibody}}{\%\ \text{specific lysis in the absence of antibody}} \times 100$$

a and *b* show two separate experiments: *a*, 30.5% lysis in the absence of blocking antibody at effector/target ratio of 50:1. Blocking antibodies: ○, C3H/Bang anti-8-5 alloantiserum; △, 28-14-8S (anti-L^d monoclonal antibody); ●, 4-9.4 (anti-L^d monoclonal antibody); ▲, 34-2-12 (anti-D^d monoclonal antibody); and □, normal mouse serum. The specificities of these monoclonal antibodies are described elsewhere[8,19]. *b*, 41.0% Lysis in the absence of blocking antibody at effector/target ratio of 100:1. Blocking antibodies: ■, C-*H-2*^{dm2} anti-2BALB/c alloantiserum; △, 28-14-8S (anti-L^d monoclonal antibody), C, 6-27.10 (anti-K^d monoclonal antibody); and *, normal mouse serum.

I genes into foreign cells provides us with one of the first opportunities to elucidate the molecular basis of cell–cell interactions.

Interferon exerts, in addition to its well recognized antiviral activity, an antiproliferative effect[1,2] and has been found to reduce plasminogen activator secretion[3], to re-establish contact inhibition[4] and to inhibit the growth in semi-solid agar[5] of neoplastic cells. Double-stranded RNA (dsRNA) is both an interferon inducer and an activator of two interferon-induced enzymes, a protein kinase and a 2',5' oligoadenylate synthetase[6]. However, the molecular bases for the antiproliferative and antineoplastic effects of interferon, and their relationship to dsRNA, are unknown. We have now characterized the antiproliferative effects of interferon and dsRNA on the human HT1080 fibrosarcoma[7] and RT4 epidermal carcinoma[8] cell lines. Luria–Delbrück fluctuation analysis[9] of interferon resistance indicates that the resistance trait is a non-randomly acquired phenotype which was probably induced by interferon at the time of selection. The interferon-resistant (IFN^r) cells retained sensitivity to the antiviral effects of interferon, as well as to the antiproliferative effects of dsRNA.

Clonal populations of interferon-sensitive (IFN^s) cells were isolated from both HT1080 and RT4 cell lines. The HT1080 (HT1080-2) and RT4 (RT4-1) clonal lines demonstrated a complete growth inhibition at 400 and 80 IU ml^{-1} human fibroblast interferon (HuIFN-β) respectively, when examined over a 72 h period (data not shown). The fluctuation analysis was initiated by establishing 10 independent cultures from each original colony and continuously growing each culture for 16 population doublings, as described in Table 1 legend, before plating in selective medium. Results are shown in Table 1. In all cultures of the HT1080-2 population, 3.7–4.5% of the cells were capable of colony formation in interferon-containing medium (1,000 IU ml^{-1}). There was no difference in average colony size or cell morphology between control and interferon-treated cells. The frequency distribution of the number of resistant colonies obtained from this series of sister cultures exhibited a variance of 7.73. The variance of the distribution of the number of colonies in a large single culture (v_2, random sampling control) was 2.04. After correction for the random sampling control, the variance-to-mean ratio [v.m.r., $(v_1 - v_2)$/mean] of the frequency distribution of the number of resistant colonies obtained from the series of cultures was 0.15. In contrast, when RT4-1 cells were similarly treated, interferon-resistant colonies arose at a frequency of 0.11%, 30–40-fold less than the frequency observed for HT1080-2 cells (Table 1). However, the v.m.r. of the distribution obtained from the series of 10 sister cultures was low—0.31. Simultaneous examination of the HT1080-2 cultures for acquisition of 6-thioguanine resistance (6TG^r), an acquired trait of known spontaneous origin, resulted in a corrected v.m.r. of 6.79 (Table 1). The high v.m.r. is indicative of a randomly acquired trait and indicates that 16 population doublings were sufficient to distinguish between randomly and non-randomly acquired phenotypes. Using the p_0 method of Luria and Delbrück[9], a mutation rate of 1.8×10^{-8} mutants per cell per generation can be calculated from the values presented in Table 1 for the acquisition of 6TG^r. This rate is consistent with known mutation rates obtained for various loci in other systems[10], and thus verifies our procedure.

* Present address: The Rockefeller University, 1230 York Avenue, New York, New York 10021, USA.

Examination of isolated colonies derived from resistant populations revealed that IFN^r cells possessed the same population doubling times in the presence and absence of interferon at concentrations normally resulting in complete cessation of growth (Fig. 1*a*, *c*). However, consistent with the notion that IFN^r is an induced trait, resistant colonies reverted to a sensitive state, albeit after varying lengths of time. One clone of HT1080-IFN^r cells retained the resistance trait after 4 weeks growth in interferon-free medium and reverted to a sensitive state by 15 weeks after removal of interferon from the culture medium (Fig. 1*a*), whereas a clone of resistant RT4 cells was fully resistant to interferon immediately after isolation, but reverted completely by 4 weeks after removal of interferon from the culture medium (Fig. 1*c*). When used as assay cells to titre an identical solution of interferon by the dye uptake method of Finter[11], resistant cells during their resistant state were at least as sensitive as their parental populations to the antiviral effects of interferon when vesicular stomatitis virus was used as the challenge virus (Table 2), suggesting that resistance to the antiproliferative effects of interferon do not necessarily correlate with changes in sensitivity to its antiviral effects. It should be mentioned, however, that different viruses can be affected by different mechanisms pertaining to the antiviral state[12–14].

In view of the participation of dsRNAs in the establishment of the antiviral state and the toxicity of exogenous dsRNA[15], we characterized the sensitivities of the interferon-resistant lines towards the antiproliferative effects of the synthetic dsRNA, $rI_n \cdot rC_n$ (Fig. 1). Resistant lines of both HT1080-2 (Fig. 1*b*) and RT4-1 (Fig. 1*d*) displayed the same sensitivity to

Table 1 Luria-Delbrück fluctuation analysis for the acquisition of interferon resistance

	HT1080		RT4

Corrected variance/mean	0.15	6.56	0.31

HT1080 cells were cloned in semi-solid agar as described by Laug *et al.*[21]. A vigorously growing colony was isolated and transferred to a 35 mm dish containing 2 ml growth medium, disbursed by repeated pipetting and allowed to attach and grow. The resultant monolayer was detached from the plate by trypsinization and was transferred to a 75 cm^2 flask for serial propagation. Cells comprising the resultant confluent monolayer were detached by trypsinization and 10 independent cultures were initiated by inoculating 10 35 mm dishes at 100 cells per dish. On reaching confluence, the total number of cells from each culture was detached by trypsinization and transferred to a separate 75 cm^2 flask to maintain the 10 cultures independently. After a total of 16 population doublings from initial establishment of the independent cultures, confluent monolayers in 75 cm^2 flasks were detached by trypsinization and the frequency of IFN^r cells in each independent culture determined by placing cells in liquid medium containing HuIFN-β at a plating density of 1×10^4 cells per 100mm dish. Fluctuation analysis for the acquisition of 6TG^r was simultaneously performed using selective conditions described previously[22]. An RT4 clone was isolated by the agar overlay method described in ref. 23, transferred to a 35 mm dish containing 2 ml growth medium and then handled in identical fashion to the HT1080 clone. RT4 cells were plated at a density of 1×10^5 cells per 100 mm dish in interferon-containing medium. Selective medium consisted of growth medium containing HuIFN-β HuIFN-β at a plating density of 1×10^4 cells per 100 mm dish. Fluctuation analysis or 6TG (3 μg ml^{-1}). Results shown are corrected for plating efficiency. Random sampling variance was determined by analysing the frequency distribution observed in a single large culture in the same way as for independent cultures. Correction for sampling error was performed by subtracting the random sampling variance from the variance of the independent cultures before division by the mean. IFN-β (fibroblast-derived) used in these studies had specific activities of 2×10^6 (HEM Research, Rockville, Maryland) to 2×10^7 (Dr W. A. Carter) IU per mg protein after purification by sequential concanavalin A–Sepharose→phenyl-Sepharose affinity chromatographies[24].

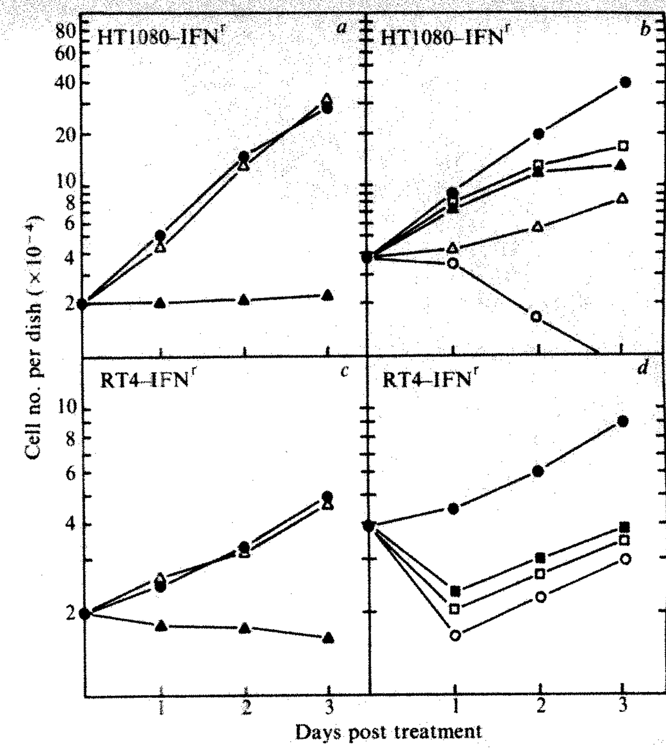

Fig. 1 Heritability of resistance to the growth inhibitory effects of interferon, and effects of $rI_n \cdot rC_n$ on the growth of IFN^r cells in culture. Colonies growing in interferon-containing medium were isolated and grown in the presence of medium containing 1,000 (HT1080) or 100 (RT4) IU ml^{-1} HuIFN-β. After ~16 population doublings, HuIFn-β was removed from the culture medium and cells were examined for interferon resistance at various passages after growth in interferon-free medium (*a*, *c*) or for sensitivity to $rIn \cdot rC_n$-mediated toxicity. (*a*) Growth of HT1080-IFN^r cells in the absence (●) or presence of HuIFN-β (1,000 IU ml^{-1}) after culture for 4 (△) and 15 weeks (▲) in interferon-free medium; (*c*), growth of RT4-IFN^r cells in the absence (●) or presence of HuIFN-β (100 IU ml^{-1}) after culture for 0 (△) and 4 (▲) weeks in interferon-free medium. For measuring dsRNA-mediated toxicity, 5×10^4 (HT1080-IFN^r)or 1×10^5 (RT4-IFN^r) cells were plated out per 35 mm dish and allowed to attach overnight. The following day (time 0), cell number per dish was determined, remaining monolayers were refed with various concentrations of $rI_n \cdot rC_n$ and cell number per dish was determined every 24 h thereafter. (*b*), HT1080-IFN^r cells grown in 0 (●), 0.1 (□), 0.2 (▲), 0.5 (△) and 2.5 (○) mM $rI_n \cdot rC_n$; (*d*), RT4-1IFN^r cells grown in 0 (●), 0.1 (■), 5.0 (□) and 10.0 (○) μM $rI_n \cdot rC_n$.

$rI_n \cdot rC_n$-mediated toxicity as did their respective parental HT1080-2 and RT4-1 lines (not shown). For HT1080-IFN^r populations, 0.5–1.0 mM $rI_n \cdot rC_n$ was required to inhibit cell proliferation completely, with $rI_n \cdot rC_n$ concentrations >1 mM producing marked cell death within 24 h. In these conditions, interferon concentrations secreted in the medium did not exceed 3 IU ml^{-1}. Detectable $rI_n \cdot rC_n$-induced toxicity in RT4-IFN^r cells was observed at concentrations as low as 0.1 μM, with no induced interferon being detectable in the medium. However, in contrast to the prolonged cytotoxic effect observed in HT1080-2 cells, some clones of RT4-IFN^r cells could recover from dsRNA-mediated toxicity after 24 h and exhibit the same growth rate as before treatment. This recovery was not the result of rapid degradation of $rI_n \cdot rC_n$ as re-addition of $rI_n \cdot rC_n$ to the culture medium at 24 or 48 h did not alter the recovered growth rate (data not shown). Addition of antisera, directed against HuIFN-β (final concentration 100 neutralizing units per ml), to the culture medium of $rI_n \cdot rC_n$-treated cells did not reduce or otherwise alter the extent of cytotoxicity induced by $rI_n \cdot rC_n$ (not shown), suggesting that low interferon concentration was not involved in $rI_n \cdot rC_n$-mediated toxicity.

The Luria–Delbrück fluctuation analysis, originally developed for microbial systems, provides a statistical method whereby the acquisition of a certain phenotype by a population

Table 2 Sensitivity of IFN^s and IFN^r lines to the antiviral effects of interferon

Cell line	Phenotype	Titre
HT1080-2	IFN^s	1.5
HT1080-2	IFN^r	4.5
RT4-1	IFN^s	30.2
RT4-4	IFN^r	28.0

Confluent monolayers (1.5 cm diameter) of IFN^S or IFN^r cells from both HT1080 and RT4 lines were used as assay cells for the titration of a stock solution of interferon (concentration 50 IU ml^{-1}), using the dye uptake method of Finter[11] with vesicular stomatitis virus as the challenge virus.

of cells can be determined to be random (spontaneous) or non-random (induced)[9]. When a series of separate cultures, all initiated from a single clone, is allowed to undergo a suitable number of population doublings, the variation of the frequency of resistant colonies obtained in each culture will be large if the resistant trait is randomly acquired, or small if the trait is non-randomly acquired. Theoretically, the v.m.r. will be ≤ 1 if the trait is acquired non-randomly, or $\gg 1$ if the trait is acquired randomly. The acquisition of interferon resistance when analysed in this way, provided v.m.rs of <1, suggesting that interferon resistance does not result from a spontaneous event, such as mutation or chromosomal rearrangement, but rather is a phenotype induced by interferon treatment. This conclusion is supported by the demonstration reported here, and elsewhere[16], that resistant cells, previously sensitive to the growth inhibitory effects of interferon, revert to a sensitive state. As no difference in average size was observed for colonies formed in control and interferon-containing medium, induction of resistance must occur rapidly, within 24–48 h after interferon exposure. Alternatively, cells in the population might exist in either an IFN^r or IFN^s state, depending on their physiological or developmental status. Addition of interferon would both select for the subpopulation of pre-existing resistant cells and maintain the resistant trait.

Our results contrast with those of Gresser *et al.*[17], who by similar analysis concluded that the resistance phenotype was randomly acquired and appeared at a frequency consistent with somatic mutation. However, Gresser *et al.* obtained their high v.m.r. from comparison of resistance displayed by different clones isolated from a mass tumour cell culture. Recent observations that clonal isolates from a population of tumour cells can vary widely in sensitivity to the antiproliferative effects of interferon[16] indicate that such interclonal comparison cannot be used for determining the randomness of acquisition of interferon resistance. Moreover, the resistant cells we used, as opposed to those described by Gresser *et al.*[17], retained their sensitivity to the antiviral effects of interferon, indicating that resistance was not due simply to the absence of an interferon receptor, and is consistent with previous reports where the antiviral state could be induced by interferon in Rous sarcoma virus-transformed human fibroblasts resistant to the growth inhibitory effects of interferon[18].

Resistant cells retained a sensitivity towards dsRNA-induced toxicity that did not differ from that exhibited by the IFN^s parental cell lines. This is an important consideration in the development of chemotherapeutic regimens for the treatment of cancer with interferon and it suggests that interferon used in combination with dsRNA would be much more effective in the treatment of cancer than interferon alone. In addition, the data argue against a role for the known interferon-induced, dsRNA-dependent enzymes in the antiproliferative effects of interferon. No reduction in interferon-mediated growth inhibition was observed in mitogen-stimulated normal human fibroblasts pretreated with interferon for periods of up to 72 h (ref. 19) and continuous subculture of a sensitive line of normal human fibroblasts in the presence of HuIFN-β for up to 6 weeks did not result in the appearance of a resistant population[20], suggesting that normal cells do not readily acquire interferon resistance. This difference between the ability of normal and neoplastic cells to acquire resistance to the growth inhibitory effects of interferon might be related to the mechanisms of uncontrolled growth characteristic of tumour cells. Further delineation of interferon-mediated growth inhibition could be important in elucidating a fundamental difference between normal and neoplastic cells, as well as in establishing the molecular basis for the antiproliferative effects of interferon.

Stimulation of adrenal mitogenesis by N-terminal proopiocortin peptides

F. E. Estivariz & F. Iturriza

Centro de Estudios Endocrinos, Facultad de Ciencias Medicas, Universidad Nacional de la Plata, Casilla de Correo 455, 1900 La Plata, Argentina

Pituitary Hormone Laboratory, Department of Chemical Pathology, St Bartholomew's Hospital, London EC1 7BE UK

Although it was generally believed that corticotropin (ACTH) maintained both the size of the adrenal gland and its level of steroid production[1], there is a growing body of evidence for a specific factor(s) distinct from ACTH which may be responsible for the stimulation of adrenocortical growth and proliferation. While direct neural influences have been proposed to be responsible for the compensatory adrenal growth following unilateral adrenalectomy[2], several observations have suggested the involvement of peptides such as angiotensin[3] and vasopressin[4], which have other hormonal effects, or, for example, fibroblast growth factor[5], which has more general mitogenic actions. Moreover ACTH inhibits cell proliferation *in vitro*[6–8], and physiological doses *in vivo* cannot induce the compensatory growth and hyperplasia seen in the remaining adrenal gland after unilateral adrenalectomy[9]. These observations coupled with the lack of effect of chronic treatment with an ACTH antiserum on adrenal size[10] and the existence of adrenal weight-maintaining activity in the plasma of patients with ACTH-secreting adenomas[11], have led to the search for a pituitary factor related to ACTH which is capable of stimulating adrenal growth. We now report that peptides derived from the N-terminal non-γ-melanocyte-stimulating hormone (MSH) portion of the precursor of ACTH, proopiocortin, are potent stimulators of adrenal DNA synthesis *in vitro* and mitosis *in vivo* and may thus be involved in the physiological control of adrenal growth.

0028–0836/82/220419—04$01.00

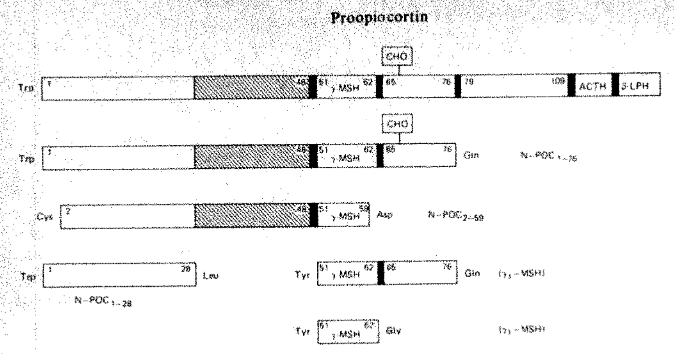

Fig. 1 Diagram of the human N-POC peptides used in this study in relation to each other and to their precursor proopiocortin. The numbering has been assigned from chemical characterization of isolated peptides[18] and cDNA[19] sequence data. The γ_2- and γ_3-MSH synthetic peptides were a gift from Dr Nicholas Ling. The hatched area corresponds to the region recognized by the antiserum[17] used in this study and the boxed CHO, the polysaccharide moiety.

ACTH is derived from a precursor which contains lipotropin (LPH)/endorphin as the C-terminal portion and an N-terminal glycopeptide (N-POC) of some 100 amino acids (Fig. 1) which contains a third melanotropin sequence (γ-MSH)[12]. A human pituitary glycopeptide (N-POC$_{1-76}$) comprising almost all of the non-ACTH non-LPH/endorphin region, which is inactive in maintaining adrenal weight and possesses weak melanotropic activity[13], has recently been found to potentiate the ACTH-induced secretion of glucocorticoids and mineralocorticoids from the adrenal cortex[14] by increasing RNA synthesis[15]. The potentiation of steroidogenesis can also be demonstrated with small synthetic peptides containing the γ-MSH sequence found in the C-terminal part of the glycopeptide[16]. Initial attempts to demonstrate adrenal weight maintenance with human N-POC$_{1-76}$ given either alone or with physiological doses of ACTH to hypophysectomized rats were unsuccessful[13].

The generation of an antiserum directed against the middle portion of this peptide (residues 29–48)[17] allowed us to test its effects on the adrenal in intact rats. Rats were injected daily for 7 days with the anti-N-POC antiserum, an antiserum which cross-reacts fully with both ACTH and β-LPH, or normal rabbit serum. Thymidine incorporation was also measured in these experiments as a more specific index of DNA synthesis. A decrease in adrenal weight (14%) was observed in the anti-N-POC antiserum-treated group although the result was not significant (results not shown). However, as shown in Fig. 2*a*, there was a significant decrease in thymidine incorporation in the anti-N-POC antiserum-treated group (B), whereas the anti-ACTH/LPH antiserum-treated group (C) did not differ significantly from controls (A). The efficacy of the anti-ACTH/LPH antiserum treatment was shown by the significantly lower levels of plasma corticosterone in this group.

In preliminary experiments, however, we had also failed to observe any effects of several days' treatment with N-POC$_{1-76}$ in rats *in vivo* using thymidine incorporation as the measure of DNA synthesis. This led us to suspect that N-POC$_{1-76}$ could be a precursor for the mitogenic factor—this indeed appeared to be the case. Figure 2*b* confirms the absence of an effect after seven daily injections of the intact N-POC$_{1-76}$ (E) but pretreatment of the peptide with trypsin revealed significant activity (F). In this experiment, dexamethazone blockade was used in order to preserve as fully as possible the endocrine status of the animals whilst avoiding the stress-induced release of ACTH-related peptides due to the daily injections. Recently[18] we have purified and chemically characterized smaller fragments from the N-terminus of N-POC$_{1-76}$, including N-POC$_{1-28}$ and N-POC$_{2-59}$, and have compared the effects of these peptides with synthetic γ_2-MSH, γ_3-MSH and ACTH on isolated adrenal cells. Whereas γ_2 and γ_3-MSH had no effect in this system

Table 1 Effect of POC peptides on adrenal growth and mitosis *in vivo*

Group	No. rats	Adrenal weight	Mitotic ratio
Control	5	28.08 ± 1.07	0.57 ± 0.21
N-POC$_{1-28}$	5	32.5 ± 0.73†	3.39 ± 0.4§
N-POC$_{1-76}$	4	28.85 ± 0.87 NS	0.81 ± 0.32
ACTH$_{1-24}$	5	30.86 ± 1.01*	2.12 ± 0.35‡

Adrenal weight was calculated per 100 g body weight and mitotic ratio was the number of mitoses per mm^2 of adrenal cortex (containing ~4,000 cells)[28]. All groups were compared with control values. The difference in mitotic ratio between N-POC$_{1-28}$- and ACTH$_{1-24}$-treated animals was significant ($P<0.05$). There was no significant variation between the groups with respect to whole body weight. Ten week old female Sprague–Dawley rats were implanted subcutaneously with Alzet osmotic minipumps (model 2001) containing 1 mM acetic acid (control) or 1 mM acetic acid containing 100 μg ml^{-1} of the appropriate peptide and delivered to each rat at ~3 μg of peptide per day. Rats were distributed randomly between cages and were allowed food and water *ad libitum*. On day 7, each rat was injected with colchicine (1 μg per g body weight) and killed 6 h later. Adrenals were removed, weighed and fixed immediately in Bouins, prepared for histology in the usual way and stained using Feulgen's method. Three mid-sections of whole cortex of each adrenal (that is, a total of 30 sections per group) were examined microscopically to calculate mitotic ratios. NS, not significant.
* $P<0.05$; † $P<0.02$; ‡ $P<0.01$; § $P<0.001$.

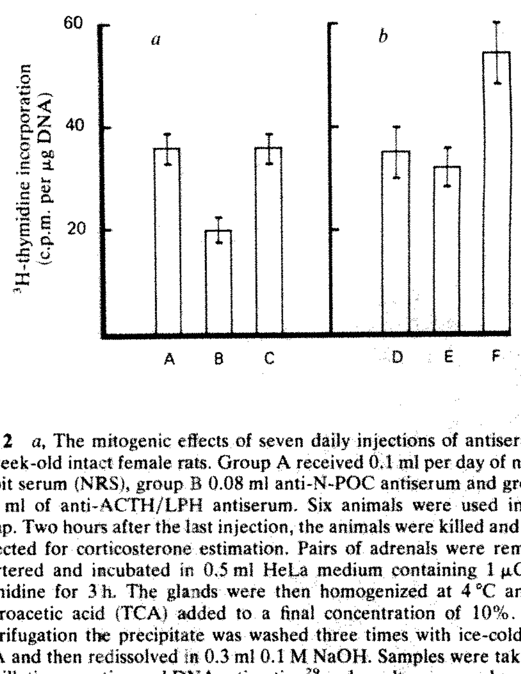

Fig. 2 *a*, The mitogenic effects of seven daily injections of antisera into 3-week-old intact female rats. Group A received 0.1 ml per day of normal rabbit serum (NRS), group B 0.08 ml anti-N-POC antiserum and group C 0.05 ml of anti-ACTH/LPH antiserum. Six animals were used in each group. Two hours after the last injection, the animals were killed and blood collected for corticosterone estimation. Pairs of adrenals were removed, quartered and incubated in 0.5 ml HeLa medium containing 1 μCi ^{3}H-thymidine for 3 h. The glands were then homogenized at 4 °C and trichloroacetic acid (TCA) added to a final concentration of 10%. After centrifugation the precipitate was washed three times with ice-cold 10% TCA and then redissolved in 0.3 ml 0.1 M NaOH. Samples were taken for scintillation counting and DNA estimation[29] and results expressed as c.p.m. per μg DNA. Group B is significantly different from both the NRS and anti-ACTH/LPH antiserum groups ($P<0.01$). Corticosterone concentrations (μg per 100 ml) in each group were: A, 15.2 ± 3.1; B, 13.4 ± 1.9; C, 9.4 ± 12. The anti-ACTH/LPH antiserum was raised in sheep by immunization with ACTH$_{1-24}$ coupled to bovine thyroglobulin by glutaraldehyde. Using radioiodinated ACTH$_{1-39}$ as label, α-MSH, β-MSH, β-LPH and γ-LPH showed full molar cross-reactivity in a radioimmunoassay using this antiserum at a final dilution of 1:12,000. *b*, The mitogenic effects of N-POC$_{1-76}$ and trypsinized N-POC$_{1-76}$ on the adrenals of 7-week-old female rats. Ten animals were used in each group and dexamethasone blockade was achieved by adding the compound (10 μg ml^{-1}) to the drinking water at the start of the experiment. Group E received seven daily injections of 5 μg N-POC in 10 μl saline. In group F, N-POC$_{1-76}$ (0.5 mg) was treated with DCC-trypsin at a concentration of 1:200 (enzyme/peptide) for 2 h in 1 ml 10 mM NaHCO$_3$ at 37 °C, and was then diluted 10 times with saline and stored at −20 °C. Rats received the same amount of peptide as in group E. The saline used for the control group (D) had incubated, heat-treated DCC-trypsin added to it equivalent to that used to digest the injection material in group F. Two hours after the last injection, the animals were killed and the adrenals treated as in *a*. Thymidine incorporation in group F was significantly higher than in control (D) and intact N-POC$_{1-76}$-treated groups ($P<0.05$). Corticosterone concentrations (μg per 100 ml) were significantly depressed in all groups: D, 6.8 ± 1.2; E, 7.4 ± 0.6; F, 8.1 ± 0.8.

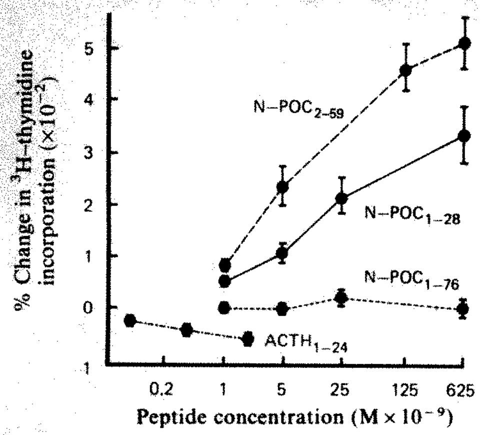

Fig. 3 Dose-response curves of N-POC peptide-mediated stimulation of ^{3}H-thymidine incorporation into DNA of dispersed rat adrenal cells. Cells were prepared as described previously[30]. Approximately 10^5 cells were distributed into each vial containing 0.5 ml of HeLa medium containing 0.2% bovine serum albumin (BSA) and 0.2% lima bean trypsin inhibitor (LBI). Cells were preincubated for 3 h before addition of N-POC peptides. After a further 3 h incubation, 1 μCi of ^{3}H-thymidine was added to each vial and incorporation was allowed to proceed for 6 h. Cells were then centrifuged (100*g*, 10 min), washed with fresh medium and sonicated in 0.5 ml ice-cold 12% TCA after addition of 100 μg BSA to each vial as carrier. After washing with 10% TCA the precipitate was redissolved in 0.1 M NaOH and treated as for Fig. 2. Control cells gave 2,108 ± 235 c.p.m.

(results not shown), both N-POC$_{1-28}$ and N-POC$_{2-59}$, at 10^{-9}–10^{-7} M, elicited a dose-dependent incorporation of thymidine into DNA, the larger peptide being more potent (Fig. 3). N-POC$_{1-76}$ had little effect at the highest dose assayed and ACTH inhibited thymidine incorporation in a dose-related manner. The synthetic γ-MSHs are very weak steroidogenic agents and N-POC$_{1-28}$ and N–POC$_{2-59}$ are devoid of this activity in the isolated adrenal cell bioassay.

The availability of the smaller N-POC peptides also allowed us to test their adrenal action *in vivo* and to exclude the possibility of artefacts in the thymidine incorporation assay caused by possible changes in the endogenous adrenal thymidine pool size in treated animals. In these experiments we used implanted minipumps to administer the peptides and thus achieved a continuous stimulus over 7 days while completely preserving the endocrine status of the animal. After 1 week's treatment there was no significant difference between the N-POC$_{1-76}$ and control groups with regard to either adrenal weight or mitotic index (Table 1). The N-POC$_{1-28}$-treated group, however, showed a highly significant increase in adrenal weight and mitotic index and seemed more potent than the ACTH$_{1-24}$ group in both respects (Table 1).

Thus although ACTH can be shown to be mitogenic *in vivo* (ref. 1 and Table 1), it initiates a different process of cellular growth *in vivo* and inhibits the hyperplasia seen in the remaining adrenal after unilateral adrenalectomy[9]. It also inhibits cell proliferation *in vitro* (refs 6–8 and Fig. 3). This, coupled with the observations that anti-ACTH antiserum treatment does not lead to adrenal atrophy (ref. 10 and Fig. 2*a*) or affect the compensatory adrenal hyperplasia in unilateral adrenalectomy[10], argue against ACTH as the physiological mitogen. However, the peptides derived from the N-terminal non-γ-MSH region of proopiocortin used in the present study were active both *in vivo* and *in vitro* and thus may resemble the major adrenal mitogenic hormones. The extensive conservation previously noted in the N-POC region from cDNA sequence data of rat[19], human[20] and bovine material is confirmed in a recent comparative immunohistochemical survey, which shows that the anti-N-POC antiserum used in our study immunostains only the corticotropes and melanotropes of a variety of vertebrate species including fish[21]. This also suggests a biological role for this region.

The need for cleavage of the N-POC region before its mitogenic activity can be expressed suggests an interesting control mechanism. Chemical[13], biosynthetic and physiological studies[22] have indicated that the main molecular form of the corticotropin in blood may be similar to the intact N-POC$_{1-76}$, which is inactive as an adrenal mitogen. The antiserum experiments, however, would suggest either secretion of smaller fragments of N-POC, for example from the pars intermedia (where limited further processing of this region has been shown to take place), or the release of a peptidase which cleaves the peptide after secretion. The most probable cleavage site would be at the double basic sequence at residues 49–50 giving rise to N-POC$_{1-48}$ and N-POC$_{50-76}$ (γ_3-MSH in the ox[23] and rat[24] has been found to start with the lysine residue at position 50). Thus the most likely physiological fragment would be N-POC$_{1-48}$. This is corroborated by the observation that the antiserum used in this study effectively removed the naturally circulating biological activity and did not cross-react with smaller biologically active fragments (N-POC$_{1-28}$) in the radioimmunoassay.

In mammals with little or no pars intermedia tissue or its associated peptides, such as humans[25,26], post-secretional modification would be the probable mechanism. Thus a change in processing of the N-POC$_{1-76}$ region could provide the necessary mitogenic stimulus to cause, for example, the onset of the adrenarche and development of the androgenic zone of the prepubertal human adrenal gland. As the secretion of peptides derived from N-POC in the corticotrope has been shown to be under the same hypothalamic control as ACTH and β-LPH/endorphin[27], their depressed levels during chronic treatment with glucocorticoids could be responsible for the adrenal atrophy observed in such cases. Administration of physiological or even pharmacological doses of peptides derived from this region, whilst continuing glucocorticoid therapy, could provide the necessary mitogenic stimulus and lead to a rapid recovery of the functioning of the hypothalamic pituitary adrenal axis on cessation of that therapy.

Thus we have the unique situation where the N-terminal region of proopiocortin, including ACTH, provides a variety of peptides capable of affecting different aspects of the adrenal gland's activity. N-POC$_{1-28}$, N-POC$_{2-59}$ and ACTH stimulate DNA synthesis, the intact N-POC$_{1-76}$ potentiates the action of ACTH by causing RNA synthesis[15], N-POC$_{51-76}$ activates cholesterol ester hydrolase[16] and ACTH switches on the translation of both the stable[1] and N-POC$_{1-76}$-stimulated mRNA pools[10] required for the initiation of corticosteroidogenesis.

N-methyl-D-aspartate-type receptors mediate striatal ^{3}H-acetylcholine release evoked by excitatory amino acids

Bernard Scatton & John Lehmann*

Synthelabo-LERS, 31 Avenue Paul Vaillant Couturier, 92220 Bagneux, France

Several lines of evidence suggest that striatal cholinergic interneurones receive an excitatory input from the cerebral cortex which utilizes an excitatory amino acid, L-glutamate or L-aspartate, as its neurotransmitter. Cortical ablation reduces striatal high-affinity glutamate uptake[1,2] and concomitantly decreases acetylcholine turnover[3]. The destruction of cholinergic, as well as other, neurones of the striatum by the rigid glutamate analogue kainic acid seems to require a functional excitatory amino acid innervation[4,5]. Furthermore, electron microscopic studies[6] suggest the existence of a cortical input to the aspiny dendrites of neurones morphologically similar to the presumed striatal cholinergic interneurones[7,8]. The recent discovery of preferential antagonists of amino acid-induced excitation in the vertebrate central nervous system has led to the classification of excitatory amino acid receptors into three subtypes: the *N*-methyl-D-aspartate (NMDA), the quisqualate- and the kainate-preferring receptors[9]. We have now attempted to characterize the receptor(s) mediating the excitatory amino acid influence on striatal cholinergic neurones by investigating the effects of specific excitatory amino acid receptor agonists and antagonists on the release of ^{3}H-acetylcholine from slices of the rat corpus striatum. We find that excitatory amino acid analogues evoke a tetrodotoxin-sensitive release of ^{3}H-acetylcholine from rat striatal slices superfused in Mg^{2+}-free medium, NMDA and ibotenate being the most potent and kainate and quisqualate the least potent. This effect is antagonized by Mg^{2+} and by (−)2-amino-7-phosphonoheptanoate (−APHept) and (±)2-amino-5-phosphonopentanoate (±APPent) but not by glutamic acid diethyl ester (GDEE). These data suggest the involvement of a NMDA-type receptor in the excitatory amino acid influence on striatal acetylcholine release.

The influence of excitatory amino acid receptor agonists on the release of striatal ^{3}H-acetylcholine was first investigated in normal Krebs medium (containing 1.2 mM Mg^{2+}). Exposure to 100 μM L-glutamate, L-aspartate and the excitatory amino acid receptor agonists, *N*-methyl-DL-aspartate, (±)ibotenate, *RS*-α-amino-3-hydroxy-5-methyl-4-isoazole-propionic acid (AMPA), L-cysteate, kainate and quisqualate of superfused rat striatal slices previously incubated with ^{3}H-choline evoked a moderate release of ^{3}H-acetylcholine (Table 1). AMPA and kainate were the most effective whereas *N*-methyl-DL-aspartate was almost ineffective. In the absence of calcium, L-glutamate-evoked ^{3}H-acetylcholine release was abolished (data not shown).

As electrophysiological studies on frog and rat spinal neurones have indicated that the different types of excitatory amino acid receptors exhibit a differential sensitivity to Mg^{2+} (low concentrations of Mg^{2+} antagonize NMDA- or L-aspar-

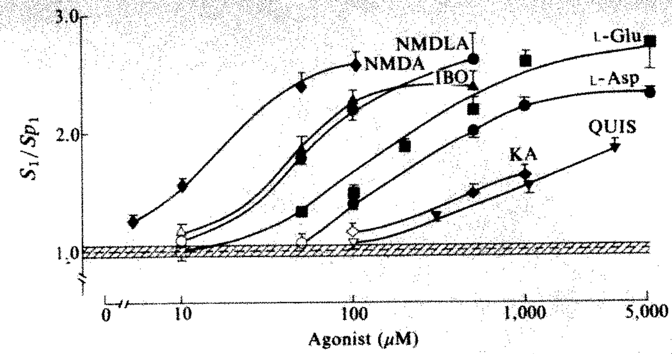

Fig. 1 Effects of excitatory amino acid receptor agonists on the outflow of ^{3}H-acetylcholine from striatal slices in Mg^{2+}-free medium: concentration dependence. Methods were as described in Table 1 legend. Each value represents the mean with s.e.m. of eight independent determinations (performed on eight rats). The dotted line and shaded area indicate the basal level with s.e.m. of the release of ^{3}H-acetylcholine in controls ($S_1/Sp_1 = 0.99 \pm 0.05$). Filled symbols: statistically significant ($P < 0.001$) compared with controls (Student's *t*-test). Open symbols: not statistically significant. IBO, (±)ibotenate; NMDA, *N*-methyl-D-aspartate; NMDLA, *N*-methyl-DL-aspartate; L-GLU, L-glutamate; L-ASP, L-aspartate; KA, kainate; QUIS, quisqualate.

Table 1 Effects of excitatory amino acid receptor agonists on outflow of ^{3}H-acetylcholine from striatal slices in medium containing 1.2 mM Mg^{2+} and in Mg^{2+}-free medium

	S_1/Sp_1	
Agonist (100 μM)	With Mg^{2+}	Without Mg^{2+}
Controls	0.93 ± 0.01	0.94 ± 0.02
N-methyl-DL-aspartate	0.97 ± 0.03	2.12 ± 0.03†‡
(±)Ibotenate	1.05 ± 0.05*	2.07 ± 0.05†‡
AMPA	1.16 ± 0.03†	1.63 ± 0.03†‡
L-glutamate	1.11 ± 0.03†	1.63 ± 0.05†‡
L-aspartate	1.09 ± 0.02†	1.43 ± 0.05†‡
L-cysteate	1.02 ± 0.03*	1.33 ± 0.04†‡
Kainate	1.14 ± 0.03†	1.19 ± 0.02†
Quisqualate	1.03 ± 0.03†	1.06 ± 0.03†

Experiments were performed on male Sprague–Dawley rats (COBS CD Charles River, France, 150 g). Striatal slices (1×1×0.3 mm prepared by using a McIlwain tissue chopper) were incubated at 37 °C with 0.05 μM [*N*-methyl-^{3}H]choline (specific activity 80 Ci mmol^{-1}; NEN) in oxygenated Krebs medium (composition in mM: NaCl 118, KCl 4.2, $NaHCO_3$ 25, NaH_2PO_4 1.0, $CaCl_2$ 2.6, glucose 11, $MgCl_2$ 1.2) for 30 min to allow high-affinity uptake to occur. The slices were subsequently washed, transferred to a Plexiglass chamber (8 mm diameter × 6 mm) and continuously superfused at a constant rate (0.5 ml min^{-1}) with normal or Mg^{2+}-free Krebs medium containing 10 μM hemicholinium-3 (a choline uptake inhibitor). The superfusate was collected every 6 min. Excitatory amino acid receptor agonists (100 μM) were added to the superfusion medium for 2 min at 48 min after the beginning of the superfusion. At the end of the experiment, slices were recovered and dissolved in 500 μl 0.5 M sodium hydroxide for radioactivity measurement. Experiments performed in the presence of eserine (30 μM) revealed that the radioactivity released in the medium consisted of 92% authentic ^{3}H-acetylcholine. For each fraction the amount of radioactivity released into the medium as a percentage of total tissue content during that interval (fractional release) was calculated. The elevation of ^{3}H-acetylcholine outflow caused by the agonists is expressed as the ratio of the fractional release obtained in the 6 min interval after the beginning of the 2 min pulse of agonist (S_1) divided by the fractional release obtained in the 6 min period preceding the 2 min pulse of agonist (Sp_1). Each value is the mean with s.e.m. of eight independent determinations (performed on eight animals). The statistical significance of the data was evaluated by the Student's two-tailed *t*-test.

* $P < 0.05$; † $P < 0.01$ compared with controls; ‡ $P < 0.001$ compared with Mg^{2+}-containing medium.

tate-induced but not kainate- and quisqualate-induced depolarization)[9], the responses evoked by excitatory amino acid receptor agonists (100 μM) were studied in Mg^{2+}-free conditions. When Mg^{2+} was removed from the medium, the ability of *N*-methyl-DL-aspartate to release ^{3}H-acetylcholine increased dramatically (Table 1). Removal of Mg^{2+} also potentiated the response elicited by (±)ibotenate, AMPA, L-glutamate, L-aspartate and L-cysteate but not that elicited by kainate. This effect was greatest for the agonists which were more specific for NMDA-type receptors (*N*-methyl-DL-aspartate, ibotenate). The relative potencies of excitatory amino acid agonists on the release of ^{3}H-acetylcholine in Mg^{2+}-free medium were compared by plotting concentration–response curves. All the curves were sigmoidal in shape, suggesting the involvement of a single saturable receptor (Fig. 1). The relative potency of the agonists was the following: NMDA > (±)ibotenate ≥ *N*-methyl-DL-aspartate > *L*-glutamate > *L*-aspartate > kainate ≥ quisqualate. This suggests that the receptor which mediates the release of ^{3}H-acetylcholine evoked by excitatory amino acid agonists shows a preference for NMDA-type agonists.

As suggested by electrophysiological studies, excitatory amino acid receptor subtypes exhibit a differential sensitivity to blockage by various organic antagonists. The most potent and selective NMDA-type receptor antagonists are the phosphonate analogues of carboxylic acids (−)APHept and (±)APPent, whereas GDEE is considered an antagonist of quisqualate-type receptors[10,11]. We further characterized the receptor involved in excitatory amino acid-evoked release of ^{3}H-acetylcholine by testing the effects of the amino acid antagonists on the response evoked by *N*-methyl-DL-aspartate and

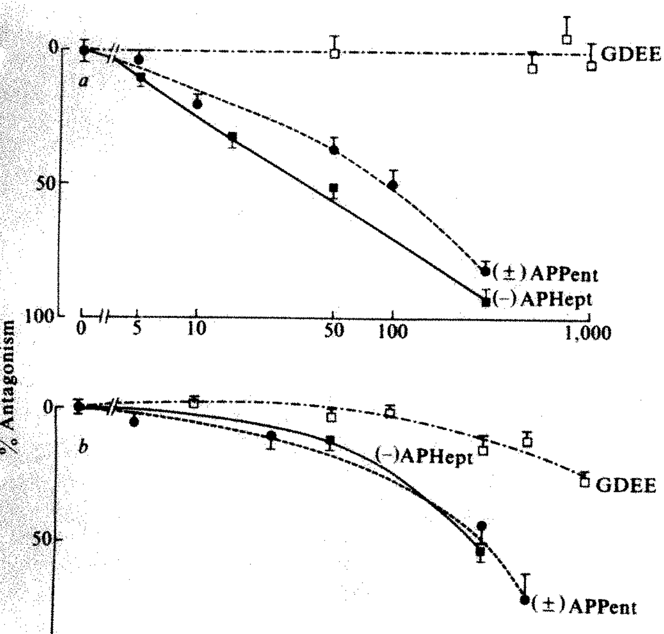

Fig. 2 Effects of excitatory amino acid receptor antagonists on *a*, *N*-methyl-DL-aspartate- and *b*, L-glutamate-evoked release of ^{3}H-acetylcholine from rat striatal slices. Methods were as described in Table 1 legend. The amino acid antagonist in the concentration indicated was added to the superfusion medium 12 min before the 2 min pulse (S_1) of *N*-methyl-DL-aspartate (50 μM) or L-glutamate (300 μM). The ratio S_1/Sp_1 was calculated as described in Table 1 legend in both the absence and presence of the antagonist and results were expressed as per cent of this value in respective controls (agonist alone). Results are means with s.e.m. of eight independent determinations (performed on eight animals). Filled symbols: statistically significant (at $P<0.01$) compared with respective controls (Student's *t*-test). Open symbols: not statistically significant.

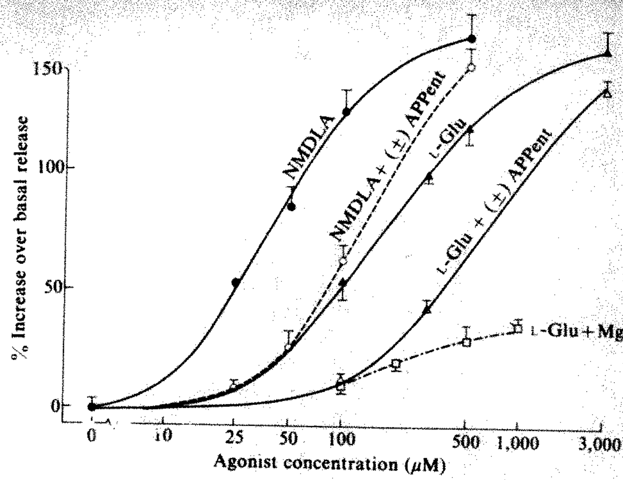

Fig. 3 Competitive antagonism by (±)APPent and non-competitive antagonism by Mg^{2+} of the N-methyl-DL-aspartate- and L-glutamate-evoked release of striatal ^{3}H-acetylcholine. For methods and expression of results see Table 1 legend. Mg^{2+} (1.2 mM) or (±)APPent (50 and 300 μM when tested against NMDLA and L-glutamate respectively) were introduced in the superfusion medium 12 min before the 2 min pulse of the excitatory amino acid agonist. Each point corresponds to the mean with s.e.m. of eight independent determinations (performed on eight animals).

L-glutamate in Mg^{2+}-free conditions. (−)APHept and (±)APPent antagonized in a concentration-dependent manner the release of ^{3}H-acetylcholine evoked by *N*-methyl-DL-aspartate (50 μM) with IC_{50}s of 40 and 90 μM respectively (Fig. 2). Both drugs also antagonized the response to L-glutamate (300 μM) with IC_{50}s of 280 and 320 μM respectively. In contrast, the quisqualate receptor antagonist GDEE failed to affect the response evoked by *N*-methyl-DL-aspartate and only weakly antagonized (as a concentration of 1 mM) the L-glutamate response. The inhibition by (±)APPent of the *N*-methyl-DL-aspartate- and L-glutamate evoked release of ^{3}H-acetylcholine is clearly competitive (Fig. 3), in contrast to the Mg^{2+} inhibition which seems to be non-competitive. In the concentration range tested, neither (−)APHept nor (±)APPent alone affected the spontaneous outflow of ^{3}H-acetylcholine. Moreover, at a concentration effective in blocking *N*-methyl-DL-aspartate or L-glutamate responses, (±)APPent only marginally inhibited the release of ^{3}H-acetylcholine evoked by other depolarizing agents—K^+ (12 mM) and veratridine (1 μM) S_1/Sp_1: controls, 0.96±0.02; K^+, 2.74±0.06; K^++(±)APPent, 2.30±0.01, $P<0.01$, Student's two-tailed *t*-test; veratridine, 1.70±0.09; veratridine+(±)APPent, 1.61±0.04, $n=8$), suggesting that the antagonism occurs at the level of specific amino acid receptors.

The present data are consistent with the involvement of an NMDA-type receptor in the excitatory amino acid influence on striatal ^{3}H-acetylcholine release. This conclusion is supported by (1) the high potency of the NMDA-type receptor agonists NMDA and (±)ibotenate to evoke the release of the labelled transmitter in Mg^{2+}-free conditions; (2) the antagonism by low concentrations of Mg^{2+} of NMDA-type agonist-evoked release of striatal ^{3}H-acetylcholine; (3) the selective blockage by antagonists of NMDA-type receptors of the *N*-methyl-DL-aspartate- and L-glutamate-evoked release of ^{3}H-acetylcholine in Mg^{2+}-free medium. Note that NMDA has also been found to be the most potent excitatory amino acid in stimulating sodium efflux from striatal slices[12]. The very weak potency of quisqualate, together with the failure of the quisqualate-type antagonist GDEE to block *N*-methyl-DL-aspartate- or L-glutamate-evoked ^{3}H-acetylcholine release in both Mg^{2+}-free conditions and Mg^{2+}-containing medium (not shown), suggest that quisqualate-type receptors do not contribute significantly to the excitatory amino acid-evoked responses of striatal cholinergic cells.

The localization of the NMDA receptors mediating ^{3}H-acetylcholine release evoked by excitatory amino acid agonists is not yet known. However, the observation that addition of tetrodotoxin (0.5 μM) abolished the *N*-methyl-DL-aspartate (50 μM) and L-glutamate (300 μM)-evoked release of ^{3}H-acetylcholine in Mg^{2+}-free medium (S_1/Sp_1: controls, 0.96±0.02; *N*-methyl-DL-aspartate, 2.88±0.06; *N*-methyl-DL-aspartate+tetrodotoxin, 1.10±0.07*; L-glutamate, 2.75±0.02; L-glutamate+tetrodotoxin, 1.09±0.03*; $*P<0.01$, Student's *t*-test, compared with agonist alone) indicates that action potentials mediate the release of ^{3}H-acetylcholine evoked by these agonists. These data are consistent with the hypothesis that excitatory amino acid receptor agonists activate receptors located on cholinergic dendrites, causing depolarization and action potential propagation along the axons of the cholinergic interneurones to the terminals, where ^{3}H-acetylcholine is released. The involvement of excitatory amino acid receptors on cells other than cholinergic neurones which affect the cholinergic neurones via an unknown transmitter cannot, however, be excluded rigorously.

In conclusion, an NMDA-type receptor has been found to mediate the excitatory influence of amino acids on striatal cholinergic neurones. These receptors, which may be located on dendrites of cholinergic cells, may play a part in transducing information received from the cerebral cortical afferents, which are thought to use an excitatory amino acid as neurotransmitter.

We thank Dr J. F. Collins, P. Krogsgaard-Larsen and J. C. Watkins for gifts of compounds, and D. Fage for technical assistance. (−)APHept was obtained from Dr Collins, Department of Chemistry, City of London Polytechnic, and (±)APPent from Dr Watkins, Department of Pharmacology and Physiology, The Medical School, Bristol.

Modulation of lateral mobility of band 3 in the red cell membrane by oxidative cross-linking of spectrin

Deborah K. Smith & Jiri Palek

The Department of Research, St Elizabeth's Hospital, Tufts University School of Medicine, Boston, Massachusetts 02135, USA

Several recent studies have shown that the lateral diffusion of erythrocyte transmembrane proteins is modulated by the submembrane network of spectrin, actin and polypeptide 4.1 (refs 1–3). The rate of lateral diffusion of the major transmembrane glycoprotein (the anion transport channel, band 3) is increased approximately 50-fold in membranes from spherocytic erythrocytes of mice which are deficient in the membrane skeletal protein spectrin[1]. Lateral mobility is increased when spectrin is removed from the membrane by extraction at low ionic strength[2] or when it is displaced by a fragment of ankyrin containing the membrane attachment site for spectrin[3]. Such experiments show that the presence of spectrin on the membrane restricts the mobility of membrane proteins, but they do not define the mechanism by which spectrin could modulate membrane protein mobility *in situ*. The oxidant diamide has been shown to cross-link spectrin via intermolecular disulphide coupling into a high molecular weight complex[4] and this is associated with inhibition of discocyte–echinocyte shape change[5] and decreased erythrocyte deformability[6]. Here we report that the lateral mobility of band 3 protein is decreased in erythrocytes in which spectrin is cross-linked via diamide. Furthermore, this inhibition of mobility is reversed when spectrin oxidative cross-links are reduced by addition of dithiothreitol (DTT).

Membranes isolated from red cells treated with 2 mM diamide or diamide followed by DTT were subjected to SDS-polyacrylamide gel electrophoresis in non-reducing conditions (Fig. 1). Membranes of cells treated with diamide showed the presence of a high molecular weight polymer ($>10^6$ molecular weight) which was reducible by addition of DTT to the gel. The polymer was absent in cells treated with DTT, indicating that it was also reversible in intact cells. Diamide-treated samples were electrophoresed in the second dimension in reducing conditions to identify components of the high molecular weight polymer. As shown in Figure 2, the polymer consisted primarily of spectrin (>90%) with small amounts of other membrane proteins. There was some spectrin dimer and some band 3 dimer, which might be expected because these proteins probably exist as tetramers in the membrane[7,8]. Cross-linked spectrin dimers were routinely detected in heavily loaded non-reducing gels, such as in the first-dimension gel of Fig. 2. There was no evidence, however, of cross-linking of band 3 to other membrane components such as ankyrin or spectrin, which might affect band 3 mobility directly. Therefore, in these conditions and in intact cells, diamide cross-linked spectrin fairly specifically. More extensive treatment with diamide (>2 mM)

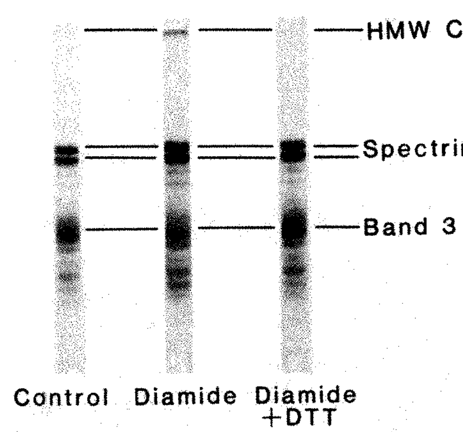

Fig. 1 Non-reducing SDS-polyacrylamide gels of membranes from diamide-treated erythrocytes. Blood was collected from healthy volunteers. Cells were washed in saline and buffy coats removed. Erythrocytes were incubated with 2 mM diamide in 5 mM Na_2HPO_4, 145 mM NaCl, *p*H 7.4 for 30 min at 37 °C. Cells were washed with the same buffer, and an aliquot of diamide-treated cells was incubated for 30 min at 37 °C with 15 mM DTT. Cells were washed, membrane ghosts prepared and samples were electrophoresed on 2.5% acrylamide–1% agarose gels as described previously[13]. All gels were stained with Coomassie brilliant blue. HMW Cx., high molecular weight complex.

caused significant cross-linking of other membrane proteins as well as spectrin (not shown).

To determine band 3 lateral diffusion rates, erythrocytes were labelled with the fluorescent molecule 5-(3,5-dichlorotriazinyl) aminofluorescein (DCTAF) in conditions where band 3 protein was specifically labelled[1]. Labelled cells were then fused with unlabelled cells by the addition of polyethylene glycol, and fused red cell doublets were observed in the fluorescence microscope for spread of fluorescence from the labelled to the unlabelled half. Label equilibrated significantly more slowly in erythrocytes in which spectrin was oxidatively cross-linked with diamide (Fig. 3). The time necessary for equilibration of label on 90% of all doublets (Fig. 3) was used to calculate a minimum diffusion constant (D_{min}) for band 3 according to the procedures of Fowler and Branton[9] and Huang[10]. D_{min} for diffusion of band 3 in normal red cell membranes was calculated to be $3\times10^{-11}\ cm^2\ s^{-1}$, which agrees with previously published values obtained by this and other methods[1-3,9,11]. D_{min} for diamide-treated cells was $\sim1.8\times10^{-11}\ cm^2\ s^{-1}$, reflecting a 40% reduction in the rate of band 3 diffusion ($P<0.005$). In diamide-treated cells which were further incubated with DTT to reduce oxidative cross-links, D_{min} was the same as for untreated cells. In experiments where DTT incompletely reduced oxidative cross-links, the extent of reversal of diamide effects on mobility were proportional to the degree of DTT reduction of the high molecular weight membrane polymer formed by diamide (not shown). These results indicate that stabilization of spectrin in a high molecular weight complex slows band 3 diffusion without cross-linking band 3 to the membrane skeleton.

Membranes isolated from red cells after fusion and equilibration of label showed no proteolysis when analysed on SDS-acrylamide gels. Furthermore, addition of the protease inhibitors phenylmethylsulphonyl fluoride (1 mM), *N*-α-*p*-tosyl-L-lysine chloromethyl ketone (1 mM) and pepstatin A ($1\ \mu g\ ml^{-1}$) had no effect on mobility of band 3 in these experiments.

Previous studies showed that the membrane skeleton serves to restrict lateral movement of transmembrane proteins, and two mechanisms have been proposed. First, studies by Golan and Veatch[2] and by Fowler and Bennett[3] on the dissociation of spectrin from the membrane suggested that the diffusion rate

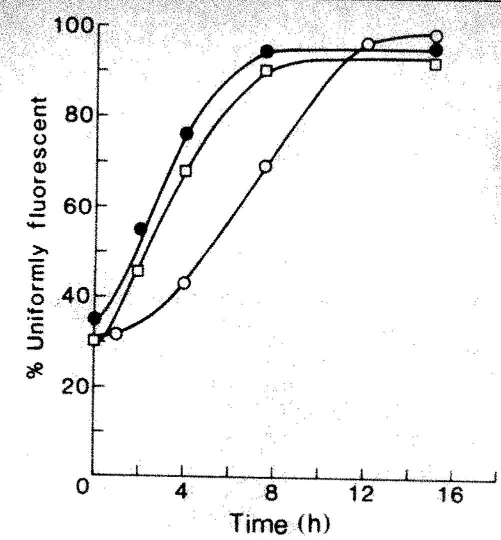

Fig. 3 Effect of diamide-induced oxidation of spectrin on lateral mobility of band 3 protein at 30 °C. Erythrocytes at 20% haematocrit in 10 mM $NaHCO_3$, 145 mM NaCl, *p*H 9.5, were incubated on ice for 1 h with $2\ mg\ ml^{-1}$ DCTAF. Cells were washed twice in 10 mM $NaHCO_3$, 95 mM NaCl, 50 mM glycine, *p*H 9.5 to remove unreacted DCTAF, then washed twice in phosphate-buffered saline (10 mM Na_2HPO_4, 145 mM NaCl, *p*H 7.4). Unlabelled cells were incubated with the same buffers in the absence of DCTAF. The labelling procedure caused no haemolysis. Labelled and unlabelled cells were fused with polyethylene glycol as described earlier[11]. Fused doublets were observed at 30 °C for diffusion and equilibration of label over the entire doublet. Data are plotted as per cent of labelled doublets which are uniformly fluorescent versus time[9]. ○, Cells treated with 2 mM diamide at 37 °C for 30 min before labelling and fusion. ●, Cells treated with diamide, washed, then incubated with 15 mM DTT at 37 °C for 30 min before labelling and fusion. □, Cells incubated at 37 °C with no diamide or DTT before labelling or fusion.

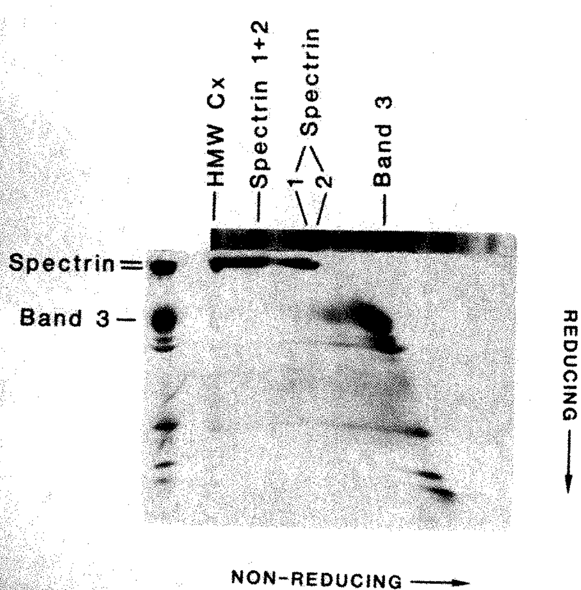

Fig. 2 Two-dimensional SDS-polyacrylamide gel electrophoresis of membranes from diamide-treated erythrocytes. Erythrocytes were diamide-treated, membrane ghosts prepared and membranes were electrophoresed in the first non-reducing dimension as in Fig. 1. This gel was then overlaid on a 7% acrylamide slab gel and electrophoresed in reducing conditions[14].

of band 3 can be controlled by reversible interaction of band 3 with spectrin via band 2.1. Second, Cherry *et al.* proposed that spectrin forms a meshwork underneath the membrane, with interstices through which band 3 can move[12]. Thus, lateral diffusion of transmembrane proteins could be modulated by the state of the spectrin meshwork itself, independently of spectrin-band 3 interactions. The latter hypothesis was supported by observations of Schindler *et al.* that agents which disrupt cytoskeletal structure also free band 3 to diffuse laterally in the membrane[11]. Our results are also consistent with this model of the membrane skeleton as a dynamic structure that modulates lateral movement of membrane proteins. When this dynamic state is stabilized, for example by cross-linking with spectrin, mobility of transmembrane proteins is reduced.

Higher plant tubulin identified by self-assembly into microtubules *in vitro*

Louis C. Morejohn & Donald E. Fosket

Department of Developmental and Cell Biology, University of California, Irvine, California 92717, USA

Microtubules are filamentous, subcellular structures present in virtually all eukaryotes. In higher plants, microtubules form the mitotic spindle[1], determine the plane of cell division[2,3] and orient cellulose microfibril deposition in growing cells[4,5], and thus are significant determinants of morphogenesis[6,7]. The main structural component of microtubules is tubulin, a conserved, heterodimeric protein having a molecular weight of 110,000 and composed of α- and β-subunits (≃55,000 each)[8]. The resistance of plant microtubules to several antimitotic drugs has suggested that plant tubulins differ from animal tubulins (see refs 5, 9, 10 for review), but further characterization has awaited the development of a method to isolate plant tubulin. As tubulin has no characteristic enzymatic activity, the positive identification of this protein depends on its ability to self-assemble *in vitro* to form structures which have the morphological features of microtubules. Recent studies[11–17] have used indirect methods to isolate tubulin-like proteins from higher plant cell extracts, but none has conclusively identified tubulin by demonstrating its self-assembly into microtubules. We report here the isolation of tubulin from cultured cells of a higher plant and its unequivocal identification by self-assembly into microtubules *in vitro*. Furthermore, we report peptide mapping data which indicate that although the β-subunits of mammalian and higher plant tubulins have been conserved, the α-subunits have diverged during evolution.

Previous work from our laboratory demonstrated that tubulin self-assembly in extracts of Paul's Scarlet rose (PSR) cells is hampered by low tubulin concentrations, by low molecular weight inhibitors and by endogenous peptidases[17]. We have circumvented these problems by designing a tubulin isolation method that is particularly suited to the physiological characteristics of PSR cells grown in suspension. Early exponential phase (day 3–5) cells were used because during this period the concentrations of cellular proteins are highest[18] and those of potentially harmful polyphenolic compounds lowest[19]. Extracts were prepared in a buffer designed to minimize proteolysis and to enzymatically cleave nucleic acids which, as polyanions, are known to inhibit *in vitro* assembly of tubulin[20]. In addition, anion-exchange chromatography was used to select and concentrate tubulin from extracts by virtue of its conserved polyanionic charge[21].

PSR cells, originally isolated from rose stem tissues (*Rosa* sp. cv. Paul's scarlet) by Nickell and Tulecke[22], were grown as stock suspension cultures in a defined medium[23], modified as previously described[17]. For the propagation of cells to be used for protein isolation, aliquots of 14-day-old stationary phase cells were diluted 6.6-fold with fresh medium and cultured for 3–5 days.

Extracts of cultured cells were prepared, and proteins were fractionated on DEAE-Sephadex A50 as modified from Weisenberg *et al.*[24] (see Fig. 1 legend) and analysed by SDS–polyacrylamide gel electrophoresis[25] (SDS-PAGE). Step gradient elution of the column separated the crude supernatant into three protein-containing fractions designated A, B and C (Fig. 1). SDS-PAGE of these fractions demonstrated that most of the cellular protein eluted in fractions A and B, while fraction C was enriched for two polypeptides with mobilities similar to those of the α- and β-subunits of bovine brain tubulin. Densitometer tracings of stained gels revealed that these bands comprised ~63% of the fraction C polypeptides that entered the gel. Thus DEAE chromatography represents a significant step in the purification of tubulin-like polypeptides from a heterologous population of proteins in PSR cell extracts. The yield of presumptive tubulin obtained by this procedure was 1–2 $\mu g\ mg^{-1}$ of crude supernatant proteins as determined by BioRad assays[26].

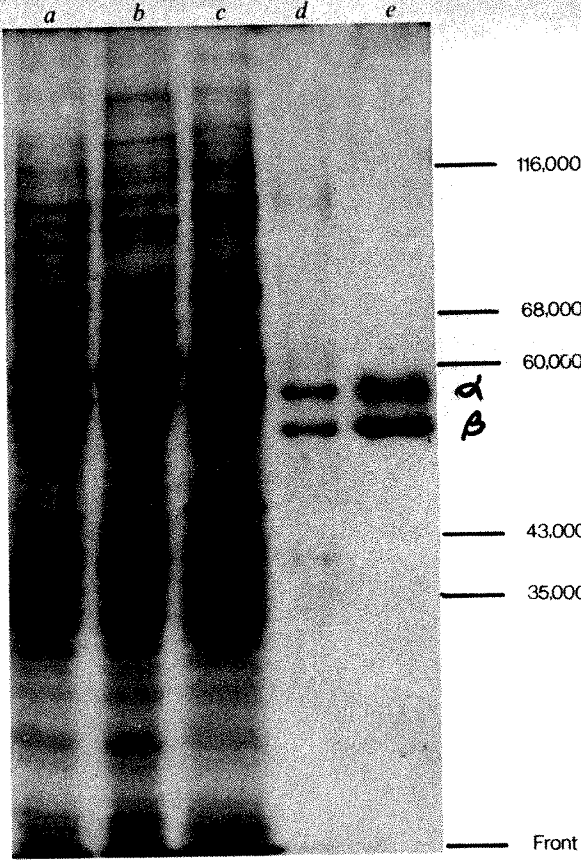

Fig. 1 Analysis of fractionated PSR proteins by SDS-PAGE[25]. Early exponential phase PSR suspension cultures were placed in a dark cold room at 4 °C with constant shaking for 2 h before collection on a Miracloth filter, washed with cold PM buffer (50 mM PIPES-KOH *p*H 6.9, 1 mM EGTA, 0.5 mM $MgCl_2$, 1 mM dithiothreitol). The cells were then weighed and homogenized in a chilled Sorval Omni-mixer in PM buffer containing 2 mM GTP (5 g cells per ml buffer) for 3 min. The homogenate was filtered through three layers of Miracloth and the filtrate was made 25 μM in leupeptin hemisulphate (Sigma) and 100 $\mu g\ ml^{-1}$ in both DNase I (Sigma) and RNase (Calbiochem). The filtered homogenate was centrifuged at 48,200 *g* for 30 min at 4 °C. The crude supernatant, which contained 2.4–3.3 $mg\ ml^{-1}$ of protein as assayed by the method of BioRad[26], was poured into a flask containing DEAE-Sephadex A50 (ref. 24) (pre-equilibrated with PM buffer) at a ratio of 0.5 ml packed volume of resin per ml of crude supernatant. The mixture was swirled in the dark at 4 °C for 1 h, briefly de-aerated and poured into a 2.6 × 40 cm column. The column was packed with crude supernatant at a flow rate of 2–3 ml min^{-1}, and unbound proteins (fraction A) were eluted directly. Weakly bound proteins (fraction B) were eluted with 3–5 bed volumes of PM buffer containing 0.4 M KCl and 0.5 mM GTP. Tightly bound proteins (fraction C) were eluted from the column with 3 bed volumes of PM buffer containing 0.8 M KCl and 0.5 mM GTP. Each fraction was collected by precipitation by 50% saturation with $(NH_4)_2SO_4$ for 30 min. Immediately prior to electrophoresis, $(NH_4)_2SO_4$ precipitates were dissolved in PM buffer, desalted on Sephadex G25 columns and acetone-precipitated, and the precipitates were boiled in SDS-sample buffer[25] for 2 min. Crude supernatant samples were boiled directly in equal volumes of SDS-sample buffer. SDS-derivatives were loaded on to 9.25% slab gels prepared according to Studier[25], except that the stacking gel was 5.1% acrylamide, the resolving gel contained 0.15 M Tris-HCl *p*H 8.8, and the SDS (Sigma) was ethanol-recrystallized. Gels were stained overnight with 0.025% Coomassie brilliant blue R-250, destained, dried and photographed with a yellow filter. *a*, PSR crude supernatant polypeptides; *b*, fraction A polypeptides; *c*, fraction B polypeptides; *d*, fraction C polypeptides containing putative tubulin α- and β-subunits; *e*, three times assembled bovine brain tubulin α- and β-subunits prepared according to ref. 33. Molecular weight standards were *Escherichia coli* β-galactosidase (116,000), bovine serum albumin (68,000), bovine liver catalase (60,000), ovalbumin (43,000) and bovine heart lactate dehydrogenase (35,000).

The proteins in fraction C were tested for their ability to form microtubules *in vitro*. Assembly reactions were performed following the addition of glycerol[27] or taxol[28], an experimental

0028–0836/82/220426—03$01.00

antitumour drug (Fig. 2 legend). Electron microscopy of the materials assembled in the presence of taxol revealed numerous short microtubules, while materials formed in the presence of glycerol contained microtubules which were less abundant and usually longer (Fig. 2). Protein determinations[26] on the microtubule pellets showed that ~7% of the total protein present in fraction C formed pelletable aggregates in the glycerol-treated sample, whereas ~44% of the total protein was pelleted from the taxol-treated sample.

Analysis of the *in vitro*-assembled materials by SDS-PAGE[25] showed that tubulin was the principal protein present in the pelleted aggregates assembled in the presence of both glycerol and taxol (Fig. 3). Furthermore, the rose tubulin polypeptides had mobilities similar to those of bovine brain tubulin polypeptides. In this particular gel system, the β-subunits co-migrated and the rose α-subunit had a slightly faster mobility than that of the brain α-subunit (compare subunits in lanes *d*, *e* of Fig. 3). Similarly, the α-subunits of flagellar tubulins from the green alga *Chlamydomonas* and the ferns *Marselia* and *Pteridium* have been shown to exhibit electrophoretic mobilities different from that of mammalian α-tubulin[29,30].

Densitometer tracings of electrophoretically separated microtubule pellets showed that tubulin represented ~36% of the total protein in the glycerol-assembled material, and ~74% of the taxol–microtubule pellet. Apparently a single round of assembly did not enrich for tubulin in the glycerol-treated samples but did so substantially in the presence of taxol. Horwitz and co-workers have shown that taxol enhances both the assembly rate and yield of brain microtubules formed *in vitro*[28,31]. They have further demonstrated that taxol cannot be readily removed from microtubules, and that it stabilizes the polymers against depolymerization by cold treatment, $CaCl_2$, podophyllotoxin or vinblastine[32]. For these reasons taxol-induced microtubules cannot be further purified by successive rounds of polymerization. Also, the low yield of tubulin from PSR cells and the low efficiency of glycerol-induced microtubule assembly have prohibited the use of cyclic assembly procedures[33]. We are now investigating methods to improve the yield of tubulin from these cells.

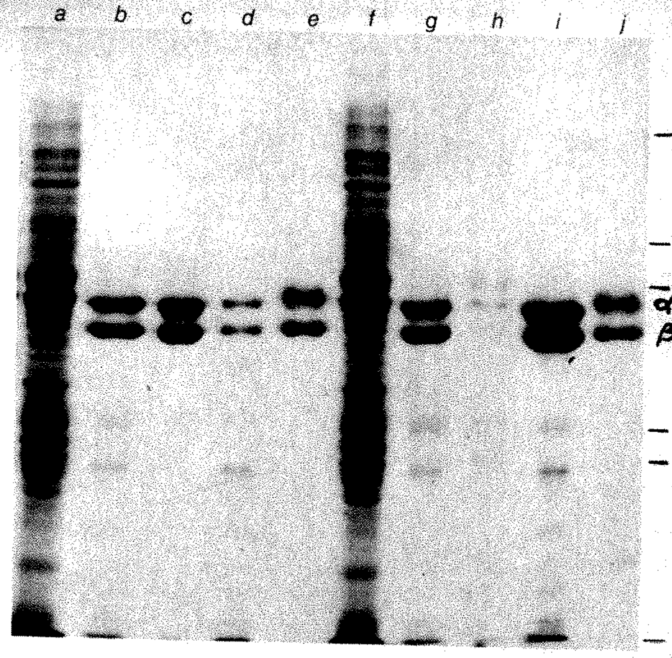

Fig. 3 Analysis of microtubule assembly mixtures by SDS-PAGE[25]. The supernatant and pellet samples described in Fig. 2 legend were boiled in equal volumes of SDS-sample buffer[25] and loaded on to the gel in equal volumes. In this way, we could compare directly the polypeptide composition and abundance of tubulin in each fraction from the glycerol (lanes *c* and *d*) and taxol (lanes *h* and *i*) treatments. *a*, *f*, PSR crude supernatant polypeptides; *b*, *g*, fraction C polypeptides; *c*, glycerol-treated supernatant polypeptides; *d*, glycerol-treated microtubule pellet polypeptides; *e*, *j*, three times assembled bovine brain tubulin[33]; *h*, taxol-treated supernatant polypeptides; *i*, taxol-treated microtubule pellet polypeptides. Molecular weight markers as in Fig. 1.

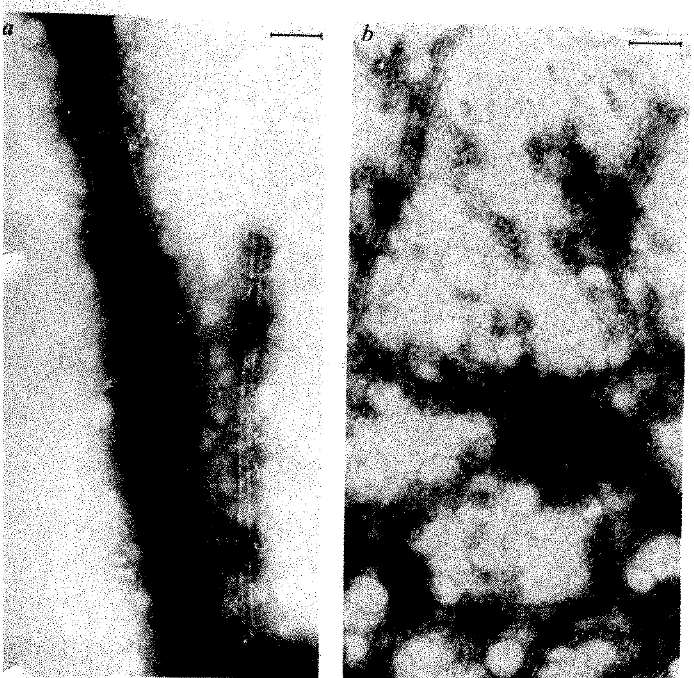

Fig. 2 Electron micrographs of negatively stained rose microtubules assembled *in vitro*. For *in vitro* assembly studies, the fraction C $(NH_4)_2SO_4$ precipitates (described in Fig. 1 legend) from ~200 g of cells were dissolved in 1–1.5 ml of PM buffer containing 2 mM GTP. The solution was desalted on a Sephadex G25 column (5 ml bed volume) which had been pre-equilibrated with the same buffer. The excluded volume was made 50 μM in leupeptin hemisulphate and concentrated by dialysis against 40 ml of the above buffer containing 8 M glycerol and 50 μM leupeptin hemisulphate at 4 °C for 2 h. This reduced the volume of the sample ~10-fold to give a 100–200 μl sample containing 2.6–3.6 mg ml^{-1} of protein as determined by the BioRad[26] procedure. This sample was tested for its ability to form microtubules after addition of glycerol or taxol. The sample was divided equally into two samples, one of which was made 4 M in glycerol[27], while the other was made 10 μM in taxol[28]. The samples were incubated at 37 °C for 1 h to permit microtubule assembly and centrifuged at 130,000 *g* in a Beckman airfuge for 1 h at 23 °C. Each supernatant was removed and divided into two aliquots, one to be used for protein determination and the other for SDS-gels. Each microtubule pellet was resuspended in 10 μl of PM buffer containing 4M glycerol. One μl of the suspension was removed for analysis by electron microscopy, while the remaining suspension was divided into two aliquots, one to be used for protein determinations and the other for SDS-gels. Samples for electron microscopy were placed on carbon- and formvar-coated copper grids, displaced with water, stained with 1% uranyl acetate for 30 s and air-dried. Samples were photographed on a Zeiss 9S electron microscope. *a*, Microtubules assembled in glycerol-treated sample; *b*, microtubules assembled in taxol-treated sample. Bar, 0.1 μm.

Previous studies on ion-exchange-purified mammalian brain tubulin have shown the *in vitro* assembly reaction to be enhanced by both glycerol[27] and taxol[31]. The present study demonstrates that plant tubulin isolated by DEAE chromatography assembles into microtubules after addition of glycerol or taxol. Both the number of microtubules and the yield of tubulin increased when taxol was present. Similar results have been obtained in studies on taxol-induced mammalian tubulin assembly[28,31], and so it seems that the tubulins from organisms as diverse as mammals and higher plants are subject to similar constraints in terms of their abilities to assemble into microtubules *in vitro*.

The microtubules in algae, fungi, ferns and higher plants show resistance to several antimicrotubule agents commonly used to disrupt animal microtubules, suggesting significant differences between plant and animal tubulins[5,10]. Indeed, recent studies have revealed several differences between the tubulins from some of these organisms and from mammals, including variations in electrophoretic mobility[29,34,35], sensitivity to drugs during *in vitro* assembly[35–37] and peptide mapping patterns[30,34].

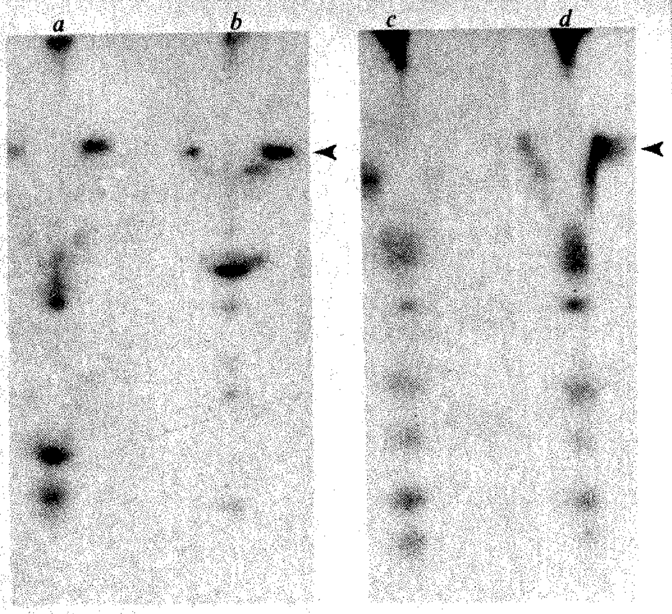

Fig. 4 Peptide mapping analysis of the α- and β-subunits of bovine brain tubulin and rose tubulin. Bovine brain tubulin purified by three rounds of assembly[33] and rose tubulin purified by taxol-induced assembly were analysed by limited proteolysis in gels according to the method of Cleveland *et al.*[38], with minor modifications. The subunits of these tubulins were first separated on the gel system described in Fig. 1 legend. Gels were stained with 0.2% Coomassie brilliant blue R-250 in 50% methanol for 30 min and destained in 5% methanol for 15 min. Bands corresponding to the α- and β-subunits were cut out, equilibrated in a solution of 0.125 M Tris-HCl *p*H 6.8, 0.1% SDS and 1 mM EDTA for 1 h, and loaded on to 15% Laemmli gels[39] together with 0.5 μg of *Staphylococcus aureus* V8 protease. Electrophoresis was performed according to Cleveland *et al.*[38]. Gels were stained and processed as described for Fig. 1. Lanes contain polypeptide fragments from *a*, bovine brain α-subunit; *b*, rose α-subunit; *c*, bovine brain β-subunit; *d*, rose β-subunit. Arrows indicate positions of uncleaved subunits.

We have started structural analysis of cytoplasmic tubulin from a higher plant by preparing peptide maps[38] of the α- and β-subunits of rose tubulin and bovine brain tubulin (Fig. 4). Cleavage of the β-subunits of both tubulins by *Staphylococcus aureus* V8 protease produced very similar patterns of polypeptide fragments. In contrast, the patterns of peptide fragments generated from the cleavage of the α-subunit of both tubulins not only differed markedly from each other, but also from the respective β-subunit patterns. These data suggest that the β-subunits of plants and animals have been more conserved during evolution than the α-subunits.

Recently published[30] peptide maps of the tubulin subunits from cow, squid, sea urchin, echiurid worm, a fern and an alga show the β-subunit maps of all these organisms to be quite similar, the α-subunit maps less similar and the plant α-subunit maps markedly different from those of the animals. Moreover, the fern and algal α-subunit maps resemble the α-subunit map of slime mold tubulin reported by Clayton *et al.*[34]. Our peptide mapping data on higher plant tubulin are consistent with the idea[34] that the α-subunits of tubulins from organisms that are generally resistant to anti-microtubule agents have diverged with respect to the α-subunits from organisms sensitive to those agents. Experiments are in progress to determine whether the resistance of higher plant cells to anti-microtubule drugs is, in fact, due to a low affinity of plant tubulin for these drugs, or to other modes of resistance[10].

We are raising antibodies to plant tubulin subunits for use in further studies on these polypeptides. Efforts are also underway to construct specific cDNA probes for use in studies on the regulation of synthesis of tubulin mRNAs in higher plants.

We thank Dr Susan Horwitz for her generous gift of taxol and Drs Marc Kirchner and Timothy Bradley for helpful suggestions during this investigation. This research was supported by grants to D.E.F. from the NSF (7722398) and the Monsanto Chemical Co., St Louis, Missouri.

Genes for immunoglobulin heavy chains and for α_1-antitrypsin are localized to specific regions of chromosome 14q

Diane W. Cox, Vera D. Markovic* & Ikuko E. Teshima

The Hospital for Sick Children, 555 University Avenue, Toronto, Canada, and Departments of Paediatrics and Medical Genetics, University of Toronto, Toronto, Ontario M5G 1X8, Canada and
* Genetics Department, Surrey Place Centre, Toronto M5S 2C2, Canada

Studies of somatic cell hybrids have assigned the gene cluster for human immunoglobulin heavy chains μ, γ and α to chromosome 14 (ref. 1). The locus for Gm (*GM*), a genetic marker on the γ heavy chain, has been shown to be linked to *PI*, the locus for α_1-antitrypsin/α_1-protease inhibitor (α_1AT), a major protease inhibitor in human serum[2,3]. This assignment has now been confirmed by studies of somatic cell hybrids which have assigned α_1AT also to chromosome 14 (refs 4, 23). From studies of two families having abnormalities involving the long arm of chromosome 14, we have localized *GM* to the terminal portion of 14q at band q32.3 and *PI* to a more proximal position, between q24.3 and q32.1. The immunoglobulin genes are within a chromosome region noted for its high frequency of breaks associated with chromosome rearrangement, which occur both spontaneously in cultured lymphocytes and in certain malignancies.

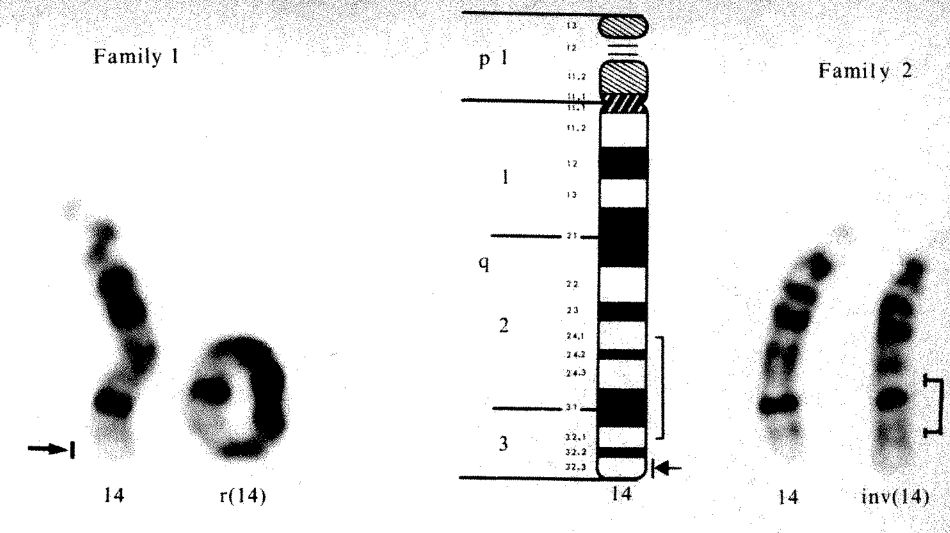

Fig. 1 Chromosomes observed with G-banding. The normal chromosome 14 and r(14) in proband of family 1 is shown with the deleted region marked by an arrow. The normal chromosome 14 and inv(14) in family 2 is shown with breakpoints indicated by brackets. The diagram (centre) shows the prometaphase band pattern according to International Nomenclature[22].

Early metaphase chromosomes in cultured lymphocytes were studied by trypsin–Giemsa G-banding[5]. Twenty or more cells of each individual were examined, at least 10 of which were banded. To define the breakpoint of the ring chromosome, C-banding[6], Giemsa-11[7] and NOR staining[8] were also used. PI typing was carried out by isoelectric focusing in polyacrylamide *p*H 3.5–6, and α_1AT was quantitated by electroimmunoassay[9]. GM allotypes were determined by haemagglutination inhibition using fresh O Rh$^+$ (Rhesus-positive) human erythrocytes sensitized with non-agglutinating anti-Rh antibody[10]. All sera were tested at a 1/20 dilution, with antibody for the γ1 markers *G1m* (*a*, *x* and *f*) and for the γ3 markers *G3m* (*b* and *g*) (reagents were given by Dr Moses Schanfield, American Red Cross). Quantitation of immunoglobulins (IgG, IgM and IgA) was carried out by laser nephelometry (Beckman). Other genetic markers were typed by standard techniques and used to verify the stated family relations: blood groups ABO, Rh and MNS; complement 3 (C3) and properdin factor B (BF) were identified by agarose electrophoresis; and group-specific component (GC) and transferrin (TF) by isoelectric focusing in polyacrylamide gels.

In family 1 (HSC–C4), the proband was an 8-year-old male with mental retardation, seizures, microcephaly and primary pulmonary hypertension. His karyotype, examined from 21 cells the first time and 100 cells on a second occasion, was 46 XY, ring 14 [r(14)]. In the two analyses, 93% of blood lymphocytes had the karyotype 46 XY, r(14), with at least one ring present, while the remainder had one copy of chromosome 14 lacking the ring. Breakpoints were distal to bands p11 and q32.2. The deleted portion of the chromosome is therefore all or part of q32.3 (Fig. 1). Further clinical and cytogenetic details of this patient will be reported elsewhere (V. D. M., R. G. Worton, C. B. Verellen and J. M. Berg, in preparation).

Both parents had normal karyotypes. Results of *PI* and *GM* typing, determined on two separate occasions, are shown in Fig. 2. The proband expressed only the paternal GM type, *fb*, and lacked a maternal GM component. This was confirmed in a repeat blood sample from proband and mother; both sera were also tested at 1/2 dilution. This result can be explained if the GM marker (γ-chain locus) is in the deleted region, q32.3. Inherited deletions of γ1 or γ3 regions have rarely been reported, however the GM types of I-2 and II-1 (Fig. 2) exclude the possibility of an inherited deletion. Serum concentrations of immunoglobulins are shown in Table 1. The IgG, IgA and IgM concentrations in serum of the proband are normal and do not show a dosage effect. This may, however, be the result of allelic exclusion, by which only one of the alleles for the immunoglobulin chains is expressed in any one immunoglobulin-producing cell, suggesting that the intact IgG region is always expressed when there is a deletion in the homologous chromosome. Genetic types of α_1AT (PI types) were not informative as proband and parents were all of PI type M1. Serum concentrations of α_1AT did not suggest a deletion for this locus; heterozygotes for the null allele of α_1AT (*PIM*−) have lower concentrations (59 ± 6.8% of normal)[11] than those found in the proband. Genetic markers were compatible with the stated parentage.

Family 2 (HSC-C3) provided information on localization of the *PI* locus. The proband was a 7-year-old boy with neutropenia. An altered banding pattern of chromosome 14 was observed in all 26 cultured lymphocytes examined by trypsin–Giemsa G-banding (Fig. 1). We concluded that the altered pattern was due to a paracentric inversion with breakpoints at bands q24.1 and q32.1; karyotype 46 XY, inv(14) (q24.1 q32.1). The inverted chromosome 14 was also found in other relatives (Fig. 2). Genetic markers were compatible with the stated family relations. Results of typing are shown in Fig. 2. If the *PI* allele, *M2* and the inversion are assumed to be coupled in I-2, then there are no recombinants among 11 offspring in this family. These results are compatible with location of the *PI* locus at the inversion, between bands q24.1 and q32.1. Genes within the inversion would be inherited together because a single cross-over in the inverted region would result in non-viable gametes. As there is an average of 1.76 chiasmata for chromosome 14q (ref. 12), and if a chiasma is equivalent to a cross-over, then a double cross-over, which would be necessary to produce viable gametes, is not likely to occur in the small distance covered by this inversion. Linkage analysis by lod scores supports the location within the inverted region. The inverted region was considered as a marker. Lod scores for the three sibships, two of which are phase known, were obtained from the tables of C. A. B. Smith as given by Emery[13]. Calculations were simplified by assuming I-1 to be of PI type M1M1, where the relative probability for this PI type, based on population frequencies from our laboratory and from PI types of the offspring, is 87%. The maximum likelihood

Table 1 Serum concentration of immunoglobulins and α_1-antitrypsin in family 1

Protein	Proband	Father	Mother	Controls [mean (95%)] confidence interval
IgG (mg dl^{-1})	808	906	998	915 (633–1280*)
IgA (mg dl^{-1})	54	134	97	90 (33–202*)
IgM (mg dl^{-1})	86	154	186	107 (48–207*)
α_1AT (% normal)	79	84	100	105 (67–198†)

* Values for children 6–8 y old (from C. R. Jolliff and K. Cost); adult values are higher.

† Obtained from 112 normal adults, in our laboratory. Values for children are similar.

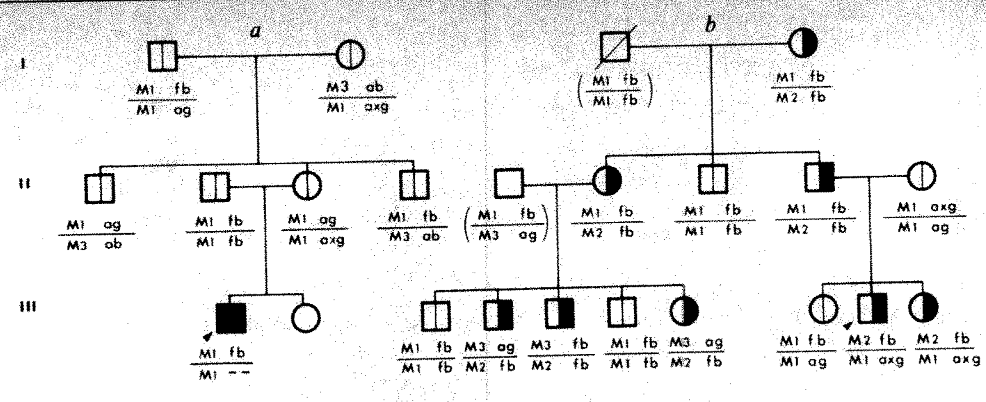

Fig. 2 Pedigrees of family 1 (*a*) and family 2 (*b*) showing abnormal chromosomes and the most probable arrangement of PI and GM types. Arrowheads indicate pro-bands. ■ Indicates the presence of r(14); ○, □ indicate the presence of inv(14).

estimate of recombination (B) from plotted values[12] is 0 with a lod score of 3.0. This indicates there is a high probability (1,000:1) of absolute linkage between *PI* and the inversion marker. A map distance of up to 5 centimorgans (cM) (recombination value, $\theta = 0.05$) would not be excluded.

Our studies in family 1 indicate that *GM* is localized at 14q32.3. While we consider the loss of the structural γ-chain locus to be probable, we cannot exclude the possibility that a promoter or sequences necessary for initiation of the γ-chain switch have been lost. Studies of the DNA of the patient carrying the deletion might clarify this question. We have recently learned, however, that *in situ* hybridization studies in the laboratory of P. Leder, using heavy-chain constant-region probes, also confirm that γ-chain loci are localized at 14q32, a region larger than, and including, our region 14q32.3 (I. Kirsch, personal communication).

Data from family 2 indicate that the *PI* locus is in the region q24.1–q32.1. The *GM–PI* linkage in males is 0.26[3] for 'non-Z' alleles. As there is an average of 1.76 chiasmata for chromosome 14q (ref. 12), and a recombination value of 0.5 in males is defined as equivalent to 50 cM, the genetic length of 14q is ~88 cM in human males. The recombination value of 0.26 for *GM–PI* falls either at the distal border of q24.3, according to Francke's band patterns based on actual chromosome measurements[14] or at the proximal portion of q24.3 in Fig. 1. However, the distribution of chiasmata in 14q is uneven, with a high concentration in terminal portions of the chromosome, thus the most likely location for *PI* is in a more distal region of the inversion. As it is unknown how the genetic map corresponds to the physical map, we must localize *PI* at q24.3–32.1. Nucleoside phosphorylase, which has been localized at the region q12–13 (ref. 15), should not be linked with *GM*, but may show linkage with *PI*, the minimal distance estimated as being 24 cM.

Our localization of *GM* at band q32.3 may have important biological implications as it is within or close to a region of the chromosome that is prone to breakage. Analysis of spontaneous breaks in cultured lymphocytes has indicated that chromosome 14 was involved in rearrangements more often than any other chromosome[16]. The 'hotspots' for breaks were 14q13 and 14q32. In ataxia telangiectasia, an inherited condition in which chromosome breaks occur frequently in cultured cells, the chromosome abnormalities frequently involve the long arm of chromosome 14, sometimes involving a tandem duplication with breaks through q11 and q32 (for review see ref. 17). In Burkitt's lymphoma and in other lymphomas, chromosome breaks are non-random. Burkett's lymphoma clones frequently contain rearrangements between chromosomes 8 and 14, specifically t(8; 14) (q24; q32)[17]. Other abnormalities of chromosome 14 are found with high frequency, consistently with breaks at q32. DNA rearrangements, which occur in the immunoglobulin gene cluster both during the switch from one type of heavy chain to the other and within differentiated cells to produce antibody variability (reviewed in ref. 18), may be related to this high frequency of breakage. The genes for human light-chain (λ) immunoglobulin chains have been assigned to chromosome 22 and association of this chromosome with translocations in malignancies has been noted[19]. The λ gene is also a region which undergoes DNA rearrangement. Malignant clone proliferation may be related to effects on the immunoglobulins, if breaks occur directly within the gene.

A restriction enzyme fragment of human DNA cloned in phage λ CH4-rHs18 has been found to be highly polymorphic, apparently because of DNA rearrangements rather than base pair substitutions or modifications[20]. This locus, D14S1, has recently been localized at the distal half of 14q[21]. If regions of DNA rearrangement do indeed promote chromosome instability, then it will be of considerable interest to determine whether this locus is the same as, or close to, the immunoglobulin locus.

We thank Dr Joseph Berg who originally made us aware of family 1; Dr Ron Worton for helpful discussions; Drs Moses Schanfield and Linda Walsh for helping to establish GM typing in our laboratory; Patricia Zavitz for obtaining blood samples from family members; and Dr Louis Siminovitch for review of the manuscript. We also acknowledge the technical assistance of Tammy Mansfield, Gail Billingsley, Shirley Smyth, Diane Wills, Vera Foldes, Aileen Brown, Chin Ho, Hannah Ho, Kim Mellick and Kwan Ng. This study was supported in part by a grant from the MRC of Canada (MA5426). I.E.T. was supported by The Hospital for Sick Children, in the laboratory of R. Worton.

Isolation and structural organization of the human preproenkephalin gene

Masaharu Noda, Yutaka Teranishi, Hideo Takahashi, Mitsuyoshi Toyosato, Mitsue Notake, Shigetada Nakanishi* & Shosaku Numa

Department of Medical Chemistry and * Institute for Immunology, Kyoto University Faculty of Medicine, Kyoto 606, Japan

Recently, we have elucidated the primary structure of bovine adrenal preproenkephalin by determining the nucleotide sequence of cloned DNA complementary to its mRNA[1]. The structure of most of this precursor molecule has also been deduced by Gubler *et al.*[2] using cDNA sequencing in conjunction with protein sequencing. Bovine preproenkephalin contains four copies of methionine-enkephalin[3] (Met-enkephalin) and one copy each of leucine-enkephalin[3] (Leu-enkephalin), Met-enkephalin-Arg^6-Phe^7 (ref. 4) and Met-enkephalin-Arg^6-Gly^7-Leu^8 (refs 1, 2, 5). The region containing the repeated enkephalin and extended enkephalin sequences, which are each bounded by paired basic amino acid residues, is connected with a cysteine-containing amino-terminal sequence preceded by a signal peptide[6]. We have now studied the relationship between the repetitive structure of preproenkephalin and the structural organization of its gene by cloning a human genomic DNA segment containing the entire gene. We find that the general organization of the preproenkephalin gene is strikingly similar to that of the gene encoding the common precursor of corticotropin (ACTH) and β-lipotropin (β-LPH)[7–9] (alternatively designated preproopiomelanocortin), another multi-hormone precursor. Furthermore, the complete mRNA and amino acid sequences of human preproenkephalin have been deduced from the corresponding gene sequence.

A human genomic DNA library[10], kindly provided by Dr T. Maniatis, was screened for phage carrying preproenkephalin gene sequences by hybridization *in situ*[11] at 60 °C with the bovine cDNA probe[1]. The DNA inserts carried by the isolated hybridization-positive phage clones were subjected to restriction mapping and blot hybridization analysis[12] with the cDNA probe (see Fig. 1 legend for details of cloning). Figure 1*a* shows a restriction map thus obtained for the hybridization-positive 2.0- and 6.7-kilobase pair (kbp) *Eco*RI fragments, which were shown to be adjacent to each other. This restriction map is in agreement with that of the mRNA-coding sequence on human placental cellular DNA constructed by blot hybridization analysis with the bovine cDNA and the 2.0-kbp *Eco*RI fragment as probes, thus assuring that the cloned 2.0- and 6.7-kbp *Eco*RI fragments are derived from a single segment of the human genome. (The *Eco*RI site at the 5′ end of the 2.0-kbp fragment is derived from the *Eco*RI linker joining this fragment to the phage vector.) These two *Eco*RI fragments were subcloned in the plasmid pBR322 (ref. 13) for further analysis.

Detailed restriction maps for the mRNA-coding sequences (exons) in the 2.0- and 6.7-kbp *Eco*RI fragments were constructed, and the DNA fragments containing an exonic sequence and its surrounding regions were subjected to nucleotide sequence analysis by the procedure of Maxam and Gilbert[14] according to the strategy indicated (Fig. 1*b*, *c*). Comparison of the human DNA sequence determined (Fig. 2) with the nucleotide sequence of the bovine cDNA[1] has enabled us to locate two intervening sequences (introns) in the human preproenkephalin gene. One of them, 469 base pairs (bp) long (intron A), is in the segment encoding the 5′-untranslated region of the mRNA 3 bp upstream from the translational initiation site. The other, ~3.4 kbp long (intron B), interrupts the protein-coding sequence between the triplets encoding amino acids 46 and 47 of preproenkephalin. The segment specifying amino acids 47–267 and the 317-bp segment corresponding to the 3′-untranslated region of the mRNA are uninterrupted. This assignment of the introns is supported by the general rule for exon–intron boundaries according to which an intron begins with a G-T and ends with an A-G dinucleotide[15]. Furthermore, the message strands at the ends of both introns are complementary to the 5′-terminal sequence of U1 small nuclear RNA, as observed for the introns of other genes[16,17].

The cloned bovine cDNA used lacked a sequence of ~65 bp encoding the 5′-terminal region of the mRNA[1]. To identify the gene sequence of this region and the 5′ terminus of the mRNA, we used two methods. First, a 5′-end-labelled DNA probe hybridized to the 5′-untranslated region of the mRNA was treated with S_1 nuclease, and the length of the protected DNA fragment measured by electrophoresing it beside a size marker prepared by chemical cleavage of a sample of the labelled probe[18] (Fig. 3*a*). Second, we estimated the size of the cDNA transcript formed by reverse transcriptase-mediated elongation of a 5′-end-labelled DNA primer hybridized to a segment of the 5′-untranslated region of the mRNA (Fig. 3*b*). The S_1 mapping procedure yielded a single DNA fragment which extended to the position corresponding to the C residue on the message strand located 217 nucleotides upstream from the 5′ end of intron A (see ref. 19 for this positioning). This position agreed approximately with that of the 5′ terminus of the mRNA

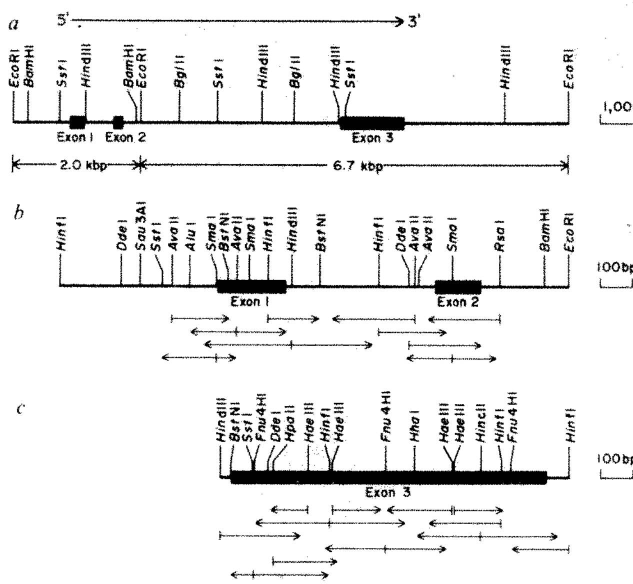

Fig. 1 Restriction mapping of cloned human genomic DNA containing the preproenkephalin gene and sequencing strategy. The library screened was a collection of recombinant phage that carried human fetal liver DNA fragments generated by partial digestion with *Hae*III and *Alu*I and joined to the λ Charon 4A arms with *Eco*RI linkers. The hybridization probe was a mixture of the *Pst*I-cleaved inserts of plasmids pENK5 and pENK45 (ref. 1) labelled with ^{32}P by nick-translation[31]. Five hybridization-positive phage clones were isolated from about 10^6 plaques by repeated plaque purification. Two of these clones (first type) carried a DNA insert containing six *Eco*RI fragments with approximate lengths of 1.1, 1.2, 1.4, 2.0, 2.9 and 6.7 kbp, and the 2.0- and 6.7-kbp fragments hybridized with the cDNA probe[12]. The inserts of the remaining three clones (second type) contained five *Eco*RI fragments approximately 1.1, 1.2, 1.8, 2.9 and 3.2 kbp long, and only the 3.2-kbp fragment was hybridization-positive. The presence of common restriction sites suggested that the two types of clone carried an overlapping DNA segment and that the 3.2-kbp fragment in the clones of the second type constituted a portion of the 6.7-kbp fragment in the clones of the first type. Restriction maps with scales on the right side are given for the DNA segment composed of the 2.0- and 6.7-kbp *Eco*RI fragments (*a*), a portion of the 2.0-kbp *Eco*RI fragment containing exons 1 and 2 (*b*) and a portion of the 6.7-kbp *Eco*RI fragment containing exon 3 (*c*). The direction of transcription is from left to right. For reference, the locations of the exons are shown by closed boxes. All existing sites for the endonucleases indicated are displayed in *a*; only relevant restriction sites are shown in *b* and *c*. The horizontal arrows beneath the restriction maps in *b* and *c* indicate the direction and extent of sequence determinations. Further experimental details have been described previously[8,25].

0028-0836/82/220431—04$01.00

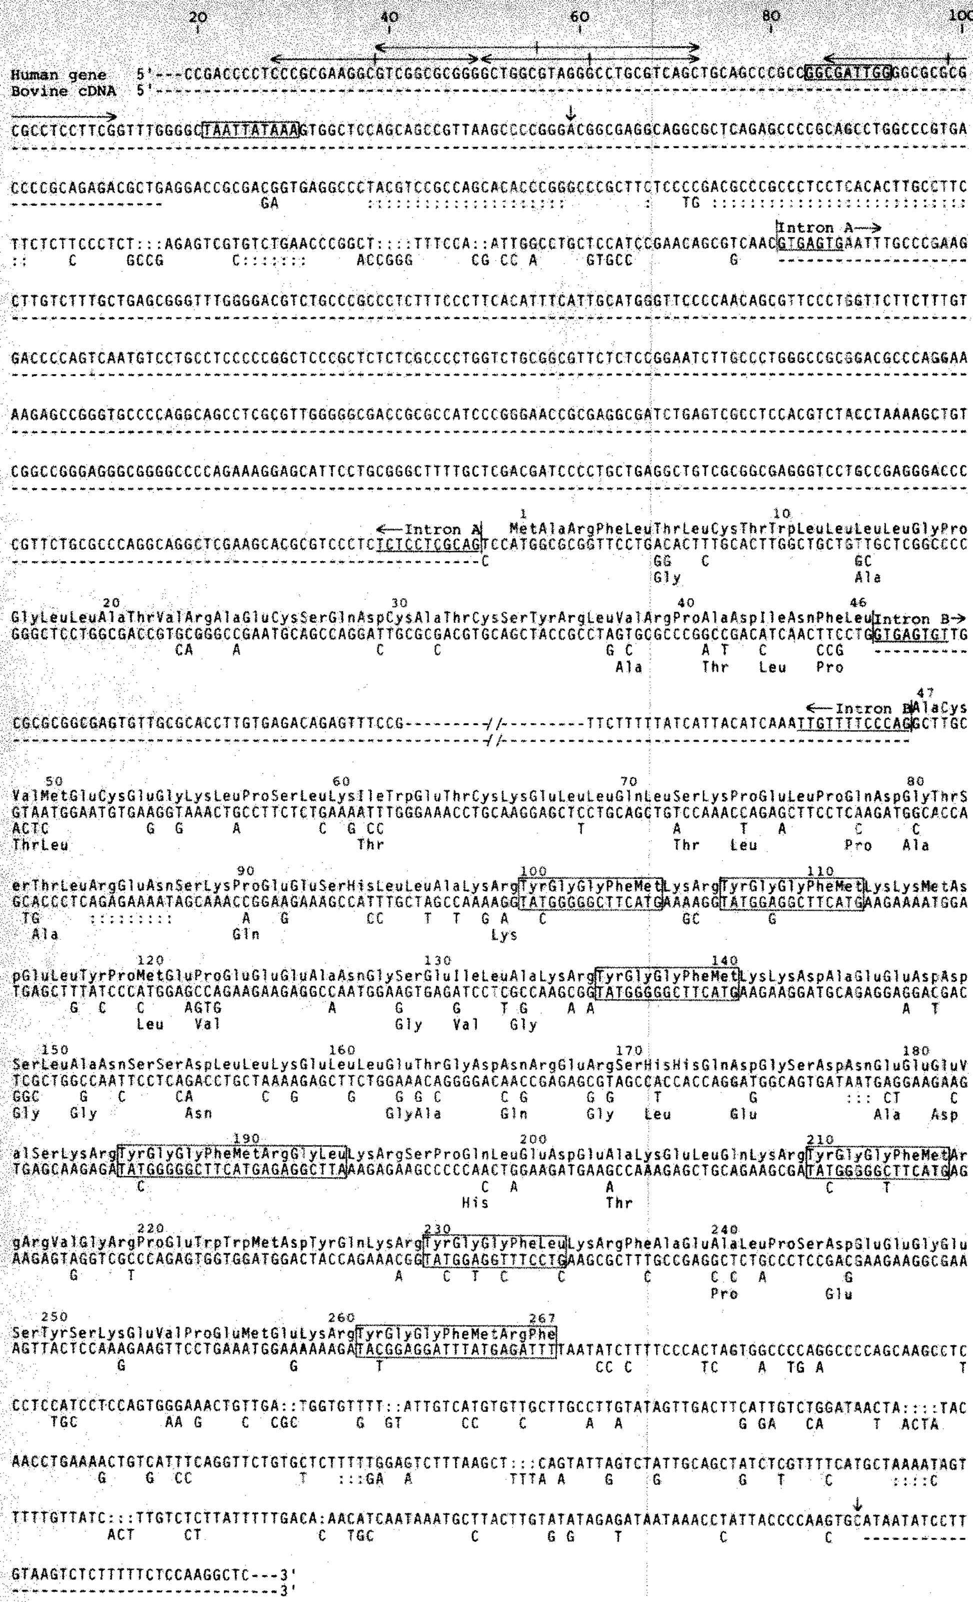

Fig. 2 Nucleotide sequence of the human preproenkephalin gene and comparison with that of the bovine cDNA. The nucleotide sequence of the human message strand, together with the deduced amino acid sequence, is shown, and the nucleotide and amino acid differences found in the bovine sequences[1] (derived from the nucleotide sequences of the cDNA clones pENK5 and pENK45) are displayed beneath the human sequences; the absence of a nucleotide or an amino acid in the bovine sequence indicates that the human and bovine sequences are the same; the presence of a colon in either nucleotide sequence indicates a gap; the hyphens indicate sequences that have not been determined or cloned. The amino acid residues in the human sequence are numbered, beginning with the initiative methionine. The sequences of Met-enkephalin, Leu-enkephalin and Met-enkephalin with a carboxyl extension, which are each bounded by paired basic amino acid residues (or by the carboxy-terminus of preproenkephalin), are boxed together with the coding nucleotides. The exon–intron junctions, which are positioned according to the G-T/A-G rule[15], are indicated by vertical lines. The sequences at both ends of the introns that are complementary to the 5′-terminal sequences of U1 small nuclear RNA are underlined. The putative sites of capping and poly(A) addition are indicated by vertical arrows. The Hogness box and a variant of the model sequence $GG^{C}_{T}CAATCT$ in the 5′-flanking region are boxed. The palindromes in the 5′-flanking region are shown by pairs of horizontal arrows starting at their centre above the nucleotide sequence.

indicated by the primer elongation experiment, so that the 5′-terminal gene sequence is uninterrupted. It is known that mouse β-globin mRNA, analysed by S_1 mapping, yields two protected DNA fragments which are four and five nucleotides longer than expected, perhaps because a cap structure at the 5′ terminus of the mRNA hinders digestion of the DNA probe by S_1 nuclease[20]. Furthermore, most eukaryotic mRNAs start with an A residue[21]. Therefore, we tentatively locate the capping site of the preproenkephalin gene at the A residue 213 bp upstream from the 5′ end of intron A. Consistent with this assignment is the presence of a 'Hogness box' (ref. 22; reviewed in ref. 21) and a variant of the model sequence $GG^{C}_{T}CAATCT$ (ref. 23) 29 and 67 bp, respectively, upstream from the capping site.

On the basis of the results described above, we conclude that the human preproenkephalin gene is ~5.2 kbp long and consists of three exons (designated exons 1, 2 and 3 in the 5′ to 3′ direction) separated by two introns. If the G-T/A-G rule for exon–intron boundaries[15] is applied and if the redundant A residue at the poly(A) addition site is not counted, exon 1 is composed of 213 bp, exon 2 of 141 bp and exon 3 of 980 bp.

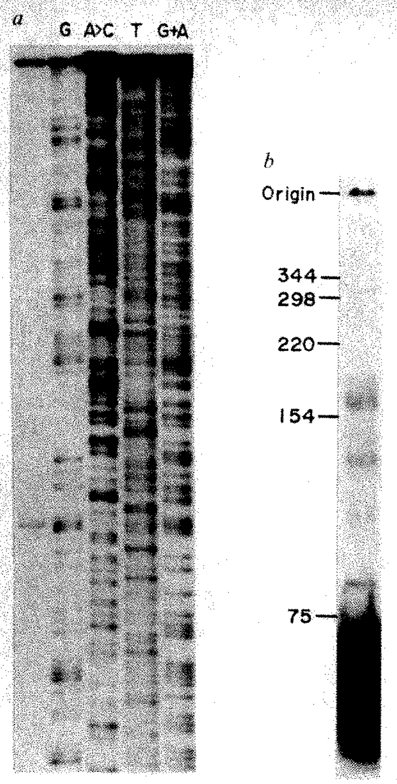

Fig. 3 Identification of the 5′ terminus of human preproenkephalin mRNA by S_1 mapping (*a*) and primer elongation (*b*). Poly(A)-containing RNA was isolated from human pheochromocytomas obtained by tumour resection according to the procedure used previously for the isolation of rat liver RNA[32]. The 2.0-kbp *Eco*RI fragment, isolated from the plasmid carrying it, was cleaved by *Hin*fI, and the ~650-bp *Hin*fI–*Hin*fI fragment (located most upstream in Fig. 1*b*) was isolated and labelled with ^{32}P at the 5′ end. In *a*, this labelled fragment was cleaved by *Sau*3AI, and the ~400-bp *Hin*fI–*Sau*3AI fragment (see Fig. 1*b*) was isolated and used as a probe. The probe (0.03 pmol, 1.2×10^5 c.p.m.) was denatured, hybridized to poly(A) RNA (20 μg) in 80% formamide at 63 °C for 3 h and digested with S_1 nuclease[18]. A sample of the labelled probe was subjected to the G, A>C, T and G+A degradations[14,33] and used as a size marker. The product of S_1 digestion and the size marker were electrophoresed on 7 M urea/8% polyacrylamide gel. In *b*, the 5′-end-labelled ~650-bp *Hin*fI–*Hin*fI fragment was cleaved by *Sma*I, and the resulting products were denatured and electrophoresed on 7 M urea/6% polyacrylamide gel for strand separation[14]. The anti-message strand (62 nucleotides) of the smaller *Hin*fI–*Sma*I fragment (4 pmol, 1.6×10^7 c.p.m.) (see Fig. 1*b*) was hybridized to poly(A) RNA (20 μg) in 0.4 M KCl at 60 °C for 1 h and then subjected to reverse transcriptase reaction[34]. The cDNA formed was electrophoresed on 7 M urea/6% polyacrylamide gel. The size of the largest cDNA species was estimated to be ~160 nucleotides by comparison with the 5′-end-labelled *Hin*fI cleavage products of pBR322 DNA, the sizes of which are given in nucleotides. For further experimental details, see ref. 25.

The structural organization of the preproenkephalin gene, together with the degree of nucleotide sequence homology between the human and bovine protein-coding regions, is schematized in Fig. 4. There are four amino acid additions in the human sequence (Arg-Glu-Asn at positions 85–87 and Asn at position 178). Thus human preproenkephalin consists of 267 amino acids and has a calculated molecular weight of 30,785. The coding regions for the enkephalin and extended enkephalin sequences and the paired basic amino acid residues flanking them exhibit no nucleotide substitution resulting in an amino acid replacement (replacement substitution), except for the substitution of Arg at codon 99 of the human sequence for Lys in the bovine sequence. The coding region for the peptide fragment positioned between the Leu-enkephalin and the preceding Met-enkephalin sequences also shows no replacement substitution. On the other hand, the remaining regions are subjected to some amino acid replacements, although they are fairly well conserved.

We have previously noted that the structural organization of preproenkephalin resembles that of the ACTH–β-LPH precursor in that both proteins are composed of multiple repetitive units (enkephalin or melanotropin sequences) connected with a cysteine-containing amino-terminal sequence preceded by a signal peptide[1]. The two proteins are composed of an identical (human) or almost identical number (bovine) of amino acid residues. The present study reveals a striking similarity between the structural organizations of the genes encoding the two proteins. Both genes contain two introns; one of them is inserted in the segment encoding the 5′-untranslated region of the mRNA near the translational initiation site, and the other in the protein-coding sequence near the signal peptide region at an almost equivalent position.

A characteristic of both the preproenkephalin gene and the ACTH–β-LPH precursor gene is that all the repeated enkephalin or melanotropin sequences are encoded by a single large exon (exon 3). When a new gene like an immunoglobulin heavy chain gene was created by duplication of a primordial DNA segment encoding a functional translation unit together with its flanking regions, the organism might have adopted a pre-existing RNA splicing mechanism to eliminate a spacer between the duplicated units[24]. Unlike the domains of immunoglobulins, the repeated peptide units of the multihormone precursors do not function as parts of an integrated protein molecule, but are destined to be separated from one another by proteolytic cleavage to exhibit coordinated biological activities[1,25,26]. In such a case, the organism might have resorted to a pre-existing protein-processing mechanism to remove the spacer region. The signals specifying the sites of proteolytic cleavage might have existed in the ancestral DNA segment or might have been created *de novo* by drift at the proper positions after duplication. This duplication process could be repeated to produce the characteristic structure of the

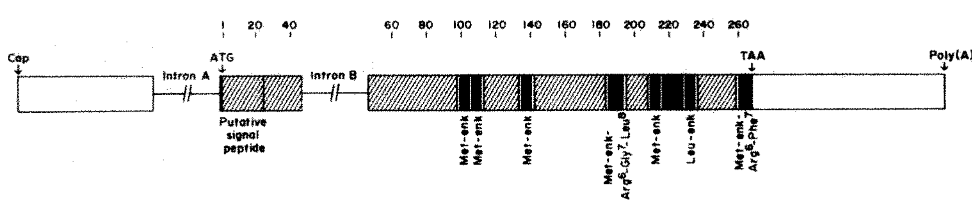

Fig. 4 Structural organization of the human preproenkephalin gene and nucleotide sequence homology between its protein-coding region and the bovine cDNA. The exons are shown by blocks, and the introns by lines; the lengths of the lines do not represent the real lengths of the introns. The sites of capping, translational initiation (ATG), translational termination (TAA) and poly(A) addition are indicated. The segments encoding the 5′- and 3′-untranslated regions of the mRNA are shown by open boxes. Amino acid numbers (see Fig. 2) are given above the gene sequence. The open slits in the protein-coding segment represent the coding nucleotides for the paired basic amino acid residues separating the component peptides, which are displayed beneath the gene sequence. The protein-coding segment is divided into 14 regions bounded by the paired basic residues (or by one of the termini or by the cleavage site of the signal peptide). The regions with and without replacement substitutions are shown by shaded and solid boxes, respectively. The corrected per cent divergence[27] calculated for the replacement substitution sites of each region is as follows (codons corresponding to gaps were excluded from the calculation): signal peptide region (amino acid residues 1–24), 8.5; residues 25–97, 10.5; residues 114–133, 13.9; residues 143–183, 16.4; residues 196–207, 9.4; residues 237–258, 5.9. enk, Enkephalin.

multi-hormone precursors. Because such a protein-processing mechanism could overcome the possible deleterious effect of an inexact deletion of an intron, introns which existed originally between the coding regions for the repeated units of the multi-hormone precursors may have been lost, as proposed for the C-peptide-coding region of the rat preproinsulin I gene[27,28]. Once a flanking peptide, connected with a duplicated unit, has acquired a specific function[1,25,26], however, the deletion of an intron would have to be precise, and this would be a rather rare event. In view of the fact that the multi-hormone precursor genes contain, in addition to the coding regions for the repeated units, many segments that apparently represent direct duplications[1,25], it seems more likely that the repetitive structure of these genes has evolved by duplication of an ancestral DNA segment at adjacent positions in conjunction with a protein-processing mechanism. On the other hand, the two introns of these genes, located upstream of the region encoding the multiple repetitive units, may have been generated by assembling primordial exons together with their flanking regions during exon shuffling (reviewed in ref. 29). The close resemblance between the structural organizations of the preproenkephalin gene and the ACTH-β-LPH precursor gene suggests that these multi-hormone precursor genes may have evolved by a similar mechanism.

This investigation was supported in part by research grants from the Ministry of Education, Science and Culture of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases.

Note added in proof: The cDNA sequence for human preproenkephalin reported recently by Comb *et al.*[30] confirms our assignment of the two introns, but indicates that nucleotides 71–157 (numbered beginning with the capping site) can be eliminated by RNA splicing. This spliced mRNA could not be detected by the probe or primer described in Fig. 3 legend, but we have now identified it as a major mRNA species in addition to the mRNA containing nucleotides 71–157 as a minor species. The 5′-terminal 113 nucleotides reported by Comb *et al.*[30] can be accounted for by an artefactual inverted repeat of the cDNA sequence starting with the second nucleotide of codon 242.

A chicken histone H3 gene contains intervening sequences

The organization of histone gene complexes in higher eukaryotes has long been a focus of study in eukaryotic molecular biology. The best studied and most extensively characterized histone gene families are those of the sea urchin *Strongylocentrotus purpuratus* and *Lytechinus pictus*[1,2], which are also the archetypal example of tandemly duplicated genes, each of the four core histone genes and the histone H1 gene being represented once in each tandem repeat unit. Recently, it has become apparent that the organization of histone gene families from higher eukaryotes does not follow these classical examples, a clustered but not tandemly duplicated arrangement having been found in chicken, mouse and humans[3–5]. In the chicken, the genes are organized in apparently random arrays with no cluster of genes being structurally analogous to another cluster[3]. In *Xenopus*, there is evidence for some degree of tandem duplication, and yet there is divergence within these clusters[6]. In yeast, the two gene clusters, each containing an H2a and H2b gene, are separate from other histone genes in the organism; furthermore these two clusters are unlinked to one another, but show evidence of close conservation of sequence between the two clusters[7]. During the routine screening and processing of a number of chicken histone gene recombinants we discovered one chicken histone H3 gene which displayed abnormal characteristics with respect to the majority of the genes in our collection. Closer examination of this gene showed it to be structurally different in that it is the first demonstrated example of a histone gene which contains intervening DNA sequences.

Two recombinants initially identified by hybridization to heterologous sea urchin and *Drosophila* histone gene coding sequences are shown in Fig. 1. Figure 1*a* shows the recombinant insert chromosomal DNA segment of λCH3d and Fig. 1*b* shows the position and orientation of an H3 gene contained within λCH3d and the subclone (pCH3dRI) used for further analysis. Figure 1*c* shows the sequencing strategy and an abbreviated restriction map in and around the H3 gene contained within λCH3d, and Fig. 1*d–f* shows the restriction map, subclone designation and sequencing strategy of the histone H3 gene in recombinant λCH4a. Mapping and hybridization details of λCH3d were published previously[3].

The histone H3 gene in λCH3d was chosen for sequence analysis because of strong suggestive evidence from RNA blots that this H3 gene was expressed in embryos (see below). In order to obtain a representative copy of each of the core histone genes for further identification of other, homologous chick histone genes within our isolated recombinants, we chose the H3 gene in λCH3d at random as an H3 gene-specific sequence. The H3 gene in λCH4a, however, was chosen for further analysis primarily because of strong hybridization of a mapping blot of this recombinant to cDNA prepared against adult red cell poly(A)$^+$ mRNA (data not shown). Since the only chick histone mRNA reported to be polyadenylated is histone H5 (ref. 8), we made the initial assumption that λCH4a contained a red cell-specific H5 histone gene. Subsequent sequence analysis (see below) proved that this particular locus encodes, rather, a novel histone H3 gene.

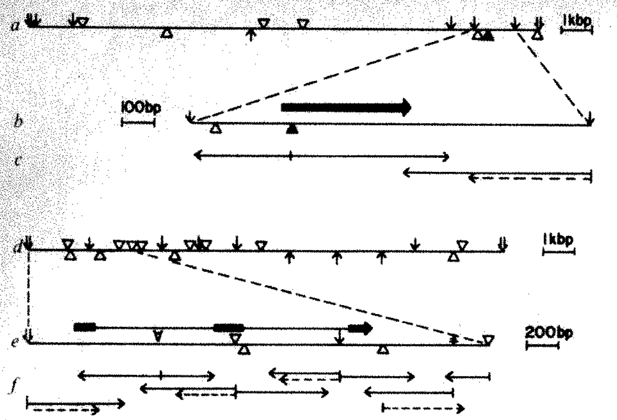

Fig. 1 Chick histone recombinants and DNA sequencing strategy. λ Charon 4A/genomic chicken DNA recombinants[19] λCH3d (ref. 3) and λCH4a are depicted in *a* and *d* respectively. Subclones containing the H3 genes from these chromosomal recombinants were prepared by ligation to homologous restriction sites of pBR322. The H3 gene in λCH3d is contained within subclone pCH3dR1 (*b*; heavy arrow indicates direction and extent of transcription), whereas the coding sequences of the H3 gene in λCH4a is contained within subclones pCH4a-2.0 (5′ and central exons) and pCH4a-2.3 (3′ exon). Restriction enzymes used were: ↓ = *Eco*RI; ↑ = *Bam*HI; ▽ = *Hin*dIII; △ = *Kpn*I; ▲ = *Sal*I; ‡ = *Hin*fI; ∀ = *Ava*I. DNA fragments used for sequence analysis were isolated by electroelution[20] and labelled at 5′ ends[21] (solid lines, *c* and *f*) or 3′ ends[22] (dashed lines, *c* and *f*). Chemical reactions[23] and polyacrylamide gel electrophoreses were performed as previously described[23–25].

As described previously[3], the H3 histone gene in λCH3d is linked to at least one other chicken histone gene, an H4 gene located in the 5′ direction (in transcriptional sense) from the H3 gene of λCH3d. However, no chicken histone genes other than the H3 gene shown in Fig. 1*e* have been identified on λCH4a (Fig. 1*d*) or on the chicken DNA sequences of an overlapping recombinant, λCH5d, which extends approximately 4 kilobases (5′ relative to the H3 gene) beyond the end of the λCH4a insert. However, we cannot yet rule out the possibility that an H1 or H5 histone gene is linked to this H3 gene, or that other histone genes are located in chicken chromosomal DNA close to this gene but beyond the λCH4a and λCH5d inserts.

The DNA sequence of the H3 genes in λCH3d and λCH4a is presented in Fig. 2. The H3 gene in λCH3d, like all other histone genes described to date, contains no introns (that is, the DNA sequence indicates that the polypeptide chain is colinear with the H3 polypeptide; Fig. 2, line B). This histone gene predicts an amino acid sequence which is identical to that of the adult chicken erythrocyte histone H3 polypeptide (line *a*) reported previously[9]. Furthermore, the gene contains 'CCAAT' and 'ATA' polymerase II consensus sequences 5′ to the gene (data not shown).

In striking contrast, the histone H3 gene represented by the chromosomal region expanded in Fig. 1*e*, is interrupted by two introns, dividing the coding sequence for this gene into three roughly equal coding parts. This DNA sequence (Fig. 2, line *c*) predicts an amino acid sequence very similar to that of a minor histone H3 polypeptide found in low abundance in somatic avian tissue (for example, in the erythrocyte, liver and perhaps other tissues)[10]. However, the predicted amino acid sequence of this gene differs by reciprocal, conservative changes from the chick erythrocyte histone H3.3 polypeptide previously described[11] at coding positions 31 and 87 (Fig. 2, line *d*). Thus we cannot be sure whether, in fact, this gene codes for the polypeptide initially described by Urban *et al.*[11], or perhaps codes for yet another (low abundance) erythrocyte histone H3 gene.

The DNA sequence of the interrupted gene contains no canonical sequences (outside of the coding sequence) indicative of an expressed gene for poly(A)$^+$ mRNAs isolated and characterized to date; that is, within 741 nucleotides 3′ to the termination codon we have been unable to find the 'AAUAAA' poly(A) addition sequence found in other eukaryotic poly(A)$^+$ mRNAs[12], nor within the 873 nucleotides 5′ to the initiation codon do we see evidence for 'CCAAT' or 'ATA' consensus sequences[13,14] (data not shown). However, the splice junction nucleotides 5′-GT and 3′-AG are present flanking both introns, as have been found in all intron-containing polymerase II-transcribed genes studied to date[15,16]. 255 bases 3′ to the termination codon, one finds an oligo d($A_{11}GA_9$) encoded in the mRNA sense strand. This oligo(A) sequence, if transcribed, would account for the selection of the mRNA synthesized from the split gene on oligo d(T) cellulose. We have no independent data to show whether, in addition, a post-transcriptionally added 3′ polyadenylate tail also exists.

To ascertain if (and if so, when) the H3 genes were expressed during avian development, RNA blotting experiments were undertaken. The results of this kind of experiment are shown in Fig. 3. The probe was generated from the histone H3 gene subclone of λCH3d used for sequencing (pCH3dR1; Fig. 1*b*) and hybridizes specifically and with high affinity to RNA prepared from several samples of 4 and 5 day embryonic RNA. Thus, this gene appears to be expressed both in the avian embryo and in embryonic red cells (Fig. 3, lanes 1, 2), but not in late embryonic or mature adult tissues (Fig. 3, lanes 3, 4). When the identical RNA samples were hybridized with similar probes which contained the split gene exons, hybridization was seen to all RNA samples examined (data not shown); however, the pattern of hybridization was more diffuse and always less

Fig. 2 DNA Sequence of linear and interrupted chicken histone H3 genes. The amino acid sequence of the major chicken erythrocyte H3 polypeptide (called H3.2 in ref. 11) is shown in *a*[9], and is also the sequence predicted by the H3 gene in pCH3dR1 (*b*). Unassigned glutamate/glutamine or aspartate/asparagine residues in the original polypeptide sequence[9] (between amino acids 73 and 85) are assigned from the DNA sequence (underlined third letter in three letter amino acid code; line *a*). The coding sequence of the split gene in λCH4a is shown in line *c* above the amino acid sequence for the minor adult H3.3 histone polypeptide[11] (identities in the two polypeptides (lines *a* and *d*) are deleted in line *d*). Differences in the two amino acid sequences are underlined; the differences between the prediction from the interrupted gene sequence (line *c*) and the H3.3 polypeptide variant[11] are boxed (positions 31 and 87). The position and size of the two introns in the split gene are shown as triangles.

intense than that of the uninterrupted H3 gene. Nonetheless, consistent hybridization was seen to the split H3 gene locus in RNA from every tissue which was examined. We conclude from these data that the histone H3 gene in λCH3d encodes an RNA species which is primarily embryonic in origin.

Thus the two chick histone H3 genes described here differ strikingly in primary DNA sequence. The H3 gene in λCH3d has a structure similar to other histone genes reported to date[2], and hybridizes exclusively to chick mRNAs which are embryonic in origin, whereas the H3 gene in λCH4a has two interruptions in the coding segment of the gene.

We have not been able to demonstrate the presence of either 5′ or 3′ consensus sequences common to other eukaryotic polymerase II transcripts in the DNA sequence of the split H3 gene. We are now examining sequences distal to the coding sequence portion of the gene reported here for the presence of these polymerase II consensus sequences. The absence of an observable poly(A) addition sequence (AAUAAA) is not surprising since this gene may not be polyadenylated by a post-transcriptional mechanism, and may appear in the poly(A)$^+$ mRNA fraction only because it contains a transcribed A-rich sequence ($A_{11}GA_9$). The absence of an 'ATA'-type 5′-flanking sequence is in contrast with several other chicken histone gene sequences examined (our unpublished results), but the actual mRNA initiation site may be outside the presently sequenced region of DNA. In particular, it is possible that another intron exists in the 5′ transcribed spacer region of the gene, and for this reason we have not yet identified the 'leader' sequence of the mature mRNA in the split gene.

It is interesting from a developmental viewpoint that the histone H3 gene in λCH3d encodes an embryonic message corresponding to a polypeptide which is likely to be identical to the major adult erythrocyte histone H3 (ref. 9), but nonetheless appears not to be expressed in the adult red cell. This suggests that a developmental switch occurs in histone biosynthesis in which an identical polypeptide is produced from two separate genes (one embryonic and one adult) which, from the RNA blots (Fig. 3) must differ significantly in nucleic acid sequence. The alternative explanation, that the two genes differ widely in amino acid sequence (for example, in the ambiguous glutamine/glutamate and asparagine/aspartate positions originally unassigned in the amino acid sequence[9]) is less compelling since the histones, as often reported, appear to show extreme amino acid sequence conservation[17].

The structure of the split histone H3 gene in λCH4a poses several important questions for further investigation. First, is this gene expressed? Several pieces of data suggest that the split gene is transcriptionally active: (1) cDNA prepared to poly(A)$^+$ chicken cellular RNA selected by oligo d(T) cellulose hybridizes exclusively and with high affinity to the presumptive exon sequences; (2) the DNA sequence predicts a polypeptide sequence which is very similar to that of an H3 histone found in adult chicken tissue; (3) no internal stop codons are found, in phase, in the three 'exons'; (4) the intervening DNA sequences are bounded by conventional (5′-GT, 3′-AG) splice junctions at the intron–exon borders; (5) in all tissues examined, RNA is transcribed which hybridizes to this locus. We are now examining the strandedness, tissue specificity, abundance and size of the transcription products at this locus. Our preliminary RNA blotting results raise the possibility that the pattern of chicken histone RNA synthesis might well be analogous to *Xenopus* 5S RNA gene expression, in which oocyte-specific 5S RNAs are synthesized only at early times (corresponding to our embryonic H3 gene in λCH3d), whereas the somatic 5S genes are expressed in both the oocyte and mature frog[18] (corresponding to expression of the split gene).

We thank Drew Rusling for discussion and help with computer analysis and Sheryl Niemiec, Patricia Creatura and Ed Diekhoff for technical assistance. We acknowledge access to the Stanford Molgen Project computer programs and data bank, made available through NIH resources and SUMEX, and helpful discussions thereof with L. Kedes. Fig. 3 Analysis of RNAs synthesized by the λCH3d histone H3 gene. Total cellular RNA and poly(A)$^+$ RNA was prepared as described elsewhere[26]; 5 μg per lane was reacted with glyoxal in dimethyl sulphoxide, electrophoresed and blotted to nitrocellulose[27]. RNAs used were: lane 1, 4-day chick embryo total cellular RNA; lane 2, 5-day chick embryo red cell cytoplasmic RNA; lane 3, adult chicken red cell cytoplasmic RNA; lane 4, oligo d(T)-cellulose selected adult chicken red cell cytoplasmic RNA. Hybridization was to nick-translated pCH3dRI (specific activity: 1.5×10^8 c.p.m. per μg). After hybridization, filters were finally washed in a solution containing total monovalent cation concentration of 20 mM. Thus the homologous T_m should be about 77 °C for a 58% G+C base-pair hybrid[28]; the filter washes were performed at 60 °C. Exposure time was 9 h.

BOOK REVIEWS

Nuclear power and the people

Eric Ashby

IN January 1977 the Secretary of State for Energy issued a paper entitled *Some Aspects of the Safety of Nuclear Installations in Great Britain*. The importance of this paper lies not in its content but in the reasons for writing it; for it was in part a response to forty-five questions put by the Friends of the Earth. In John Chicken's words, it "established the precedent for questions by interest groups to the Government on nuclear safety to be answered publicly".

Chicken's book recounts the brief history of public concern about hazards from nuclear power and the effects of this concern upon policy. Do not be put off by the elephantine adjectival nouns in the title: the book is a clearly written for the general reader and well documented for the specialist who may want to consult the sources. Its theme is that the terrors of nuclear warfare have, by association, coloured attitudes towards the real, but quite different, risks in the nuclear power industry. The effect of this has been a preoccupation with safety forced upon the Establishment, impulsive reaction — fanned by the media — to every report of an accident and a refusal to accept the evidence that, so far, it has been safer to generate power from uranium than from coal or oil. The climax of the book is an analysis of the Windscale Inquiry published in 1978 and the value of the book is that it puts this Inquiry into historical perspective. It explains (what might otherwise be inexplicable) how nuclear power stations are regarded by some people as polluting in the ancient meaning of the word "pollute": "to render morally impure, desecrate, destroy the sanctity of . . .". As was demonstrated at the Inquiry, the very use of radioactive materials for peaceful purposes is tainted by their possible use for deliberate destruction.

Chicken's sober and modest chronicle begins with a summary of the development of nuclear power and the ways in which it is now controlled. Against this background he sets his story. First, there was the development of a British atomic bomb, described in the superb official history by Margaret Gowing. The decision to make the bomb was taken by a Labour Government under Attlee; or, rather, by a small group of men working in such secrecy that (it is said) even the Cabinet was "excluded from discussion of many of the major decisions on atomic policy". During the whole of the Labour Government's period of office (writes Chicken) "from 1946 to 1951 there was not a single debate

Nuclear Power Hazard Control Policy. By John C. Chicken. Pp.272. Hbk ISBN 0-08-023254-X; pbk ISBN 0-08-023255-8. (Pergamon: 1982.) Hbk £20, $40; pbk £7.50, $15.

on Atomic Energy in the House of Commons . . .".

It seemed at first as though the peaceful uses of atomic energy could be developed with as little participation from the public as had occurred in its use for defence. The Atomic Energy Authority was set up in 1954. Its first report evidently did not anticipate hostility from the public. It carried a mild reassurance about risk: the reactors would "present no more danger to people living nearby than many existing industrial works that are sited within built-up areas". In 1957 Britain's first nuclear power station was opened and it was announced that more would follow; a Safety Branch of the Authority was created: all without any serious signs of concern among the public. It was a period of "quiet acceptance"; policy for energy was being left to the experts.

In the 1960s this quiet acceptance was overturned by a worldwide surge of disenchantment with technocrats and the establishments that employed them. The episode is too close to us for an objective historical analysis to be made of it. Chicken concentrates upon its impact on policies for energy, though he quite rightly sees that nuclear power was only one of several issues used by the so-called "counter culture" as tools for protest. The movement began in the United States before it reached Britain, fuelled by resentment about the Vietnam war and the denial of civil rights to minority groups. It spread to an indictment of industry, symbolized by Ralph Nader's withering criticism of negligence over safety in the design of automobiles. A wave of anxiety about pollution and a mood of guilt about exploitation of the environment swept across the affluent industrial nations. Radiation is the most ominous form of pollution; its military uses, its temptation for terrorists, its association with cancer, its persistence if released into the environment, the delayed action of its alarming toxicity, even its invisibility: all combined to make nuclear power a prime target for suspicion and protest.

Anti-nuclear lobbies work at two quite different levels, often simultaneously. At one level they question the need for nuclear power at all; they want an energy policy based on coal or, better, renewable resources, and much greater economy in the use of energy. They are willing to accept a lower material standard of living to achieve these ends. At the other level are those who question the safety of specific reactors on specific sites. It is at this second level that assurances about hazard-control become essential if there is to be a viable nuclear power industry. In 1975 two events occurred that concentrated attention upon hazard-control: one was the accident to a reactor at Browns Ferry in Alabama which — though nobody was hurt — was useful ammunition for the anti-nuclear lobbies. The other event was the publication of the Rasmussen Report, which became — and remains — the most useful weapon in the armoury of pro-nuclear lobbies. At the time of the Presidential Election in the United States in 1976 the call for a moratorium in the building of nuclear reactors became an election issue. In the following year tens of thousands of demonstrators challenged the building of a fast reactor in France. In Britain there was comparative quiet on these issues until British Nuclear Fuels proposed to extend their fuel reprocessing plant at Windscale. The Government wisely decided to throw the whole issue open to public scrutiny and discussion.

There is already a shelf-load of books, articles and pamphlets about the Windscale Inquiry. Nevertheless Chicken's careful analysis of the decisions about risk and the influence of public interest groups on these decisions is a valuable addition to this literature. The important and encouraging point he makes is that the public interest groups, despite their reliance on voluntary subscriptions to pay the costs of conducting their case, did have a significant influence on the findings of the Inquiry and taught the proponents of the proposal lessons they would not have learnt without the dedicated and competent efforts of such bodies as the Friends of the Earth.

Chicken's analysis leads him to make some tentative suggestions about procedures for involving the public in decisions about what they regard as "acceptable risks". Despite criticisms (some of which, for example in *The Ecologist*, quoted on p. 172, were contemptible) the style of the Inquiry was satisfactory. But there is room for improvement in three respects. First, it is important that public interest groups should be financed from public funds for the significant part they play in such inquiries. Chicken does not mention the

successful way in which this has been done for similar inquiries in Canada. Second, it is essential that the public interest groups should have access to all the technical data possessed by the proponents. Third, and equally essential, Parliament, as the legally constituted forum for the ventilation of public opinion, should participate in decisions as to how safe is safe enough.

Finally, a word about the style and production of the book. John Chicken is to be congratulated on the impeccable way in which he refers the reader back and forth to the details of his complex chronicle: the book is admirably signposted. As to production, the book has been published from camera-ready copy which is a good thing because it keeps the price at a reasonable level; but there are a lot of misprints: surely these could have been corrected as easily in typescript as in ordinary set type. □

Eric Ashby is a Fellow of Clare College, Cambridge. He is joint author with Mary Anderson of The Politics of Clean Air *published by the Clarendon Press late last year.*

Journals' review issue 1982

On October 7th *Nature* will publish a second review supplement devoted to science journals. Last year's supplement, covering journals first published between January 1978 and May 1980, appeared in *Nature* **293**, 341-369; see p.343 of that issue for details.

Criteria for inclusion of a journal in the 1982 issue are that:

- the first number appeared, or the journal was re-titled, between June 1980 and May 1981;
- it is published at least three times a year;
- the main language used is English.

Broadly, periodicals of professional interest to scientists will be considered for review, with the exception of abstracts' journals.

In addition it is hoped to cover publicly available newsletters, first published between January 1978 and May 1981, in that issue.

Publishers and societies are invited to submit four sample issues of periodicals satisfying the above criteria, *including the first and most recent numbers*, to the Review Editor, *Nature*, 4 Little Essex St, London WC2R 3LF, England (London 836 6633 ext 2570) as soon as possible.

● **Oliphant** by Stewart Cockburn and David Ellyard (reviewed in *Nature* **296**, 685; 1982) is available in the UK from W. Heffer, 20 Trinity St, Cambridge CB2 3NG or C.M. Watkins, 44 Madrid Rd, London SW13. Price is £14.90 + post and packaging.

●Vernon Booth's **Writing a Scientific Paper and Speaking at Scientific Meetings, 5th Edn** (reviewed in *Nature* **296**, 499; 1982) can be obtained from The Biochemical Society Book Depot, PO Box 32, Commerce Way, Colchester CO2 8HP, UK.

Catastrophes in science and engineering

Colin Upstill

Catastrophe Theory for Scientists and Engineers. By R. Gilmore. Pp.680. ISBN 0-471-05064-4. (Wiley: 1981.) £32.15, $61.
Instabilities and Catastrophes in Science and Engineering. By J.M.T. Thompson. Pp.226. Hbk ISBN 0-471-09973-2; pbk ISBN 0-471-10071-4. (Wiley: 1982.) Hbk £14.50, $34.75; pbk £8.25, $19.50.

THE term "catastrophe theory" is open to wide interpretation, depending upon the scope accorded it. René Thom considered catastrophe theory to be a theory of general morphology, a topological bifurcation theory for systems and bifurcations of very general type, and this usage is now common. Under this broad roof lives a great body of work including such topics as bifurcation theory, dynamical systems theory, singularity theory and elementary catastrophe theory. The lines of demarcation between topics are neither fixed nor of zero width: something of a consensus is emerging, but many authors have used, do use, and no doubt will use, these and other terms without clearly stating what they mean by them.

Elementary catastrophe theory (ECT), the study of the equilibria of gradient systems, is the part of catastrophe theory which embodies the most simplifying assumptions, and is the most developed and accessible part of the theory. The qualifying adjective is often dropped for ease of exposition; thus catastrophe theory may mean something very general or something quite specific. When, as sometimes happens, the same author uses the term in both senses, the potential for confusion is maximized. Neither Gilmore nor Thompson is actually guilty of this, but there is a marked difference in the manner in which they deal with the welter of jargon.

In the first three pages of an excellent text, Gilmore explains briefly and clearly what catastrophe theory is, and what dynamical and gradient systems are and how they and ECT fit together. In the first of four parts of the text, he goes on to "present Elementary Catastrophe Theory from an elementary point of view" in a way which is well tailored to the needs and background of most physical scientists and engineers, defining technical terms crisply and clearly without recourse to the cryptic notations and abstraction of the mathematical literature.

Thompson's book is not so much a text as a review of many (but by no means all) current applications of catastrophe theory in the physical sciences and in engineering. It performs this task splendidly, provided that one has some knowledge of the subject to start with. For, despite the claim of the preface that the presentation is "at the level of popular magazines such as *Scientific American* or *New Scientist*", a great variety of jargon, both catastrophe theoretic and specific to the specialist fields covered, is used without ever being explicitly defined. The first use of many such terms is flagged by their being italicized, but setting something in italics is no substitute for explaining what it means. In collaboration with G.W. Hunt, Thompson is preparing a companion book to deal with much of the underlying theory, so it may well be that the decision to use unexplained technical terms is a deliberate one. Nonetheless, I believe that the book is considerably less accessible to many of the intended readers than it would have been with the occasional extra sentence of definition and explanation. This problem is exacerbated by Thompson's use of a transcript of his inaugural lecture as a basis for the introductory chapter, which gives a brief historical survey of the subject and an overview of the contents of the rest of the book. This is excellent for the *cognoscente*, but at the price of presenting the reader new to the subject with a high density of unexplained technical terms, and with a number of complicated diagrams referred to by phrases such as "the familiar such-and-such", which will almost certainly be anything but familiar to him.

Having taken Thompson to task for not writing the book the cover and the preface lead one to expect, let me repeat that the book he has actually written is a good one, well illustrated — essential when dealing with so many intrinsically geometric notions — and with copious references. He distinguishes clearly between static and dynamic bifurcations whilst showing how they are related, particularly in the context of engineering structures: among the other instability phenomena reviewed are gravitational stellar collapse, atomic lattices, biochemical reactions (including the celebrated Brusselator), population dynamics and ecology, hydrodynamical turbulence and the chaotic dynamics of strange attractors.

In Part 2 of his text, Gilmore considers some applications of ECT, and in Part 3 he first takes us beyond ECT into dynamical systems theory and then considers some examples. These parts of his text are, broadly speaking, complementary to Thompson's book; there is some overlap, but most of the topics Gilmore discusses are not considered at any length by Thompson, and vice versa. Gilmore deals with such topics as phase transitions in classical and quantum mechanical systems, climatology, and optical caustics and diffraction patterns. His discussion of optics is noticeably out of date in comparison with that of other topics, but he neither makes nor implies any claim to be reviewing the state of the art, giving few references and more relaxed and yet deeper discussions than Thompson.

Indeed, Gilmore's relaxed style will not be to everyone's taste; for example, after a page or two describing a standard treatment of some phenomenon, he concludes with the acerbic aside "In short, an intractable problem is replaced by an intractable problem". It is a style he handles well; it could so easily be overdone, but in my view it is not, and greatly enhances readability and thence understanding. The most formal section, also the shortest, is Part 4, in which he presents in some detail the mathematics underlying ECT. In contrast with Part 1, this is (necessarily) couched in sophisticated mathematical language. It would have been easy to have included this material in Part 1, and many readers would not then get beyond it: it is greatly to the benefit of the book that this mistake was avoided. Coincidentally, Part 4 is the least satisfactory part of the book, when judged against the standard work in the field, the classic text of Poston and Stewart (*Catastrophe Theory and its Applications;* Pitman, 1978) whose treatment of Thom's theorem, transversality, determinacy and unfoldings stands head and shoulders above Gilmore's. That criticism is more than offset by the fact that, particularly for the reader not well versed in the language of modern pure mathematics, the first nine-tenths of Gilmore's text is excellent.

In his epilogue, Gilmore asks the question "Is catastrophe theory useful and important?" and concludes by asserting his belief that it is. I share that view, and both his and Thompson's books are convincing evidence in support of it. □

Colin Upstill is at the H.H. Wills Physics Laboratory of the University of Bristol.

All around andesites, and beyond

Alexander R. McBirney

Orogenic Andesites and Plate Tectonics. By J.B. Gill. Pp.390. ISBN 3-540-10666-9. (Springer-Verlag: 1981.) DM 98, $44.60.

A THOROUGH, up-to-date review of orogenic andesites has long been needed and is especially welcome at this time, when many petrologists are taking stock of this group of rocks and their interpretation in terms of accepted concepts of plate tectonics. In undertaking this formidable task, James Gill has performed a notable service to petrology. His book is certainly the most comprehensive compilation of data and ideas that has yet been attempted.

The book summarizes almost every aspect of the occurrence, composition and genetic relations of andesites. It reviews their structural and tectonic setting, rheological properties, eruptive behaviour, geochemical and mineralogical features, compositional variations in time and space, and all the major petrogenetic theories proposed to explain their relations to plate tectonics. This mass of data is presented in a concise, well-organized fashion. In his evaluation of the various schemes which have been proposed to account for orogenic igneous rocks, Gill turns much of his attention to their relationship to subduction, and a large part of the book is an attempt to reconcile the occurrence and unusual features of the rocks with a party-line view of plate tectonics. In doing so, he has made a conscientious effort to mention all observed relationships, together with every known exception; the result is a text which tends towards the encyclopaedic, with awkward sentences that one must read two or three times to sort out an elusive trivial point. The style improves, however, when Gill comes to a question of interpretation that clearly interests him. The text then blossoms and becomes quite readable.

The book is burdened by the long-standing difficulty of defining what rocks should be included under the name andesite. The reader encounters this problem in the very first sentence, which tells him that "active volcanoes on Earth erupt andesite more than any other rock type". Before recovering from this, he reads, further down the same page, that these andesitic volcanoes include Kilimanjaro and Hekla! The explanation for these startling assertions soon becomes apparent when Gill gives his definition of andesite as any hypersthene-normative rock with a silica content between 53 and 65 weight per cent. Although this definition is offered in the interests of "simplicity" the resulting confusion in the mind of the reader persists throughout the book, for one is often in doubt as to whether, in referring to "andesites", Gill means calc-alkaline andesites or some other intermediate sub-alkaline rock. Much needless discussion is devoted to rocks that have no relevance to andesitic volcanism as most geologists perceive it.

There is a certain logic in including among andesites the important group of intermediate tholeiitic rocks of island arcs that are clearly related to subduction and share many genetic features in common with the "true" calc-alkaline andesites with which they are closely associated, sometimes even in the same volcano. It seems illogical not to refer to these rocks as tholeiitic andesites, but most petrologists would certainly agree that they are quite distinct from rocks of similar composition in settings such as Iceland, the Galapagos Islands or East Africa. The problem is made more difficult by the way in which Gill attempts to distinguish tholeiitic and calc-alkaline andesites. While he recognizes the importance of iron content, he ignores the more reliable compositional criteria of Irvine and Baragar and makes no mention of the high alumina and normative plagioclase contents that many petrologists consider compositionally diagnostic and crucial to any petrogenetic interpretation of calc-alkaline andesites.

Because much of the evidence bearing on these rocks comes from geochemical relations, any book of this kind must deal with complex trace-element patterns and isotopic ratios, and with how these may be related to the processes of magmatic evolution. Gill uses these data to weigh the relative importance of melting subducted oceanic lithosphere, assimilating crustal material and differentiating basaltic magma. In this way he systematically assesses essentially all the current ideas on the origin of andesitic magmas. While he does not hesitate to give his own judgement on these questions, he does so in the context of an overall appraisal of the evidence, so that readers can accept or reject Gill's conclusions according to their own view of the facts.

No two persons would agree as to how much weight should be given to various types of evidence bearing on the origins of these rocks. I would personally have preferred more data on geologic relations and less on trace-element geochemistry. It astonishes me that anyone can write an entire book about andesites and never present a single geologic map or structural section of an andesitic volcano. The book, like most modern work which covers orogenic igneous rocks, deals almost exclusively with the structural relations observed today around the Circum-Pacific and gives much less attention to the geologic past. If it is important to note that all active andesitic volcanoes are in well-defined belts close to convergent plate boundaries, is it not equally important to stress that the same has not always been true in the past? Many rules of thumb based on modern relations fail when we look beyond the Quaternary, and I suspect that one can learn more about andesites from the anomalous cases that violate our conventional models than from all the examples that neatly fit them.

These, of course, are petty differences of view, and they detract in no way from my unreserved recommendation of this book as a timely, scholarly survey of a very complex subject. The sincerest praise I can offer any book is to say, as I can of this one, that I have adopted it as a text in my graduate-level petrology course. No student of orogenic igneous rocks should neglect adding it to his professional library.

Alexander R. McBirney is a Professor in the Department of Geology at the University of Oregon, Eugene.

How ionizing radiation affects cells

R.B. Setlow

The Molecular Theory of Radiation Biology. By K.H. Chadwick and H.P. Leenhouts. Pp.377. ISBN 3-540-10297-3/0-387-10297-3. (Springer-Verlag: 1981.) DM 128, $67.20.

SOME of the best epidemiological data relating carcinogenic risks to environmental hazards comes from research into the consequences of exposure to ionizing radiation. The recent recalculation of dosimetry at Hiroshima and Nagasaki has just about eliminated any effects in these populations ascribable to neutrons, and, because gamma ray data are not robust below 30 rads, there are, for practical purposes, no human data at low doses or for particles of higher linear energy transfer. Thus, even in this best case, one needs models and theories for extrapolating from acute high dose effects to chronic low dose ones. If such a problem cannot be solved for ionizing radiation with its relatively good dosimetry, the chances are negligible that it will be solved for populations exposed to chemical agents.

In this book, Chadwick and Leenhouts describe the development of a theory that can be used to extrapolate the biological effects of ionizing radiation to low doses, many different LET particles, and to interactions between radiation and chemical agents for end points such as cytotoxicity, mutation, chromosome aberrations and carcinogenesis. Their theory is based on the premise that DNA is the target and that double-strand breaks in it are the molecular lesions reponsible for the biological effects of radiation. The authors are led to this assumption for a number of reasons, the principal one of which is that the dependence of many biological effects on dose contains both a linear and a square term. The linear term is thought of as representing double-strand breaks arising from the passage of a single ionizing particle close to DNA, and the square term represents double-strand breaks arising from two nearby single-strand breaks made by two ionizing particles.

The text is a careful and complete exposition of the implications of these assumptions. Of necessity, other concepts and hence additional parameters and suppositions must be introduced, such as allowance for the repair of double-strand breaks and the assumption that *all* radiation mutations arise from double-strand breaks. Thus, the analysis rapidly accumulates other variables that are often difficult to evaluate independently and that must be adjusted to fit the experimental results. The general problem faced by the authors is equivalent to that of determining enzyme mechanisms at the molecular level from enzyme kinetics: it cannot be done. Certainly, there is no unique solution to the problem especially because there have been relatively few good determinations of double-strand breaks as a function of dose and, because of a lack of basic knowledge of events at the molecular level, of how ionizing radiation affects even simple end points — such as the inhibition of the initiation of clusters of eukaryotic replicons — and inhibits the progression of cells through the cell cycle.

The authors do themselves an injustice by overstating their case. The assumption made early in the book that double-strand breaks are important becomes a fact later on. Such confidence is misplaced because it ignores data on the effects of radiation on the replicative form of ΦX174, in either protective or dilute solution, in which inactivation is not correlated with double-strand breaks but with some type of base damage. Moreover, although fibroblasts from individuals with the disease ataxia telangiectasia are more sensitive to the cytotoxic effects of ionizing radiation than are normal cells, and show more chromosomal aberrations as a result of radiation, they are hypomutable. Hence, not all of the biological end points are comparable and the simple theory expounded in the text seems to need major revision based on solid biology.

These are obviously serious criticisms. Nevertheless *The Theory of Radiation Biology* is an important book for radiation and environmental biologists for, if nothing else, it is sure to stimulate new experiments and ideas. □

Counting calories

John R. Krebs

Physiological Ecology: An Evolutionary Approach to Resource Use. Edited by Colin R. Townsend and Peter Calow. Pp.393. Hbk ISBN 0-632-00555-6; pbk ISBN 0-632-00617-X. (Blackwell Scientific/Sinauer: 1981.) Hbk £21, $38; pbk £11.80, $23.60.

I WAS once told by a fellow graduate student, trained in herpetology, that physiological ecology was the science of shoving thermometers up lizards'cloacas. A quick check in the subject index of this volume revealed that, given the veracity of my colleague's assertion, things have come a long way in the past 15 years.

The book, comprising a collection of original articles and intended as a text for undergraduate courses, is mainly about how plants and animals get their daily calories and what they then do with them. The unifying theme linking such diverse topics as photosynthesis, digestion, cellular repair and social behaviour is that all aspects of earning and spending calories can be treated from a functional viewpoint as optimization problems. Different chapters illustrate different degrees of progress in applying this approach. In some areas, for example leaf design and foraging behaviour, the first generation of explicit models has been formulated and tested fairly thoroughly, while in others such as defence mechanisms and social behaviour the questions have, in the main, been formulated only qualitatively.

The articles also vary in the extent to which they present totally new ideas. R.M. Sibly, in one of the more original chapters, provides a fresh and stimulating approach to digestive strategies. He starts with a version of the marginal value theorem to predict optimal retention times for food in the gut, and leads via a discussion of gut morphology to consider why food empties from the stomach at an exponentially decreasing rate from the time of the last meal (no simple answer to this question emerges, but the relevant data and hypotheses are neatly brought together). The highlight of the book in terms of entertainment value is D.H. Janzen's fireside chat about defences against predators and parasites. Among the aphorisms that abound in this chapter is the answer to "Why should some species of seed be so well defended when the plant makes so many?" — ". . . for the same reason that a young man protested at being sent to Vietnam". At the same time, I should add that Janzen does not, to my mind, succeed in pushing the study of plant and animal defences from a series of intriguing evolutionary stories to forming a coherent theory. He appeals for a change in attitude from "descriptions of yet another alkaloid [to measuring] fitness gains and costs that the organism accrues with and without its defences" without stating explicitly how these hard-won measurements will be used to make a general theory of defences.

Some contributors — for example Pianka on resource acquisition and allocation among animals, and Gosling and Petrie on the economics of social organization — try to cover too wide a field, and in so doing do not analyse any single problem beyond introductory textbook level, while others — Kirkwood on repair and its evolution, for example — deal in detail with a more restricted range of topics. Overall, however, the book is a worthy collection of reviews which covers a range of subjects that are not normally assembled in one volume. □

The principles of vision enumerated

Oliver Braddick

A Taxonomy of Visual Processes. By William R. Uttal. Pp.1,097. ISBN 0-89859-075-2. (Lawrence Erlbaum: 1981.) $100, £50.

THE stated aim of Uttal's book is to "... systematize the data base of perceptual psychology into a comprehensive intellectual scheme ...". When the route to this goal runs through 1,100 pages and over 3,000 references, it must involve to a fair degree the exposition of the "data base" itself, and there is here a generous view of its extent, including the discovery of alpha particles, how a cathode ray tube works, the embryology of frog rods and the theory of rainbows. More conventionally, the field of vision is covered from photometry to geometrical illusions. It would not be reasonable to expect a single author to compete in authority over this range with the several multi-author handbooks of similar scope that have appeared in recent years, and Uttal does not do so.

The author shows a propensity for organizing his data base in lists, which rather blunt the reader's appreciation of what might be the relative significance of the information. This culminates in the closing pages in a list of 67 "general principles" from which we may sample No.4:

> For millennia, philosophers, scientists, and laymen alike have felt a deep-seated urge to explain the phenomena of perception. . . . No perceptual theory, however, has ever withstood the test of time . . .

and No.59: "The magnitude of many illusions depends on the orientation of the pattern . . .". Several of the lists contain direct contradictions that remain unresolved and without comment by Uttal. The general air is one of abstracting rather than digesting the scientific literature; opportunities for integration are conspicuously missed, for example the use of the temporal modulation transfer function to express data on the visual response to a variety of time-varying stimuli.

But it would be unfair to dwell on Uttal's presentation of the data base, rather than his intention of providing a framework for systematizing it, the "taxonomy" of the title. This taxonomy is one of sequential levels of processing, from Level 0 in the optics of the environment and the eye, to Level 5 which consists of active, attentive manipulations of perceived information which are reserved for another projected book. Most visual scientists use some such idea of levels, albeit informally, as a way of compartmentalizing problems. This is not to say that it is the best principle for the organized presentation of our knowledge of visual perception, and several disadvantages become apparent in Uttal's attempt to do so. One is that there are many phenomena about which we know a good deal, and which are clearly important, but which we cannot partition among levels with any certainty. Ironically, Uttal's own experimental work largely falls into this category, and into a chapter on temporal interactions which he has to present as a frank digression, unassignable to any of his levels on present understanding. In other cases, the organization of the book by levels makes it difficult to evaluate alternative explanations critically. For example, the issue of lateral inhibition versus more global processes in brightness contrast is raised, with vigorous assertions of the importance of the latter, but the plan of the book does not allow them to confront each other. Another consequence is an absence of any functional perspective. The purposes for which vision is used cut right across these levels, so they get little attention here.

A reason for the taxonomic approach becomes apparent in a chapter entitled "Mezzolog: On the Limits of Neuroreductionism". Uttal is concerned that much current theorizing, providing speculative neural bases for perceptual phenomena, is premature. Once again, this view is expressed centrally as a list: "Questionable Dogmas", Nos 1–18. Some of the dogmas are general suppositions about the relation between brain activity and perception, and indeed some of these are quite widely believed, at least implicitly. Others (for example No. 15: "Metacontrast results from peripheral lateral inhibitory interactions that diminish the strength of the conducted neural signals") may be specific instances of neuroreductionism, but are not necessarily widely accepted even by those committed to neural reductionist explanations of the phenomenon concerned. Dogmas of these two kinds need rather different kinds of critique, but it is not clear that the difference is appreciated.

The role of the taxonomy is to draw a sharp line between Levels 1–2, where Uttal offers accounts in terms of interaction of neural signals, and Level 3–4 where the processes are "interpretive", the neural representations involved are not at all understood, and theories are psychological or purely formal.

Uttal's charge of premature reductionism is just in many cases. However the structure and style of his book do not favour a critical marshalling of the arguments on the neural basis of specific visual phenomena. Indeed, given the scale of the book, any particular issue is pursued in surprisingly little depth. The temptation of encyclopaedic breadth seems to have deflected the author's purpose of exploring the limits of current neural explanation, which is a pity, for that purpose is a very worthwhile one.

Uttal recounts in his preface that when he "chose to become an explicit generalist rather than a totally dedicated ... laboratory scientist" the reaction of some of his colleagues was such that "some of the experiences encountered were non-supportive to say the least". He defends his role as one of "analysis, criticism, integration and synthesis". I fear that generalism has caused these activities to be diluted and dispersed to a rather unsatisfying degree. □

The art of M.C. Escher: this picture, Möbius Strip II (Red Ants), is reproduced from *Escher*, edited by J.L. Locher and recently published by Thames & Hudson, London, and Abrams, New York. The book, containing both a copiously illustrated catalogue of Escher's graphic work and a biography, costs £35, $65.

Inner machinery of the silicon chip

Andrew Holmes-Siedle

Instabilities in MOS Devices. By J.R. Davis. Pp.190. ISBN 0-677-05590-9. (Gordon & Breach: 1982.) $24.50.

MOST silicon integrated circuits are smaller in size than a fingernail and contain many thousands of working elements, the most common of which is the metal-oxide-semiconductor (MOS) transistor. In this, all of the important electronic activity takes place in a minute volume, a layered structure composed of crystalline silicon, thermally-grown silicon dioxide and a conductor. Attempts are always being made to reduce the unit size of the transistor element, but during such development it is crucial to maintain the performance of the intimately interwoven materials of the layered structure. *Instabilities in MOS Devices* is a discussion of the physical processes occurring in this metal-oxide-silicon system.

In MOS structures under electrical fields, electrons, holes and ions sometimes migrate. This movement produces the instabilities in electrical properties referred to in the title. In their constant endeavour to ensure that instability effects do not wreck new designs, physicists regard the silicon dioxide layer as the key element; it is a complex film but, in this work, can often be regarded as a simple, wide-band-gap insulator region, sandwiched between the "electron sea" of a metallic electrode and the "bendable" energy bands of the semiconductor. In this context, the instabilities are interpreted either as the unwanted carrying of holes and electrons across the two high, interfacial potential-energy barriers by tunnelling or carrier excitation; or the internal drift of various ionic species, often sodium or hydrogen. The transport medium can often be regarded as very pure fused silica, which allows us to use the large fund of knowledge of the physics of crystalline and fused quartz — makers of science policy might note that this is a good example of the benefits imparted to technology by apparently unrelated basic research.

The understanding of charge movement in silica may seem to be a somewhat esoteric field; but, for obvious reasons, it is increasingly important to convey this knowledge to electronics undergraduates and to the growing numbers of workers entering the broader field of the development of "electronic systems on a chip". This book fills such a need. It is, for example, the first time I have seen a large and carefully selected set of references on instability research.

Such research is carried out using a limited number of specialized electrical and optical techniques. These are outlined in 30 concise pages. The theoretical principles required include those of defect solid state physics, surface physics, lattice dynamics, conduction physics and molecular quantum mechanics, and treatment of these concepts is woven into the subsequent chapters. Among the research findings discussed are recent developments in surface states, mobile ions, polarization, hole trapping, electron trapping and electrical breakdown.

For many of the intended audience the book will be tough going. Readers are provided with reference to a few of the best, general solid-state technology textbooks, but the style of writing is somewhat flat and the graphics are unimaginative, coming, in the main, directly from research papers or other textbooks. Nonetheless, the author does address all of the important conduction and trapping effects which determine whether or not a given MOS device will be "good".

The exploitation of conduction and trapping effects in the MOS system is only just beginning, and the practical aspects of instability research reinforce the usefulness of a review such as that provided by Dr Davis. The use of new and more subtle effects in MOS devices not only ensures "good" (i.e. stable) devices, but also leads to ones which are "better" than those of rival makers. In this context, it must not be forgotten that microelectronic devices are used not only in parlour games but also in machine tools, racing cars and missiles. The country which possesses the fastest and best microcircuits will perhaps win not only commercial success but also more explicitly gladiatorial contests. □

Andrew Holmes-Siedle is Consultant to the Physics Department of the Fulmer Research Institute, Stoke Poges, Buckinghamshire.

● Another recent textbook on MOS devices is Oliver McCarthy's *MOS Device and Circuit Design.* The book, primarily aimed at students of electronic engineering, but also intended for practising engineers, is published by Wiley at £19.50, $44.95.

Statistical expertise on the shelf

P.T. Saunders

Biometry: The Principles and Practice of Statistics in Biological Research, 2nd Edn. By Robert R. Sokal and James F. Rohlf. Pp.859 plus tables. ISBN 0-7167-1254-7. (W.H. Freeman: 1981.) £19.50, $31.95. Tables hbk £16.30, $22; pbk £6.95, $9.95.

FOR some years now, Sokal and Rohlf's *Biometry* has enjoyed considerable success as a statistics text for biologists. Knowing this, my first impressions of the second edition were less favourable than I had expected. While the opening chapters are written in an attractive enough style and deal with the right sort of material, I found them too long and diffuse. The authors seem so intent on ensuring that every aspect of the subject is covered that they leave the reader in danger of not seeing the wood for the trees. To give just one example, the crucial idea of the testing of hypotheses seems to get lost in a long section devoted mainly to Type I and Type II errors and power functions. It is not that the latter are not worth discussing, though they are relatively less important in a text in which derivations are omitted, but that the balance is wrong.

But while I have some reservations about the introductory material, the remainder of the book, which consists of detailed accounts of a large number of statistical techniques applicable to a wide variety of problems, is very good indeed. The authors make excellent use of boxes, set aside from the main text, in which they show precisely how each test is to be carried out. They provide sample calculations for the benefit of those readers who are uncomfortable with subscripts and summation signs; more mathematically minded users will find them invaluable for testing computer programs. There are also informal discussions of the ideas behind the tests and other relevant points.

A number of improvements have been incorporated into the new edition and some additional material has been included, mainly concerned with correlation and regression. Inevitably the coverage is still not complete; for example, the authors have judged that their intended readership will be able to manage without such topics as sequential testing and Bayesian techniques. They have also chosen to publish the statistical tables separately instead of binding them with the book, which has its advantages so long as you can keep the two together.

Biometry would not be my first choice for someone with no previous knowledge of statistics, though it is certainly well worth considering. I would, however, strongly recommend it for anyone who already knows a bit about the subject and now finds himself in need of something beyond what he was taught. It is not quite as good as having a friendly statistician across the hall, but it can come surprisingly close. □

10 June 1982

Colleges back from the dead

United States universities and colleges are celebrating their commencement days with relief. The prospects for the next academic year seemed even worse a few months ago. But they are still grim.

In *Tom Sawyer* the hero attends his own funeral, only later to reveal to everyone that he wasn't dead after all This spring US colleges and universities are in a situation very much like Tom's For most of the year, the death of American higher education has been lamented by the higher education lobby in Washington, fighting the cuts in student loan finance proposed in President Reagan's budget Now, however, it looks as though Congress has heard the cries of middle-class parents throughout the country, and will rescue the education monies so that the young people who need government loans to pay tuition bills can go on attending college in the fall So higher education is alive, after all

But to be alive is not to be well A major debate has been going on in the US education community about the changing shape of US higher education including, literally, the ability of some kinds of schools to survive the next decade The month of June, when most schools' terms end, when final revenue figures are known and re-enrolment data are available, is a good time to take stock Moreover the blistering fight over government student loans, which has preoccupied university spokesmen, the Administration and the Congress for months, is now winding down The smoke is clearing And everyone agrees that US colleges and universities are under unprecedented stress

The most obvious source of stress is the declining number of 18-year-olds in the US population projected from the early 1980s onwards As a study by Princeton's president William Bowen said a few years ago, this could presage a general shrinkage in the size of the US university system Applications figures for enrolment in the fall of 1982 are down a mite (0 9 per cent), but educationists attribute this decline to other factors, such as rising tuition fees, high interest rates on private loans and the uncertainty of government loans The population factor will show up, they say, next year, when the number of applicants for the fall of 1983 drop off Eventually, the drop will mean that schools will have to compete harder to get students (or lower their standards) To anticipate this prospect Bowen recommended that the universities should plan to shrink

A second source of stress is the financial crisis in state governments, due to the taxpayers' revolt that spread to many states after it began some years back in California, and the loss of revenue from traditional federal programmes under the Reagan Administration Some states, such as Michigan, Missouri and Minnesota, simply cannot meet expenses any longer, are running enormous deficits and so are cutting back funds to their state universities State university financing has become an annual roller-coaster that would give ulcers to the average modestly comfortable professor in Cambridge, for example Some state systems have grown, over the years, into large, comprehensive undergraduate and graduate programmes, of high quality and easy access through nominal tuition fees They fulfill the best ideals of American education But some states have laws requiring that the budget be balanced every year So, for most of the year, university administrators do not know how much money will be given by the legislature for the next year, or whether the university will be the target of some last-minute cut

The easiest response is to conserve fuel, cut down on office staffs and maintenance, defer new building or expensive new computers or other instrumentation, to shave the number of faculty evenly across the board — and to avoid fights But that does not maintain quality To maintain quality a school must cut out the fat (weak departments) or do away with tenure — both of which can lead to embittered fights on campus and also lawsuits Another course is to raise tuition fees at state schools above the traditional nominal level (freshmen at the University of Southern California next autumn will have to pay $7,000, for example) But while this raises revenue, it discourages applicants and contradicts the very idea that state schools are meant to embody high quality education for everyone None of these remedies is pleasant, let alone conducive to an unperturbed environment for study

Not all state schools are in this same plight Some, such as Pennsylvania State University, are doing well But these are schools with strong ties with local industry and a well-understood tradition of service to the state and the community Applications for next autumn for Pennsylvania State University, for example, are up 10 per cent Industry finance is already a school tradition, so that door is open And so long as the cost of private and other state school tuition keeps rising, prospective students shopping for the best deal will come

The stresses on private schools are variations on those afflicting the state schools They cost more, so applications for next fall are down at most of them, according to a survey by John Minter Associates for the *Chronicle of Higher Education* The swing of the marketplace is clearest in the west and south-west, where 67 per cent of private schools report decreases in applications while 71 per cent of the public schools report increases Hardest hit of the private schools are the mid-ranked colleges, particularly liberal arts colleges, which cannot advertise quickly usable skills to the career-minded young and which must charge substantial tuition fees The choice facing these schools is either to lower admissions standards or "planned shrinkage"

Meanwhile, the rich get richer The top private schools are doing well, although they face several shifts in student choices and faculty availability The top schools often have large and important research laboratories supported by industry and the government, or major graduate schools or medical schools that are sources of overhead to help carry along departments, such as the liberal arts, that do not generally have outside income Part of the new, conservative public mood in the United States, as Chester E Finn Jr has written, is a concern with educational quality And, when parents, students, alumni and industry are all preoccupied with quality, they will tend to gravitate to institutions of proven quality Thus, Harvard's tuition fees have never been higher (next fall they will be $8,195) and its fund-raising has never been more successful

What does all this mean for science? It means that the trends in academic science identified in 1977 by Bruce Smith and William Karlesky* are probably going to be even more pronounced Smith and Karlesky surveyed many different kinds of US colleges and universities — four-year community colleges, state schools and top rank research institutions They identified about four principal trends, which would combine, they said, to squeeze out the "middle" of US academic research in the future At the lower level, the vocational schools would prosper (as, indeed, they have) because when people are unemployed, they go to school to get

*Smith, B & Karlesky, W *The State of Academic Science* (Change Magazine Press, Washington D C , 1977)

0028-0836/82/230443-02$01 00

skills But as funds become tight, mid-ranked schools which can compete less well for federal funds, industry gifts and students will become less and less able to carry out a research as well as a teaching role Their research programmes will diminish Meanwhile, the top-ranked schools, while facing critical problems such as a decline in places for young faculty, will ride out the storm Like Tom Sawyer, they will live on

New ways with weapons

Bilateral negotiations on strategic arms are to begin later in the month. Where will they lead?

The passage of time has curious healing qualities Two years ago, Mr Ronald Reagan, campaigning successfully for the presidency of the United States, was outspoken in his condemnation of President Jimmy Carter's second instalment of the treaty that emerged from the Strategic Arms Limitations Talks (Salt II), originally devised by Dr Henry Kissinger for once-President Richard M Nixon Reagan was pushing at an open door, for his political opponent knew that the US Senate would not ratify the treaty he had signed, indeed, the Soviet occupation of Afghanistan gave him a handy excuse to withdraw his request for ratification without too much loss of face The Senate's objections to Salt II were largely technical — verification, the equity of the equation of one long-range missile with another and, perhaps more important, the knowledge that nobody from the Carter White House had faced the problem of persuading the Pentagon that the rules of the strategic arms race should be changed Candidate Reagan could afford to be more radical and rhetorical how is it possible to trust in an agreement with people whom we do not trust? President Reagan has nevertheless found that his administration has kept within the unratified rules of Salt II, if only because it has been hard to know what should be done about the disposition of the MX missiles, the long-range missiles destined to replace the Minuteman In the Soviet Union, likewise, the same rules have adventitiously been kept And now, the emollient passage of time has persuaded President Reagan that he must follow his predecessor's path and propose bilateral talks with the Soviet Union on strategic arms (see *Nature* 20 May, p 169) The surprise is that the Soviet Union has so quickly agreed the talks are due to begin in Geneva on 27 June

A modicum of muck-raking is in order even in these hopeful circumstances The Reagan Administration's original indifference to strategic arms talks appears to have been largely ideological — sup with the devil only with a long spoon, negotiate on strategic arms only from strength This position has been undermined by predictable (and predicted) forces — political pressure from allied governments, political pressure from domestic voters, fears that another review conference of the Non-Proliferation Treaty (in 1985) as arid as that of 1980 might drive some middle-sized powers into the nuclear club, the sheer cost but also the technical difficulty of developing the new generation of strategic arms and the recognition that the world, with the Falklands and the Middle East, is a dangerous place

So what should the Reagan Administration be aiming for? Its opening bid is simple enough — let each side be constrained within a limit of 5,000 strategic warheads with the proviso that no more than half of these should be based on land The proposal is rational enough — submarine missiles are for the time being relatively invulnerable to attack, while ground-based missiles are potentially vulnerable to a first strike by the other side and are thus destabilizing The Soviet Union's predictable but far from final objection is that the proposal would more immediately affect the Soviet Union than the United States The success of the Geneva enterprise will crucially depend on the willingness of the two sides to acknowledge that 5,000 nuclear warheads, each of them at least ten times larger than the bombs dropped on Hiroshima and Nagasaki, are outrageously too many for the now classical purposes of deterrence Indeed, these huge numbers can be explained only if each superpower is prepared to attack the other's ground-based missiles in a supposedly pre-emptive first strike, in the process presumably inviting an attack on its cities by the other's submarine missiles Are the two superpowers prepared to return to the simple view that nuclear weapons are intended simply as deterrents?

Other difficulties will arise before that question is faced How, for example, will the new strategic arms talks be linked with the talks on "theatre nuclear weapons" already under way in Geneva? That the two negotiations should be linked is sensible, while the United States proposal that its FB111 bombers based in Europe should be counted within the separate limit for strategic aircraft is an important concession But where will the British and even French nuclear forces fit in? And would the attainment of President Reagan's "zero option" for European "theatre weapons" be the equivalent of the nuclear-free zone for which the Palme commission was pressing last week (see page 446)?

These questions are so difficult that there can be no quick end to the proceedings in Geneva The best hope is that there will be some quick agreement on a warhead ceiling below which further reductions will be sought During that second stage of the negotiations, the Soviet Union will be faced with the theoretically sensible but politically sensitive proposal by the United States that limits on strategic weapons should be determined not by counting missiles or even warheads but by their throw-weight of carrying capacity The obvious snag is that this criterion would more severely penalize the Soviet Union (with its large rockets) than the United States, while everybody would know that the effective power of a warhead is at least partly a function of its accuracy, quantifiable but hardly verifiable This is why the most important potential benefit of the Geneva process is that it may change the way the superpowers think — and that it might in particular persuade people like Mr Alexander Haig, the US Secretary of State, to avoid statements like that the other day in which he said that no strategic arms agreement would be acceptable if it made conventional wars more likely Is that a sensible criterion? Nobody thinks conventional wars desirable in themselves, but an effective agreement on strategic nuclear weapons must surely be one that will allow conventional warfare to break out without the immediate risk of nuclear conflict

Waiting for Merrison

British university research is threatened by attrition and neglect. The Merrison report will not help.

After more than two years of brooding, Sir Alec Merrison's committee on the condition of British university research seems to have confirmed people's worst fears but to have failed to show how they may be exorcised Its report just published (see facing page) is a masterpiece of judiciousness The dual support system whose collapse in the past decade was the chief reason for the committee's existence is said to be in all ways admirable, and therefore is to be preserved at all costs Indeed, to judge from what the committee says, there is only one defect in this excellent and peculiarly British device for sharing the cost of university research between one public purse (the University Grants Committee) and another (the research councils) the system appears not to function as intended In much the same spirit might a man sent to rescue a motor-car fallen in a river report that the car was in excellent condition but that it had sunk

Nobody, or hardly anybody, is to blame for this debacle The committee had the bad luck to have been established before the full severity of the British government's intentions towards its universities had become apparent And the committee's terms of reference (behind which it shelters) were in truth too narrow It was allowable to observe (as the committee does) that universities' internal arrangements for deciding priorities in their discharge of responsibility for research and scholarship are inadequate, but outside its brief to enquire why things have come to such a pass The more serious difficulty, however, is that British universities are in such a mess, one so arbitrarily brought about, that the safeguarding of research also requires arbitrariness on somebody's part Only the research councils are at present capable of being as selective as circumstances require

Nuclear waste bill now in sight

But critics fear stop-gap stores will last

Washington

Congress is now closer than ever to passing a nuclear waste management bill, but its terms seem likely to be much more appealing to the atomic industry than to environmental groups, both of which, in a strange alliance, have for years been calling for a legislative solution to the growing mass of spent commercial fuel.

The Senate has already passed a bill that the industry is satisfied will end the uncertainty plaguing the government's waste disposal programme. In the absence of legislative directions, each administration has been free to set its own policy, usually inconsistent with that of the previous administration.

The environmental lobby, on the other hand, is worried that the Senate bill and its counterparts now under consideration in the House gloss over the serious technical problems of waste management in favour of political expediency.

At present, 8,000 tonnes of spent commercial fuel is in temporary storage at reactor sites. By the end of the century, the figure is expected to reach 72,000 tonnes. The ultimate solution, everyone seems to agree, is to dispose of it in deep geological repositories. This solution is provided for in all versions of the bill.

The bone of contention, however, has become whether the federal government should in addition provide some form of interim storage. According to the Atomic Industrial Forum, which represents the nuclear power industry, roughly half a dozen reactors will run out of on-site storage space by 1985, the problem will be widespread by the 1990s. The industry is thus very pleased that the Senate bill provides for stop-gap storage to cover any delays in a permanent repository.

The environmental groups see something more sinister going on. The interim storage envisaged in the Senate bill will be of two kinds. The first is "away-from-reactor" (AFR) storage, which is essentially the arrangement used at reactor sites: spent fuel elements are simply stacked in a water-filled "swimming pool" which absorbs the radiation and heat. The environmental groups charge that AFR is a way for the industry to avoid the licensing procedure required to expand on-site storage. The second kind of facility is "monitored retrievable storage" (MRS), which is only vaguely defined. The chief worry among the environmental groups is that MRS will become the *de facto* permanent solution.

Brooks Yeager of the Sierra Club says that the Senate bill virtually guarantees that. It sets "not just ambitious, but unmeetable deadlines" for the construction of a geological repository. "They want to arrive at the issuance of a construction permit by the end of the decade. That's seven years faster than the Department of Energy's plans for construction in order to resolve all the technical problems." The timetable may also guarantee that the choice of sites will be limited to the three at which the Department of Energy has already begun tests — the Hanford Reservation in Washington state, the Nevada test site and a group of sites along the Gulf of Mexico.

Professor Henry Kendall of the Massachusetts Institute of Technology, who is active in the Union of Concerned Scientists, a group critical of US nuclear policy, agrees that building an MRS facility "basically means you don't have confidence in permanent disposal". He says that what is needed is time to make a careful hydrological study of the actual site.

These worries seem to be backed up by a recent study by the Congress's Office of Technology Assessment (OTA). The

British research — no cure yet

British university research is in trouble, but only the universities themselves can work their way out of it. This is the chief conclusion of the much delayed report of the committee under Sir Alec Merrison, vice-chancellor of the University of Bristol, set up two and a half years ago to brood about financial support for university research and published this week (Cmnd 8567, HMSO, £4.35).

The report comes down squarely in favour of the British dual-support system, whereby the University Grants Committee (UGC) provides universities with the basic wherewithal for research and the research councils provide extra funds (but no overhead) for particular projects. But the committee also says that "the system has been under strains for several years".

One of the committee's chief proposals is that universities should more deliberately channel part of the funds they receive from the UGC into areas of research in which they consider themselves to be strong, for which purpose it says that British universities should set up research committees to supervise the internal allocation of funds. But the committee also says that as a stop-gap, the research councils should be prepared to "meet costs they would not normally meet" (a euphemism for paying overhead) or think of moving people doing good work in unfavourable circumstances to other places.

The essence of the committee's support for the continuation of the dual-support system is its repeated reaffirmation of the belief that if universities were not provided with funds that can be spent on their own discretion on research projects that would not normally win research council support, genuinely innovative ideas would never see the light of day. It considers but rejects on the same grounds that UGC support for research should be linked directly with the volume of financial support provided by the research councils, while it considers that if UGC were to earmark any but a small proportion of its university support for specific projects, the resulting rigidity would be self-defeating.

The chief targets for the committee's advice are the universities, which are told that in the long run — "the prospects for achieving any significant shift in the near future are next to impossible" — they must be prepared to spend more of their resources on research rather than teaching, that they should "concentrate research funds into selected areas", look at the problems occasioned by academic tenure, find ways (with the help of the research councils) of bringing in "new blood" and be prepared to form associations with other universities for more effective prosecution of research. Both partners in the dual-support system are asked to be more sensitive to researchers' need to travel.

The research councils are given two principal tasks — to adjust the support provided for graduate students more regularly in tune with the increasing cost of living and to "study" the balance between their support of research in universities and in their own establishments. In a memorable sentence, the report says that "we are not satisfied that the balance of research council expenditure between such support and the work of their own institutes is in all cases right".

The committee's belief that university research is in trouble is based on statistical evidence that the committee says should be improved. The data do, however, show that the decline in research support from universities' own budgets goes back to the early 1970s, and that between the beginning and the end of that decade the average sum of money available to university departments per head of academic staff employed declined by 28 per cent in real terms.

These and supporting figures appear to have prompted the only note of near-acerbity in the committee's report — that while the British Prime Minister has repeatedly stated that the science budget has been protected, "the health of university scientific research does not depend only on the science vote". ●

0028-0836/82/230445-02$01.00

report* urges that waste be kept at reactor sites until a permanent repository is built to "avoid diverting the attention and efforts of the waste management agency away from the repository program toward provision of an independent interim storage facility"

Another sore point for environmental groups in the Senate bill is an amendment that Senator James McClure succeeded in attaching, which declares that the legislation itself represents reasonable assurance that a safe disposal method exists Yeager says "It's a clear attempt to end-run several court cases and state laws" California, Oregon and several other states have passed laws restricting new power plants until such reasonable assurance exists

To the industry, however, the amendment is nothing more than recognition of what they see as the obvious the waste disposal problem is political, not technical And here, the Office of Technology Assessment report backs the industry view It found "no insurmountable technical obstacles" to development of geological repositories, rather, the chief obstacle is eroded public confidence, aggravated by a vacillating federal policy President Carter, for example, reversed the previous policy of handling defence and commercial wastes separately, President Reagan reversed the Carter policy Presidents Reagan, Carter and Ford each changed the number of sites under study for geological repositories and their construction schedules

If a bill does emerge from Congress this year, it will almost certainly contain provisions to end this instability Both Senate and House versions provide for long-term funding through a surcharge on nuclear electricity, which could raise $300 million in the first year

Both Senate and House versions also set up mechanisms for state participation in the site-selection process The federal government's insensitivity to the concern of the states in previous siting decisions is viewed as a major factor in the loss of public confidence in the programme

The chances that Congress will act this year are, according to all parties involved, better than they have been in past years In 1980, both the Senate and the House passed bills, but failed to work out a compromise This time, they start closer

According to a staff member of Morris Udall on the House Interior Committee (Udall introduced the House bill), "there's no reason we can't get a bill except time" The prediction is that if the bill reaches the full House by mid-July, it should pass

But passage may ultimately hinge on the complex politics of the House committees No fewer than three have asserted jurisdiction over the measure, which is now tied up in the Energy and Commerce Committee **Stephen Budiansky**

Managing Commercial High-Level Radioactive Waste (Office of Technology Assessment, May 1982)

International disarmament

Palme's palm

A nuclear-weapons-free zone in Europe and greater United Nations (UN) power to prevent hostilities in developing countries are the chief recommendations of the Independent Commission on Disarmament and Security Issues whose report, *Common Security a programme for survival,* was published last week Although neither recommendation is new, Dr David Owen MP, former British Foreign Secretary, and Sir Shridath Ramphal, Secretary-General of the Commonwealth Secretariat, who presented the report in London, argued that their revival now is timely

So, partly by design and partly by accident, was the publication of the report The original intention was to produce recommendations for the UN Special Session on Disarmament which began this week But the commission now also hopes that its document will inform the Strategic Arms Reduction Talks (START) due to begin in Geneva on 27 June Dr Owen is optimistic that the South Atlantic conflict will focus attention on the recommendation for a UN fact-finding mission which could be called in by a country fearing imminent aggression by a neighbour

The report comes after more than a year's deliberation by 17 distinguished politicians from as many countries under the chairmanship of Olof Palme, former prime minister of Sweden The task of the commissioners, each of whom was chosen for their understanding of international affairs and not as a national representative, was to prepare a report on the consequences of the arms race along the lines of the Brandt report on economics

The result is an analysis of global conflict and tension which embraces the effects of nuclear arms build up on North–South as well as East–West relations and the effects of the increasing sophistication and strength of conventional forces on relations between developing countries The commission believes that the risk of a devastating war is increasing in spite of attempts at arms limitation It says that national security can no longer be assured by military means

The idea of a limited nuclear war and the conventional strategies of the NATO and Warsaw alliances on the early use of strategic nuclear weapons are challenged The commission's answer is to create a nuclear-weapons-free zone in Europe by negotiating parity in conventional forces at reduced levels

Over the past eight years, the report says, developing nations have been drawn into the arms race, while vertical proliferation in the five recognized nuclear powers has increased the probability of horizontal proliferation Industrial nations have also made matters worse by selling sophisticated conventional arms to developing countries, making the escalation of local disputes more likely The commission is particularly critical of the high level of military spending by nations that can least afford it Security for developing nations, particularly those with small populations whose borders are in dispute, must be assured by other means — hence the recommendation to revitalize the original intention of the UN charter by increasing the powers of the Security Council to pre-empt conflicts

The commission's "programme of action" is divided into short and medium-term measures, for implementation within two and five years respectively The programme includes measures to reduce nuclear and conventional forces in the NATO and Warsaw alliances, a nuclear-weapons-free zone, a comprehensive chemical weapons disarmament treaty, agreement on guidelines for conventional arms transfer, a substantial reduction in military spending and the transfer of military scientists to civilian research

Little advice is offered on how to achieve these measures But the commission is clearly hoping that the chief impact of its report will be to focus increasing public concern **Judy Redfearn**

Italian science policy

New consensus

Venice

Italian science policy appears at last to be getting into gear, despite the almost annual changes of government that confound most long-term planning in this country The reason? Politicians here have reached a consensus close to the French position that research is necessary to pull Italy out of its economic crisis

This consensus is beginning to survive the rise and fall of governments, so the present science minister, lawyer Giancarlo Tesini, who has been in post for a year now in President Giovanni Spadolini's shaky five-party coalition, has been able to take some action

One of his key moves has been to achieve five-party agreement on a reform of the Italian national research council (CNR) which until recently has dominated Italian government research and development both inside and outside universities "CNR is a major problem of the Italian science ministry", Tesini said here last week, where he is attending a scientific meeting

Broadly, Tesini wants to shift CNR, with most of its laboratories in universities, into a closer relationship with industry The reform would put industrial scientists into key CNR positions and streamline an organization which is widely regarded as being massively bureaucratic — so bureaucratic, in fact, that in 1980 it failed to spend an important part of its budget concerning the Italian space programme For its pains, the result in 1981 was a budget cut of 10 per cent in current lira (much more in real terms) to the present figure of

0028-0836/82/230446-02$01 00

around 420,000 million lira (£180 million)

Under the previous government, CNR also lost control of university research (that is, research in universities outside CNR laboratories), which is now in the hands of the national council of universities (CUN), where the same professional groups take similar decisions but outside the CNR bureaucratic structure

Tesini's reforms, now before parliament, would revitalize the crumbling structure of CNR Already CNR is spending an increasing part of its budget on applied projects, the latest list of seven amounting to 300,000 million lira over five years (Two examples of these projects are an effort to increase Italian agricultural productivity, particularly in the south, since Italy is a nett food importer, and a recently completed project to develop an electronically-controlled fuel-efficient engine in collaboration with Alfa Romeo)

But Tesini does not want to make CNR entirely into an organ of industrial research "It would be dangerous to create a gulf between university work and CNR" he says

Now the future of CNR is in the hands of parliament, but in the nature of Italian politics it may be two weeks or a year before the vote is taken on the Tesini reforms, by which time his government may well be out of office and a new minister in place to take the credit **Robert Walgate**

Private help

Washington

In a move that will help fill the void left by the Reagan Administration's cutbacks in environmental research, a private group — the MacArthur Foundation — has stepped in to offer $15 million for a new research organization The Institute for World Environment and Resources will concentrate on issues in global ecology such as species loss, inadvertent climate modification, desertification, deforestation and population

A key government agency that had been following long-term global issues, the Council on Environment Quality (CEQ) was cut back to a bare-bones staff as soon as President Reagan took office The director of the new institute, James G ("Gus") Speth, was chairman of CEQ under President Carter

The institute, which expects to begin operations by October, will however attempt a broader and more scientific approach than CEQ has taken It seeks to bring together scientists from the physical, biological and social sciences to work on interdisciplinary problems of significance to public policy

Although the institute will be based in Washington, roughly one-quarter of its $4 million annual budget is expected to go to established research contracts with university centres of expertise in the environment and resource fields

Stephen Budiansky

Humid tropics

Cautious growth

Washington

In a report released last Thursday, the National Academy of Sciences has recommended cautious but expanded development in the humid tropics The study, commissioned by the US Agency for International Development*, found that concern over the environmental consequences of tropical deforestation is legitimate, but often overstated, and moreover that development is inevitable Ninety per cent of the world's population increase from now to the end of the century will take place in the tropical countries — an addition of 1,500 million people

One of the main messages of the report is that despite the inherent difficulties in managing tropical areas — and the study recites them all, including annual rainfall of 5–35 feet, tremendous species diversity, and poorly understood ecology — new technologies are appearing that can get around these problems

According to Dr Pedro Sanchez of North Carolina State University, a member of the panel that prepared the report, some myths about tropical soils need to be dispelled He points out that "there's nothing fundamentally different in the agronomy between the humid tropics and the southeastern United States Contrary to myth", he adds "tropical soils though often infertile and acid are not fragile They are not especially low in organic matter nor especially prone to erosion A lot of the erosion pictures in the popular press are 'civil engineering erosion' pictures taken around roads and drainage systems"

Sustained agriculture on cleared land does, however, require careful management and new technology, in particular continuing application of fertilizer Sustainable agriculture, as opposed to traditional shifting cultivation, is considered the key to attaining the greatest benefit with the least deforestation and thus the least environmental disruption

Still, much may be possible through the fine-tuning of indigenous technologies For example, the traditional slash-and-burn method of clearing turns out to be much easier on topsoil than are bulldozers, and furthermore provides free fertilizer in the form of nutrient-rich ash

Dr H Garrison Wilkes of the University of Massachusetts, Boston, another panel member, points out that too little has been done to exploit and improve on tropical germ plasm resources "The amount we know about cowpeas," he says, "or other tropical crops such as casaba, palms, tropical cabbages is very small — so the potential for genetic improvement is tremendous " **Stephen Budiansky**

**Ecological Aspects of Development in the Humid Tropics* (National Academy Press, Washington DC, 1982)

Soviet agriculture

Food for all?

The Soviet Union's new food production programme designed to make Soviet food production match demand was announced last month at a plenary meeting of the Central Committee and introduced in a major speech by first Secretary Leonid Brezhnev himself

To avoid emergency purchases from the non-Socialist world while this drift from agricultural to industrial employment continues will demand a major investment in agricultural research Several lines of investigation are specifically mentioned in the programme, but their implementation is formally entrusted to the leading Soviet scientific bodies — the Academy of Sciences, the Lenin Academy of Agricultural Sciences and the State Committee for Science and Technology

According to the programme, however, the practical work is to be the responsibility, primarily, of the network of "scientific production associations" set up in the past few years to link research and development organizations with production enterprises These associations are to form the basis for the production of high quality and hybrid seeds and plants of "superior reproductive quality" as well as the rearing of pedigree cattle for state and collective farms

The targets laid down by the new programme are precise varieties of winter wheat must be developed with a yield of not less than 80–90 q ha^{-1}, spring wheat of 45–60 q ha^{-1}, maize hybrids of 12–130 q ha^{-1} on irrigated land and 80–90 q ha^{-1} on non-irrigated land and peas of 40–45 q ha^{-1} (1q = 100 kg) Fodder crops must yield 10,000–15,000 fodder units per hectare under irrigation and 5,000–6,000 fodder units without, while technology or fodder storage must ensure retention of at least 90 per cent of nutrients

In addition to these precise targets, there are less specific directives Research is to be directed at saving energy in soil conservation, the rational usage of water resources, anti-pollution measures and the mass examination and treatment of animals Special attention is to be paid to the development and mass production of biological and chemotherapeutic veterinary pharmaceuticals

To support this applied research, the two all-union academies, together with the republic academies of sciences, are to develop theoretical work in genetic engineering This will include the breeding of new strains of plants, microorganisms and animals, the biotechnology of protein synthesis and biologically active substances The academies will also be responsible for new pesticides and herbicides, growth regulators and similar sophisticated agricultural preparations, and for designing the industrial technology for their commercial preparation **Vera Rich**

0028-0836/82/230447 01$01 00

US National Institutes of Health

New clinical trials

Washington

Dr James B Wyngaarden has finally been sworn in as director of the National Institutes of Health (NIH), the US health research agency, and so has come out of the shadows where he has been hiding, in a sense, since his name surfaced as the Administration's candidate for the post last autumn He has now begun interviewing candidates for those institutes that have no permanent directors at the moment (some of the posts have been vacant for months)

Last month Wyngaarden also held his first press conference in his new capacity, and the debut produced one serious slip — a statement that his personal belief favoured freedom of individual choice regarding abortion — which was immediately attacked by anti-abortionists, who are very active in Washington these days He also said, speaking personally, that he would have "no problem" with carrying forward NIH's research in animal *in vitro* fertilization to the human level Whether NIH should sponsor research on human *in vitro* fertilization has been a controversial subject — so controversial that possible government guidelines have been pending, but not issued, since the time of the Carter Administration

But when he spoke officially, Wyngaarden indicated his views for the future of NIH — which he has had ample time to work out in the long months of warm-up for the job He said he wants to keep the present balance of activities, particularly the level of 50 per cent of NIH funding allocated for basic science including investigator-initiated grants He also favours continuing use of training grants and fellowships as a means of producing good basic biomedical scientists He said he agreed "fundamentally" with the stabilization programme meant to insulate NIH from budget swings that was introduced by his predecessor, Donald K Fredrickson Wyngaarden also defended peer review as a "brilliant creation" of one of his predecessors, James A Shannon, and said that NIH were not at the moment well placed to embrace more institutes All this was hardly surprising, given Wyngaarden's background in academic medicine at Duke University School of Medicine

Wyngaarden did, however, express interest in starting new clinical trials NIH still run several, but some have come under criticism for being very expensive and sometimes not useful No new clinical trials have been initiated by NIH since 1978 But Wyngaarden said he was considering suggestions for new clinical trials in the cancer, cardiovascular and arthritis fields that might well be worth starting even though they would commit funds for many years and take money away from investigator-initiated grants New clinical trials would, of course, mean a change of the balance of activities of NIH But such a change, if it comes, is some time off, as Wyngaarden has much to do now to get NIH running again **Deborah Shapley**

Biotechnology

Yugoslav plan

Zagreb

Yugoslavia is planning a major drive in biotechnology, based on a projected new institute on the Dalmatian coast The new scheme, which now awaits federal approval, has the backing of the government of the Croatian Republic, and is intended both to enhance the international prestige of Yugoslav science and to help the drive to develop science-based industry

The present stagnation of the Yugoslav economy has made it impossible for science and industry to continue its recent course of dependence on foreign licences and the import of obsolescent technologies Indeed last year's Congress of Self-Management stressed unequivocally the need for home-grown technology

Some research institutes embarked on such a course several years ago Thus the Jozef Stefan physics institute in Ljubljana supplies knowhow to a range of industries from medical technology to nuclear power and the Immunology Institute of the University of Zagreb has become a major earner of hard currency by means of sales of sera and sophisticated pharmaceuticals, including interferon

The new emphasis on science-based industry, however, accords well with the desire of Yugoslav — and particularly Croatian — biologists to see their country take a lead position in biotechnology During the academic year 1979–80 a group headed by Dr Marija Alaceivic of the Department of Biotechnology of the University of Zagreb raised the possibility of founding an international institute for molecular genetics somewhere on the Croatian coast

Several coastal towns were asked to tender for providing a site Dubrovnik, which already boasts an Inter-University Centre of Postgraduate Studies, was tipped as favourite Just before the closing date, however, Split made an intriguing counter-proposal The institute, Split suggested, could be housed in the Villa Dalmatia, one of the residences of the late President Tito The proposal now only awaits official ratification Apart from symbolic implications, Split has other advantages including a long-standing academic tradition which, in 1974, culminated in the foundation of a university

The choice of biotechnology seems to be dictated partly by economic considerations — the costs involved in biotechnology, while not negligible, are modest Moreover, Yugoslavia has a long tradition in organic chemistry and can boast two Nobel prize winners — Ruzicka and Prelog — in this field

Supporters of the institute already speak of the projected institute as "international" There is hope that the European Molecular Biology Organization (EMBO) will help but that would mean that Yugoslavia would first have to join EMBO — a proposal already formally made by the Yugoslav scientific community to the federal government Yugoslav participation in international scientific research has not always been auspicious — although a founding member of CERN, for example, Yugoslavia had to drop out because it could not meet the financial contributions

According to Professor Ivo Slaus, the chairman of the steering committee for the institute, even if no international support is forthcoming, the Croatian scientific community would still wish the institute to be "international" in the wider sense of the word The Republic of Croatia has already allotted 15 million dinars (£188,000) for preliminary work and part of this sum will be spent on a conference next year to launch the new institute and to ensure that it does not duplicate the work of existing institutes (such as Szeged in Hungary) **Vera Rich**

UK–Argentine cooperation

Shadows of war

The storm clouds over the South Atlantic are casting long shadows over scientific relations between Argentina and the United Kingdom Scientific collaboration between the two countries had been growing but it now looks as though several promising projects may be blighted The rumblings have already caused the postponement of the Sixteenth International Symposium on Remote Sensing of Environment, which was to have been held in Buenos Aires this week Organized jointly by the Environmental Research Institute of Michigan and the Comisión Nacional de Investigaciones Espaciales, the conference was to have heard 200 papers When the Falklands crisis erupted, many intended participants withdrew their papers and gave notice that they would not attend the symposium

Scientific collaboration between Britain and Argentina — in the form of joint university projects, exchange visitors and fellowships — has been nurtured over the past few years by the Royal Society and the British Council The Royal Society and Conicet (its Argentine equivalent) have had a reciprocal agreement for some ten years — 110 scientists a year have been exchanged All this has now been put on ice The Royal Society recently sent out a letter to scientists it had planned to sponsor on visits to Argentina saying that, in view of present circumstances, all exchanges should be halted

The British Council has increasingly encouraged British academics to put out

0028-0836/82/230448-02$01 00

feelers and develop reciprocal research projects with Argentina. Through the council's office in Buenos Aires, Argentine universities would suggest projects for possible cooperation and the council would then approach the universities in Britain. Travel expenses were paid by the visiting country's organization, the council or Conicet, and subsistence by the host. The council has now closed its office in Buenos Aires and recalled its staff.

When the Falklands crisis broke, eighteen jointly-funded university projects were under way. In the past year the British Council has sponsored 7 long-term scholarships, 36 visitors and 17 lecture trips. The numbers may not be great but the Royal Society, the British Council and many academics have expressed their profound regret that the present situation may put a big question mark over such agreements.

Several promising projects have been nipped in the bud. Imperial College and the Centro de Investigaciones Opitcas (CIOP), La Plata, have for the past eighteen months been discussing the setting up of a joint laser physics research project. Professor G H C New of Imperial College recently paid a visit to Argentina to give a series of lectures and arrange future collaboration. As well as exchanging postdoctoral fellows on extended visits — beneficial for each party in providing highly specialist researchers free — it was also hoped that a British specialist would go out to Argentina to teach and act as a consultant at CIOP.

Professor J Barber (Pure and Applied Biology, Imperial College) has also recently been to Argentina to coordinate a joint photosynthesis research project. The oceanography department at the University of Southampton has been making moves to coordinate research with Argentina, particularly in the area of oil exploration. Professor A P M Lockwood has been closely involved in talks to set up training exercises particularly in his capacity as a delegate of TEMA (Training and Education for Mutual Advantage), part of UNESCO's International Oceanographic Commission.

Both Argentine and British scientists are concerned that the Falklands crisis will seriously damage opportunities for scientific cooperation. In particular, many Argentine scientists in Britain are worried that if they leave the country to attend conferences abroad, they may have problems getting back into Britain. In April, both Britain and Argentina introduced a visa requirement. A spokesman for the Home Office did say, however, that he could not foresee any problem if Argentine nationals applied for re-entry visas before leaving the country. What is clear is that many academics feel uncomfortable in a situation where politics is impinging on their research. As one who has recently visited Argentina said, "They're a wonderful country and wonderful people. It's very, very sad."

Jane Wynn

Australian telesatellites

Outback opened

Canberra

Australia will have its own domestic communications satellite by the end of 1985. In a statement to the House of Representatives on 6 May, the then Minister for Communications, Mr Ian Sinclair, announced that Hughes Communications International will build the space segment of a domestic satellite. The system, known as Aussat, will be owned and operated from the start as a commercial venture by Aussat Pty Ltd. Although Aussat is at present wholly owned by the federal government, the government intends to sell 49 per cent of its equity to the private sector as soon as practicable, in line with its free-market policy principles.

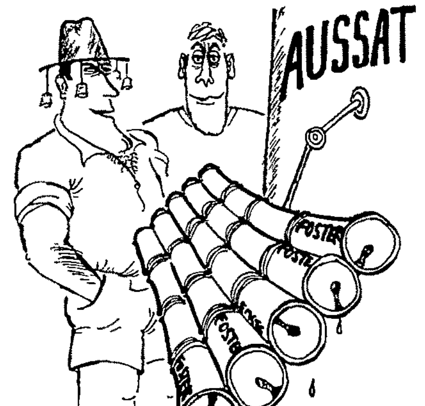
The contract with Hughes, the sealing of which seems imminent, specifies three satellites for the system — two in orbit and one on ground standby, with the option of a fourth satellite should demand justify it. The satellites will have an operational lifetime of seven years and function in the super-high frequency (gigahertz) range with four high-power and eleven low-power transponders. The net result will be a versatile satellite of limited capacity, primarily suitable for television networks. Provisional bookings with the European Ariane launch vehicle and with NASA's Space Shuttle or Delta rocket have been secured. The fixed-price package offered by Hughes, including the launching and construction of two ground control stations, will cost A$166 million (£95 million). Of this, only A$5.1 million will be spent on local technology, which is a sad reflection on the dearth of innovation in the Australian electronics industry.

Aussat promises a glittering array of services including direct television broadcasting to widely scattered homes throughout the continent, business communications and remote educational and medical services. Both the School of the Air, plagued by poor reception, and the Royal Flying Doctor Service will get a new lease of life. The satellite will also bring telephone services to the outback as well as a back-up service for trunk lines between major cities. Unfortunately, the more imaginative aspects of satellite telecommunications such as "teleconferencing", direct radio contacts and electronic news gathering are ruled out in this satellite because of its frequency allocation and limited number of transponders.

The principal government user of Aussat will be the Australian Broadcasting Commission, which has reserved all the four high-power transponders on the first satellite for its Homestead and Community Broadcast Satellite Service. The beneficiaries will be farmers and station-owners who can afford A$1,000 for the purchase of a 1.2-metre diameter reception dish. For the rest of Australian viewers, the satellite will bring more of the same, the Australian Broadcasting Commission is likely to increase the proportion of its programmes relayed in real time, rather than on film or tape, to its network. On the other hand, Aussat may facilitate the production of special-interest programmes for small groups such as ethnic communities, for which there is insufficient local appeal but which may be viable on a national basis.

Other public users will be Telecom, who will provide the remote telephony and business services, the Department of Transport, which will use the facility for aeronautical and marine communications and the state police departments.

The commercial television stations are expected to be the principal private users. There is, however, the possibility of using



"At least we made the solar panels"

the high-power transponders on the second satellite on a pre-emptive basis, in which case the fourth satellite will certainly be needed. Significantly, Aussat will provide the first opportunity for a private operator to compete with Telecom. At present, legislation ensures that Telecom has a monopoly in all landlines and terrestrial microwave links. However, Telecom has a statutory obligation to weight its charges for profitable services in order to cross-subsidize telephone services in rural areas. A competitor, not hampered by these obligations nor by having to contend with the growing union activism within Telecom, could under-cut Telecom for its business services via satellite and still make massive profits.

The substantial private equity in Aussat raises political questions of regulating ownership, access and frequency allocation. The satellite, by enhancing television networking, will undermine the position of commercial stations not having access to it. Consequently there is a real danger that the media, now already in a few private hands, will be even further concentrated. Another problem to be tackled is the possible piracy of the downlink beam by neighbouring countries or illegitimate access to international and overseas databanks. Australian legislators will have to resolve these problems with little by way of precedent.

CORRESPONDENCE

A history of the Falkland Islands

SIR — In your leading article referring to the Falkland Islands conflict (see *Nature* 8 April, p 480), it is stated that the only claim of Argentina to the ownership of the islands is the proximity to the Argentine coast Since we consider this statement to be in error we give here a detailed account of the historical events and the cause of the present conflict

The discovery: The strongest evidence available indicates that the discovery of the islands can be attributed to the crew of the ship "San Anton", a member of the Spanish expedition led by Hernando de Magallanes (Magellan) With the name of "Islas de Sanson" (an abbreviation and slight modification of the ship's name) the islands are depicted in several Spanish maps from 1522 to 1590, as well as in the Italian map of Agnese, of 1536, where the Magellan route is indicated

Naturally, Spanish dominion over the islands was proclaimed (in accordance with Papal bulls and treaties with Portugal) and in 1580 a garrison was settled near the Magellan Strait having jurisdiction over the mainland and the nearby islands

In 1619, on a map made under the direction of the Dutch sailor Sebald de Weert, the islands appear with the name of "Sebaldin islands" The first British descriptions were published in 1622 but even British scholars are doubtful about these reports

However, the British sea rover William Dampier was there by 1648 and in 1690 John Strong gave the name "Falkland Sound" to the strait between the two main islands, a name that in the English literature was later extended to the whole archipelago

The occupation: The islands were first occupied in 1764 by the Frenchman Louis Antoine de Bougainville who established a small colony in a place he named Port Louis Since most settlers were from the French port of St Malo the islands took the name of "Iles des Malouines", which in the Spanish literature became "Islas Malvinas"

Once Spain realized that the French had settled there the Crown made the appropriate claims to France and in 1767 the French left A small Spanish garrison subsequently remained in Port Louis, which took the name of "Puerto Soledad"

In the meantime (1765) a small group of people from Britain had settled in a place which they called Port Egmont Once again, Spain made the respective claims and since the British did not want to leave peacefully they were expelled by force in 1770 The diplomatic conflict that started ended by an agreement between Britain and Spain in which the British were reinstalled in Port Egmont in 1771 and left "spontaneously" in 1774 The British occupation lasted four years in all

In 1811, after 44 years of regular occupation, the Spanish garrison was sent to Montevideo because of the War of Independence that had started in Buenos Aires in 1810 This war led to the Declaration of Independence in 1816, following the North American example

Argentina, as heir to the Spanish possessions, took charge of the Islas Malvinas in 1820 and left a representative of the Government of Buenos Aires

In 1825 Britain recognized the independence of Argentina and signed a treaty of peace and commerce without questioning the Argentine possession over the islands

In 1829 the administration of the island was reorganized and a governor was sent from Buenos Aires He settled there with his family

On 2 January 1833 John James Onslow, commanding the British frigate "Clio", dismissed the Argentine authorities by force The British forces stayed there until 2 April 1982

The claims: The Argentine government considered the British action to be plunder and immediately made the corresponding claim Since then this claim has been repeated by the Argentine government (regardless of its political affiliation) at every convenient opportunity but no satisfactory answer has been obtained

The creation of the United Nations opened a new possibility, particularly when in 1960 it decided to end colonialism Britain spontaneously presented the "Falkland Islands" as a "non-autonomous territory", an expression that replaced the old term "colony" (Resolution No 1514, XV General Assembly)

Since Argentina claimed the property of the islands, in 1965, after patient diplomatic procedures, the 20th General Assembly issued Resolution No 2065 (approved by 94 votes in favour, none against and 14 abstentions, Britain among them) in which both Britain and Argentina were invited to solve the conflict in a peaceful way

Conversations started and during this time Argentina has steadily contributed to the improvement of the living conditions of the islanders which were neglected by the British government Schools were improved, an airport was built (the only one in the islands) and twice-weekly air communication with the continent through an Argentine airline was started, thus ending the island's long isolation Free health assistance and education on the continent were also offered to the islanders It is important to stress that the islanders were primarily dependent on the "Falkland Islands Company" which controlled every aspect of their lives production, commerce and even food supply The company also owns most of the useful land

At first Britain seemed to accept a diplomatic solution and even stated that she would transfer the islands to Argentina provided the interest of the 1,800 inhabitants was taken into consideration However, Britain subsequently paid no further attention to the subject and no more steps were made in the negotiation

The conflict: The present conflict originated as follows At Grytviken, San Pedro Island, a Malvinas Islands dependence, there was on old and abandoned whaling factory An Argentine scrap dealer made the proper arrangements with the owner of the factory to dismantle it and sell it for scrap The arrangements were made according to British law and with the British authorities' approval Nevertheless, once the Argentine workers were at Grytviken, they were considered to be "invaders" and a warship was sent to clear them out Argentina in turn first sent another warship to protect the workers and then occupied the islands The recovery of the whole archipelago was made without any harm to the British Not a single drop of British blood was shed but four Argentine people lost their lives

Asociacion Argentina Para el Progreso de las Ciencias, Buenos Aires, Argentina

Logarithmic SI

SIR — I have for some time made private use of a notation for expressing numbers and measurements that others might perhaps also find useful It was suggested to me by the symbol "*p*H"

The first step is to let the prefix p mean "antilog to the base 10" So p0 is 1, p6 is 1,000,000, 2,000 is 2p3 or, to one decimal place, p3 3 For, say, 0 02 there is a choice of $\bar{p}$2 3, $\bar{p}$1 7 or 2$\bar{p}$2 (More generally, p may be regarded as p^1, giving $p^0 2$ as 2, $p^1 2$ as 100, $p^2 2$ as p100, and so on — so $p^9 9$ is a very large number)

The next step is to let pQ0 mean the SI unit value of some quantity Q, this generates a notation that is particularly useful for very large or very small measurements

My own practice is to use pL0, pM0 and pT0 for 1m, 1kg and 1s respectively Area, volume, speed and acceleration may conveniently be written pL^2, pL^3, pL* and pL** (I say 'pL stars' — c f x), the two latter pL/T and pL/T^2 alternatively For other units I use the SI symbol itself — 1 joule is pJ0 (I also write pD0 for 1 kg m^{-2})

As examples, electron mass and radius (m_e and r_e) are $\bar{p}$M30 0 and $\bar{p}$L14 6, the solar mass pM30 3 and the Solar System's diameter about pL13, the speed of light $\bar{p}$L*8 5 and of continental drift about pL*9, and a year is within 1 part in 500 of pT7½

This notation is particularly practical in that it avoids the awkwardness of the half-sized superscript (2×10^{30} kg), while getting round the somewhat clumsy SI prefix system, which in general usage has caught on only rather patchily

Support the Zoo

SIR — The article by Jane Wynn in *Nature* 13 May (p 97) points up what seems to me to be an obvious anomaly Kew Gardens is (rightly) given enough Exchequer support to enable it to charge an entry fee of 10p, and to have over 1 million visitors a year London Zoo, which has similar functions, is forced to try to charge an "economic" entrance fee and hence price itself out of existence Why the difference?

NEWS AND VIEWS

The oncogenic circle closes

from Peter W.J Rigby

A LITTLE over a year ago I discussed in these columns[1] recent work from the laboratories of Geoffrey Cooper (Harvard Medical School) and Robert Weinberg (MIT) which showed that the NIH3T3 line of mouse fibroblasts can be morphologically transformed by transfection with DNA from chemically induced and spontaneous tumour cell lines The use of DNA-mediated gene transfer techniques to define and characterize the oncogenes of non-virally induced tumours marked a significant step forwards in molecular oncology Yet in March 1981 many questions remained Nothing was known of the nature of these oncogenes or of their products and there was much speculation as to the relationship between these cellular transforming genes and proto-oncogenes, the cellular homologues of the oncogenes carried by strongly transforming retroviruses[2] Now an extraordinary series of reports from the groups of Cooper and Weinberg and of Michael Wigler (Cold Spring Harbor Laboratory), Mariano Barbacid, Edward Scolnick and Douglas Lowy (National Institutes of Health) has precisely identified several cellular oncogenes and their products and has shown that in two cases, the genes detected by transfection are proto-oncogenes

Cellular oncogenes were first characterized in terms of their sensitivity to restriction enzymes It was shown that the DNA of different tumour types transferred different oncogenes but that within a tumour type, for example, mammary carcinomas, the same oncogene was transferred by the DNAs of independent tumours even when the tumours arose in different species, suggesting that the oncogenes are specific for a particular cell type This idea has now been extended by Cooper's group in a study of twenty B- and T-lymphocyte neoplasms of human and murine origins[3] that shows that different oncogenes are activated in tumours derived from cells of the same lineage at different stages of differentiation Either different oncogenes are highly susceptible to activation at different stages of differentiation or the expression of a particular oncogene is required to transform cells of a given differentiation state This latter explanation, of target specificity within a lineage, has parallels in the interactions of defective avian leukaemia viruses with their target haematopoietic cells[4]

The expected application of recombinant DNA techniques has now occurred, the favourite target being the human bladder carcinoma oncogene which has been cloned by the groups of Barbacid, Weinberg and Wigler[5–7] The gene is contained within an approximately 6 6 kilobase (kb) *BamI* fragment and Barbacid's group has further localized the transforming activity to a 3 0 kb *SacI* fragment[8] Southern blotting experiments show that NIH cells transformed by bladder carcinoma DNA always carry this fragment of human DNA and that the allele of the gene carried in bladder carcinoma cells is not detectably rearranged in comparison with the allele present in normal human DNA Barbacid's group has cloned the homologous sequence from normal human fetal liver DNA and shown that within the biologically active 3 0 kb *SacI* fragment there are no differences detectable by restriction enzyme or heteroduplex mapping[8] The fact that the T24, J82 and EJ lines of bladder carcinoma cells transfer the same oncogene is not surprising because at a recent meeting in Squaw Valley, California*, Wigler reported restriction site polymorphism and isoenzyme data which show that the T24 and J82 bladder carcinoma lines are identical and that the EJ line is, at the least, very closely related At the same meeting, Cooper reported the cloning of another oncogene transferred by DNA from bursal lymphomas of the chicken The striking aspect of this gene is its small size, only 1 8 kb of DNA are required for biological activity and much of this segment is comprised of highly repeated sequences The region that hybridizes to mRNA is very short, approximately 0 3 kb, suggesting that the gene product will be a rather small polypeptide

The relationship between cellular oncogenes and proto-oncogenes has been studied by all the groups About fifteen proto-oncogenes are now known and they have acquired a genetic notation of their own[9] Each gene has a three letter symbol derived from the name of the virus in which it was first defined Thus *abl* is the transforming gene of the Abelson murine leukaemia virus, *fes* the gene of feline sarcoma virus, *myc* the gene of avian myelocytomatosis virus (MC29) and so on The prefix v- indicates the intronless version of the gene carried by the retrovirus, c- the homologue in normal cellular DNA

Cooper and Weinberg and their colleagues have used cloned retrovirus *onc* gene probes in Southern blotting experiments to analyse the DNAs of NIH cells transformed by a variety of cellular oncogenes[10,11] The mouse homologues of the *onc* genes are always detected but if the donor DNA is of a different species, say human, and if the transferred cellular oncogene is related to the retrovirus probe, the question remains whether additional fragments corresponding to the transferred human gene will be detected To the great delight, and probably even greater surprise, of all retrovirologists, such relationships have been revealed in the first series of experiments Weinberg's group has shown that the EJ bladder carcinoma oncogene is homologous to c-Ha-*ras1*, the cellular equivalent of the transforming gene of Harvey murine sarcoma virus (HaMSV) Cooper's group report similar data for the EJ and J82 oncogenes but even more surprisingly show that the oncogene transferred by the DNA of the LX-1 human lung carcinoma line is homologous to v-Ki-*ras*, the transforming gene of the Kirsten murine sarcoma virus (KiMSV) Wigler (Squaw Valley meeting) has also reported the same results Weinberg's data show that a novel fragment hybridizing to c-Ha-*ras1* is present in all NIH cells transfected with EJ or T24 DNA and in secondary transfectants Moreover, if DNA from a secondary EJ transfectant is cleaved with *BamI*, an enzyme known not to inactivate this oncogene, and transfected into NIH cells, one again sees a novel fragment homologous to c-Ha-*ras1* These novel fragments are also detected by the cloned oncogene and both probes hybridize to the same fragment of normal human DNA The groups of Barbacid and Weinberg have compared the cloned *ras*

Peter W J Rigby is a member of the Cancer Research Campaign Eukaryotic Molecular Genetics Research Group and a Senior Lecturer in Biochemistry at the Imperial College of Science and Technology, London SW7 2BZ

gene and the cloned bladder oncogene[8,11], and have shown that the sequence homology resides within the 3 0 kb *SacI* fragment required for biological activity Quite unexpectedly, Barbacid's group also demonstrates weak homology between the T24 oncogene clone and v-*myc*, although this homology lies within a 0 85 kb *SacI* fragment not required for biological activity

These data show clearly that the 3 0 kb *SacI* fragment contains the bladder oncogene and that there is homology to *ras*, but do not prove that the two genes are identical, they could merely be closely linked or interdigitated However, analyses of expression make this latter possibility highly unlikely Wigler's group showed[7] that the T24 oncogene detects an approximately 1 2 kb cytoplasmic RNA in T24 cells and in NIH cells transformed by the T24 oncogene but not in untransformed NIH cells Weinberg's group has now shown[11] that this RNA, and a 5 1 kb transcript, hybridize to both the cloned oncogene and c-Ha-*ras*1, and Barbacid's group reach the same conclusion[8] using the cloned oncogene and v-*bas*, the transforming gene of the BALB murine sarcoma virus, which is identical to *ras* Final evidence for identity comes from studies at the protein level Scolnick's group has extensively analysed the protein encoded by v-*ras* and has raised a panel of monoclonal antibodies against this phosphoprotein of apparent molecular weight 21,000 (p21) Barbacid's and Cooper's groups show[8,10] that NIH cells transformed by the bladder oncogene contain higher levels of p21 than do untransformed cells and Weinberg's group mention that they have similar data[11]

Thus the cloned human bladder carcinoma oncogene is homologous to *ras*, the transforming gene of HaMSV, cells transformed by the bladder oncogene express an RNA which hybridizes to both oncogene and *ras*, and such transformed cells contain elevated levels of the protein encoded by *ras* The inescapable conclusion is that the bladder oncogene is an allele of the normal human homologue of *ras*, activated in a subtle, yet to be determined way If this is the case, then the normal human gene, if artificially activated, should transform NIH cells Lowy and Scolnick and their colleagues have shown that this does indeed occur As part of their wide-ranging studies of the *ras* system they have cloned four segments of human DNA with homology to *ras*, one of which, human c-Ha-*ras*1, is very similar to the rat c-Ha-*ras*1 probe used by Weinberg This cloned segment does not transform NIH cells If, however, the 3 0 kb *SacI* fragment from this clone, which is, of course, equivalent to the 3 0 kb *SacI* fragment of the bladder oncogene, is linked to the long terminal repeat (LTR) of HaMSV, the resultant chimaeric molecule transforms Similar activation can be achieved using the LTR of feline sarcoma virus The transformed cells contain within their DNA the human c-Ha-*ras*1 gene linked to the viral LTR and express the p21 protein

A normal human gene can thus be activated either by some as yet undefined change occurring during the induction or progression of a human tumour or by linkage to the control sequences contained within a retroviral LTR The consequence of this activation is the expression of elevated levels of p21 which is also the transforming agent of a murine retrovirus It should be noted that transformation does not result simply from the expression of p21 but from elevated expression of this protein Both the corresponding RNA and p21 are found at low levels in normal human cells (ref 12 and Wigler at the Squaw Valley meeting) The notion that cancer is a disease caused by dosage, that it results from elevated expression of normal gene products, is thus further supported

Cooper and Weinberg have also taken a separate approach to the identification of the products of cellular oncogenes[13,14] NIH cells transformed by a cellular oncogene can be used to induce tumours in young mice and sera from the tumour-bearing animals can then be employed to immunoprecipitate labelled extracts from cells transformed by that oncogene Any proteins specifically immunoprecipitated are likely to be either the product of the oncogene or a protein directly induced by its action Sera taken from animals bearing tumours induced by NIH cells transformed by other oncogenes should not recognize this protein and, conversely, the protein(s) should not be present in extracts of cells transformed by other oncogenes In this way, Weinberg's group has identified a non-glycosylated phosphoprotein of apparent molecular weight 185,000 synthesized in NIH cells transformed by the oncogene of nitrosoethylurea-induced rat neuroblastomas This protein is also found in cells transformed by DNA from a rat glioblastoma but this tumour was obtained by the same protocol as the neuroblastomas and derives from a similar tissue type Cooper's group has concentrated on cells transformed by the oncogene of the human mammary carcinoma line MCF-7 The antisera obtained immunoprecipitate a non-phosphorylated glycoprotein of apparent molecular weight 86,000 (gp86) and often a protein of apparent molecular weight 19,000 Restriction enzyme digestion experiments have shown that the MCF-7 oncogene is closely related to the oncogene of mouse mammary carcinomas induced by mouse mammary tumour virus (MMTV) or by dimethylbenzanthracene (DMBA) In agreement with this result, gp86 is precipitated from extracts of cells transformed by the MCF-7 oncogene by sera from mice bearing tumours induced by cells transformed by DNA from MMTV- and DMBA-induced mammary carcinomas and by sera from mice bearing primary MMTV-induced carcinomas gp86 cannot be detected, however, in cells transformed by DNA from MMTV- or DMBA-induced carcinomas, or in primary MMTV-induced carcinomas or in MCF-7 cells Thus while the connection between gp86 and the cellular oncogene is not clear-cut, it seems likely that this protein will turn out to be either the product of the mammary carcinoma oncogene or to be directly induced by it

Despite the astonishing advances that have been made in the past year, many important questions remain unanswered First, what is the general validity of the NIH3T3 cell assay for cellular oncogenes? Almost all the work has used this cell line simply because it transfects extremely efficiently These cells are not normal however, and could be described as teetering on the edge of transformation Many are the tales of those who, in their first experiments with these cells, succeed in generating many foci without the application of any DNA! In more scientific terms, these cells transform with kinetics indicating that only a single event is required, whereas most data suggest that natural carcinogenesis is a multi-step phenomenon However, Sager and her colleagues have recently shown that the bladder carcinoma oncogene will efficiently transform CHEF/18 cells[15] This Chinese hamster embryo fibroblast line has been extensively studied by Sager's group and their data indicate that transformation in this system normally requires multiple events They conclude that the activated bladder oncogene is the end product of the multi-step carcinogenic process Weinberg's group has shown[14] that the rat neuroblastoma oncogene will transform Rat-1 cells, a line of rat fibroblasts that (in my experience at least) is more normal than NIH3T3 cells The development of additional cell systems for the assay of oncogenes will be important but in the final analysis we need to know whether an oncogene will transform its apparent target cell type However, the development of efficiently transfectable cells derived from a wide variety of specialized tissues will be technically difficult

The second major question is whether

oncogenes detected by the NIH cell assay are the primary causative agent of the tumour from which they are derived or is their activation the end result of a complex series of genetic events? That this latter possibility may be correct is suggested by work on bursal lymphomas of chickens If chickens are infected with lymphoid leukosis viruses, avian retroviruses which do not carry an *onc* gene, bursal lymphomas arise with long latency periods Analysis of the DNA of such tumours shows[16-18] that the retrovirus integrates so that its LTR, the segment of the viral genome containing both a promoter and an enhancer, is adjacent to c-*myc* and transcription of this proto-oncogene is thus activated However, if bursal lymphoma DNA is used to transform NIH3T3 cells the oncogene transferred is not c-*myc*[19] but the gene now cloned by Cooper and discussed above By analogy with this situation the primary target during the induction of bladder carcinoma may not be the gene which has been cloned If so, quite different experimental approaches will be needed to identify it, and the oncogenes of the many tumours not active in the NIH cell assay

There can, however, be no doubt that the work discussed here is a very significant landmark in the development of our understanding of carcinogenesis The application of modern genetic and immunological techniques has led to insights undreamed of even a few years ago The argument that fundamental research in molecular biology is irrelevant to the cancer problem is surely truly dead and buried □

In, out and about meteorites

from N J McNaughton and P K Swart

AT a recent conference* in Houston much attention was given to the search for evidence of what must have been (if, indeed, it did occur) the most dramatic interaction between the Earth and an extraterrestrial object — the impact of the 10 km diameter meteorite that Alvarez has proposed was responsible for the mass extinction of the dinosaurs and many diverse faunal and floral groups at the end of the Cretaceous period Alvarez based his hypothesis on the observation of anomalous iridium levels at the Cretaceous–Tertiary (K–T) boundary (*Science* **208**, 1095, 1982) and, judging from the conference, a growing number of scientists are now committed to his view

Theoretical and experimental studies clearly demonstrate both the catastrophic consequences of a meteorite impact in the ocean and the global dispersal of ejecta A massive 5 km high tidal wave (Ahrens and O'Keefe, Caltech) would be produced and disrupt food chains by extensive stripping of sediments and silting A worldwide dust layer would be raised by the impact Atmospheric temperatures would fluctuate rapidly as a result of the production of volatilized steam and ejecta from the impact and then drop as ejected dust obscured the Sun To understand how the possible extinction mechanisms operated, scientists have studied the isotopic composition of the ejecta, particularly the layers of sanidine, glass spherules and microtektites which coincide with the extinct marine phytoplankton in the deep-ocean sediments

Epstein (Caltech) showed that the sanidine spherules have a terrestrial ratio of ^{17}O to ^{18}O, but their unusually heavy $\delta^{18}O$ may be due to either exchange with atmospheric oxygen at the very high temperatures that would accompany impact, or diagenesis DePaulo's group (University of California, Los Angeles) also noted the high $\delta^{18}O$ of the K–T boundary and further suggested from Sr and Nd isotopic studies that the layer resulted from an oceanic impact in which most of the material is of terrestrial origin, but only a small proportion is in fact derived from the local sea floor Shaw and Wasserburg (Caltech) argue from their Sr and Nd isotopic data that the sanidine spherules are of non-oceanic derivation Although this apparent conflict undoubtedly arises from the different types of samples studied, all the isotopic evidence supports the view of Ahrens and O'Keefe that the meteoritic component in the ejecta is minor

The impact site has not been identified as neither a continental nor an oceanic crater of the appropriate size and age has been found An oceanic impact would seem more likely, however, because a greater proportion of the Earth was ocean at that time Over half the late Cretaceous oceanic crust has now disappeared into subduction zones, and the lack of evidence of an oceanic crater is thus not necessarily a problem for the hypothesis

While the ejecta of meteorite impacts on Earth are sought for further study, the debris from similar collisions on other planets may already be represented in our meteorite collections The achondritic shergottites, nakhlites and chassignites (SNC), represented by only nine of the several thousand meteorites held in museum collections, are argued to have an origin in meteorite impact with asteroid or planet The SNC are distinguished by relatively young ages, 1 3 billion years, unique but consistent oxygen isotope composition (Clayton and Mayeda, University of Chicago), unusual 'cumulated' texture indicative of crystal settling under gravity, and complex chemical composition The most obvious initial source, the asteroids, are precluded as these have insufficient mass to sustain the igneous activity that could account for the young age Sufficient melting could occur, however, as a result of collision between the meteorite and either an asteroid or a planet such as Mars

Opponents of the idea that SNC meteorites are martian ejecta argue that the proposed 100 m diameter SNC parent body could not reach the required escape velocity of 5 km s^{-1} An impact of sufficient size would vaporize, melt and crush to fine dust most of the ejecta (Singer and Melosh, University of New York) and, in any case, the resultant fragment should be highly shocked, but this is not observed Singer and Melosh propose instead that SNC meteorites repesent 'pockets' of melted rock caused by impacts on large asteroids The proponents of the martian impact theory counter that such melt sheets cannot produce the required textures and point to chemical similarities between martian soil and SNC meteorites Nyquist (Johnson Space Center) argues that the problem of reaching the escape velocity may be overcome if incoming projectiles were to strike the surface of Mars at a shallow angle, so that debris ricocheted away at high velocity Such impacts would leave characteristic 'butterfly' pattern craters which are, indeed, plentiful on Mars A more rigorous chemical and isotopic comparison with martian data obtained from the Viking programme or, in the future, with returned samples, will perhaps resolve the origin of the SNCs

To understand chondrule formation and meteorite agglomeration, meteoriticists are increasingly turning to the stable isotopes of the light elements for new insight Clayton and Mayeda (University of Chicago) demonstrated that two separate processes are recorded in the oxygen isotope composition of density separates from Murchison The heavy-density separates, ostensibly from the chondrules, and olivine-pyroxene and spinel separates define a line of slope around 1 on a plot of $\delta^{17}O$ versus $\delta^{18}O$ which is best explained by high-temperature mixing and exchange between ^{16}O-rich solids with ^{16}O-poor gas The low-density and calcite separates define a line of slope around 0 5 which diverges from the mixing line and is explained by low-temperature alteration of the pre-existing materials by water from the same gaseous reservoir that produced the mixing line That the carbonate, in particular, is formed significantly later

*The 13th Lunar and Planetary Science conference was held in Houston, Texas on 15–19 March 1982

than the chondrules and the high-temperature silicates is further supported by new Rb/Sr data for Orgueil, which suggest an age gap as large as 160 Myr (Macdougall and co-workers, University of California, San Diego) The secondary nature of the carbonates has important implications, not the least of which is its enrichment in carbon-13 compared with other co-existing carbon-bearing phases

Several workers have attempted to separate the carbonaceous components by HF/HCl demineralization of the meteorites Kerridge (University of California, Los Angeles) found that stepwise oxidation of the acid residue from the CM2 chondrite Murray yielded a minor phase which did not oxidize until over 1,000°C and had a $\delta^{13}C$ and $\delta^{15}N$ of around $+100°/_{oo}$ (PDB) and $+90°/_{oo}$ (AIR) respectively, as well as a low δD A carbonaceous phase of this nature has not been recognized either from other meteorites or from Murray by workers in the field However, attempts to confirm Kerridge's data should renew interest in identifying and explaining the phase Acid-insoluble residues, which contain major D enrichments for some carbonaceous chondrites, also appear to be the D carrier in the primitive ordinary chondrites (Yang and Epstein, Caltech) The Cambridge–East Kilbride group also demonstrated that most type 3 ordinary chondrites have enrichments in D above the terrestrial range, but only the least metamorphosed show extreme enrichments Furthermore, the D carrier in one of the least altered type 3 chondrites, Semarkona, seems to be a minor phase, which decomposes when heated to 550–650°C and has a minimum δD of over $+5,500°/_{oo}$ (SMOW)

A controversial issue is whether ^{26}Mg excesses in Al-rich minerals are a result of *in situ* decay of ^{26}Al or whether ^{26}Mg is a relict species that was already present at the time of Solar System formation The idea of 'fossil' ^{26}Mg was again forcefully argued by Clayton (Rice University) as being the more plausible explanation because of mixing constraints in the early solar nebula, and because of certain other isotopic anomalies such as ^{16}O and ^{50}Ti Advocates of the *in situ* decay model point to data obtained using the ion microprobe (Huneke, Caltech), which show uniform distribution of ^{26}Mg in minerals from Allende □

Hard facts on structure: hot air about mobility

from David M Blow

THE idea that the inherent flexibility of biomolecules relates to their function received another airing at the CIBA Foundation Meeting* on March 2-4, 1982 Improvements of technique now make available a wide portfolio of techniques for the measurement of mobility in macromolecules The most important is NMR, which allows separate relaxation times to be measured for every line in the spectrum Almost any other spectroscopic technique, from fluorescence to EPR, can give highly specific information about the mobility of a chromophore or a spin label Time-resolved X-ray diffraction, which in principle can give a 'flash' picture of a structure any time after triggering an event, is still in its infancy But X-ray crystallography can measure the time-averaged motion of individual atoms, so long as the motion is not too large, and can delineate domains of correlated motion

Computational capacity has increased to the point where all the atomic interactions for a small protein can be simulated, allowing the dynamics of the molecule to be calculated over a period of a few picoseconds The achievable time span is far too short to cover a significant chemical event, but the results do appear realistic so far as they go Martin Karplus (Harvard University) has used simulations to measure correlation times of a few picoseconds between atomic motions, and has estimated the apparent viscosity of the protein fluid in which an individual atom moves People speak of analysing the normal modes of vibration of a protein molecule, though nobody has done so yet

What has all this to do with the biological function of a molecule? Fred Richards (Yale University), stern but perceptive chairman of this rather unruly symposium, stressed this question in his introduction Is mobility essential or incidental to biological action? What experiments and theories can be devised to establish a relation between them? He got few answers

The most thoughtful came from Greg Petsko (MIT) who stressed that in many cases, access to an active site, and release of product, would be greatly hindered, if not prevented, if the adjacent structure were rigid He cited triose phosphate isomerase and pancreatic ribonuclease as examples where substrate binding is accompanied by the ordering of an adjacent mobile part of the structure — a kind of flexible lid which closes over the substrate The entropy change of such a process destabilizes the enzyme–substrate complex and thus facilitates release of products In cases where a linked function is invoked, this ordering of a mobile chain may convey a signal to a part of the molecule which the disordered chain can touch In the pyruvate and 2-oxoglutarate multi-enzyme complex, Gordon Roberts (National Institute of Medical Research) and Richard Perham (University of Cambridge) showed that lipoyl-lysine residues act like flexible arms to allow the transfer of substrate from the active site of one enzyme subunit to another

Many examples of mobile molecules and many different techniques were discussed Nucleosomes show a high degree of mobility on the nanosecond to microsecond time scale, making them a good subject for NMR study Michael Hogan (Princeton University) has used ^{31}P magnetic resonance to study the motions of DNA in both the isolated state and in nucleosomes, supplementing these studies with fluorescence anisotropy decay measurements using DNA-binding dyes The observed motion suggests twist or flexure of the DNA helix Mort Bradbury (University of California, Davis) reported NMR mobility studies on the histone and non-histone proteins of nucleosomes The unusually high mobility of these proteins seems to result from their highly charged character, which causes them to be fully or partly unfolded under almost all conditions

Bob Williams (University of Oxford) suggested that the action of calcium-binding trigger proteins depended on motion of hydrophobic groups detectable by NMR In muscle, motion of the 'head' part of the myosin molecule, which forms a cross-bridge linking the actin and myosin filaments, achieves relative motion between them Measurements reported by Stefan Highsmith and Oleg Jardetzky (University of California, San Francisco) showed that mobility in parts of the myosin molecule was quenched on binding to F- or G-actin David Thomas (University of Minneapolis) had studied the same system by EPR and spin label, and found a two-state 'relaxed' and 'attached' system with different degrees of order, modulated by calcium The function of muscle clearly depends on molecular motion, but are these motions related to mobility on the NMR and EPR time scales? Bill Harrington (University of Baltimore) went so far as to suggest that the rotation of the myosin head was achieved by a transition between a folded and an unfolded state in the stem of heavy meromyosin which carries it

Any dissatisfaction felt about these inconclusive speculations was dispelled by two exciting PMR papers which gave clear

*The proceedings of the meeting will be published by Pitman Books, London, in winter 1982 under the title *Mobility and function in proteins and Nucleic acids* (Ciba Foundation symposium 93)

David M Blow is Professor of Biophysics and Dean, Royal College of Science at Imperial College, London SW7 2BZ

0028-0836/82/230454-02$01 00

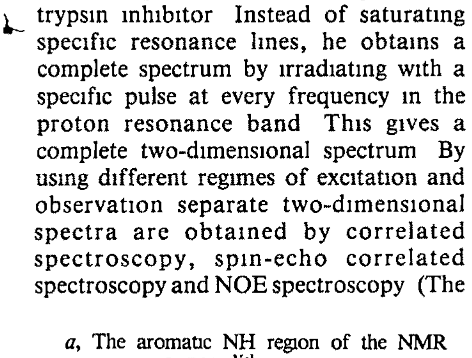
and definite results, using the nuclear Overhauser effect (NOE) to detect dipolar interactions between protons which are close together If the relative populations of the nuclear spin energy levels of one proton are perturbed — for example, by saturating its resonance frequency — the dipolar interactions transmit the perturbation to adjacent protons, resulting in an altered resonance intensity Pulses may be specifically shaped to avoid exciting the H_2O resonance Redfield has pioneered the use of this technique in the analysis of tRNA spectra, and has been able to assign resonance lines in the D stem of $tRNA^{Asp}$, and also in reverse-Hoogsteen base pairs (*Nucleic Acids Res* **9**, 7073, 1981)

Brian Reid (University of Seattle) has applied this technique to the aromatic NH band, which contains just one resonance for each base pair When such a resonance is perturbed, either one or two other NH resonances show up by NOE These are resonances in adjacent stacked base pairs An example is shown in the figure In this way Reid has been able to survey all the stacked base pairs, and to assign all the corresponding 28 ring NH resonances, in $tRNA^{Tyr}$

Kurt Wuthrich (University of Zurich) is tackling with Richard Ernst the more ambitious problem of the basic pancreatic trypsin inhibitor Instead of saturating specific resonance lines, he obtains a complete spectrum by irradiating with a specific pulse at every frequency in the proton resonance band This gives a complete two-dimensional spectrum By using different regimes of excitation and observation separate two-dimensional spectra are obtained by correlated spectroscopy, spin-echo correlated spectroscopy and NOE spectroscopy (The engaging acronyms COSY and SECSY were coined for the first two, the last having a more nasal connotation) COSY has enabled NH and $C^{\alpha}H$ resonances in the same amino acid to be correlated, while NOESY allows the identification of β-structure interactions by the proximity of $C^{\alpha}H$ and NH protons in adjacent residues (*J molec Biol* **155**, 311, 1982) By further development of these methods, almost every resonance in glucagon and in the pancreatic trypsin inhibitor has been assigned Individual changes of internal mobility can be observed as pressure and temperature are changed

The claim that a three-dimensional protein structure may, in the near future, be totally determined from NMR data is beginning to look more realistic, if only for a very small, rigid protein molecule □

a, The aromatic NH region of the NMR spectrum of $tRNA^{Val}$ (*E coli*) The imino NH proton resonances lie between -9 and -15 p p m In this region only the resonances whose exchange is slowed down by hydrogen bonding appear Each represents an NH in one hydrogen bond of a base pair *b*, Saturation of the resonance at -14 4 p p m leads, by the NOE, to a signal at -7 6 p p m from a non-hydrogen-bonded resonance in the same base pair, and also to two signals at -11 7 and -12 5 p p m from adjacent hydrogen-bonded imino groups These two signals come from base pairs stacked on either side of the base pair whose resonance is saturated (Courtesy of B R Reid, University of Washington)



Do stepping stones guide axon growth?

from Hilary J Anderson

In a recent issue of *Nature* (June 3, p 404), Ho and Goodman present data supporting the idea that peripheral pioneer neurones in the grasshopper are guided to their destinations by a series of cellular 'stepping stones' The 'pioneer' neurones are of vital significance because they establish the basic pathways and tracts within the nervous system that act as guides for neurones that develop later The term was first used by Ross Harrison, in his now classic studies of frog embryos, to describe the neurones that grow out and establish connections very early in development when the distance to their target regions is very small Even though the animal subsequently grows and changes form and the pioneer tracts twist and lengthen they continue to provide the guides that allow other neurones to reach their appropriate destinations

Several mechanisms of pioneer axon guidance — mechanical channeling, basement membrane markers and cellular landmarks — have been suggested and to distinguish between them it is necessary to study the behaviour of growing neurones in some detail The tip of a growing axon is expanded into a growth cone from whose leading edge extend numerous filopodia which are 0 1–0 2 μm in diameter and many micrometres in length and filled with actin filaments The growth cone makes 'searching' movements over its substrate, extending and retracting its filopodia, and probably plays a fundamental part in the interactions with the environment that direct and control neurone growth Harrison proposed that the pioneers were guided by the configurations of tissues in their environment, grooves and spaces in the embryonic tissue providing "paths of predilection" along which the growth cones progress This idea has been supported by several recent studies using electron microscopy which show that developing or regenerating axons often grow through preformed channels or spaces (see *Nature, News & Views* **283**, 428, 1980) In other instances, however, pioneers grow over regions seemingly devoid of obvious physical regularities, suggesting that there are other factors that direct pioneering axon growth

Pioneering axon growth in the central and peripheral nervous systems of insect embryos has proved particularly amenable to experimental study The central pioneers that will be discussed below are those that establish the primary longitudinal tracts of each ganglion in the central nervous system (CNS) (see ref 2 and *News & Views* **293**, 510, 1981) Ho and Goodman studied the peripheral pioneers which establish the peripheral nerves linking the CNS and the appendages (see also refs 3–6) These neurones have been observed as they grow in the living embryo, and examined by electron microscopy, by staining with intracellularly injected fluorescent dyes and by staining with particular antibodies In this way several different aspects of their behaviour have been successfully described

In their recent paper Ho and Goodman establish the important point that the pioneers are not a special class of cell but may be motor neurones, interneurones, or sensory neurones Furthermore, the pioneers themselves may grow along other pioneers for short distances during growth It thus seems likely that the mechanisms underlying pioneering axon growth are common to all growing neurones

Electron microscopy has shown that a basement membrane lies over the neuro-ectodermal layer from which the CNS develops[2] The central pioneer growth cones always track along this basement membrane and do so at a consistent location and in a consistent direction to form a characteristic tract[2] Similarly, in the periphery, where the embryonic appendages are hollow epithelial buds, the pioneer growth cones grow only over the inner surface of this epithelium[3-5] and do so only at certain locations to form characteristic pathways[3-5] It has been suggested that cues within the basement membrane might provide directional information for growth cone navigation[2] Such cues would be imposed on the basement membrane by the underlying sheet of cells and could take

Hilary J Anderson is a staff scientist at the European Molecular Biology Laboratory, 6900 Heidelberg

0028-0836/82/230455-02$01 00

the form of a simple indicator of longitudinal polarity, or a continuous gradient of information or a series of discrete markers.

Other observations have suggested the cellular landmark hypothesis favoured by Ho and Goodman. Before the peripheral pioneers axons appear, glia-like cells are found in the lumen of the appendage and in contact with the inner surface ofthe epithelium. These cells are found at regular intervals along the presumptive path of the pioneers[3-5] and could provide a series of stepping stones between the tip of the appendage and its base[3]. Later the glia ensheath the pioneers to form a proper nerve bundle. Ho and Goodman observed several other conspicuously located cells which could act as landmarks for the pioneers. Furthermore, the monoclonal antibody which they used for many of their observations stains growth cone filopodia very clearly and shows that they extend for some 50 μm. Thus, at no time need an axon be navigating without being in 'filopodial grasp' of a landmark cell.

The three proposed substrates for guiding pioneer axon growth now need to be tested by experimental manipulation, such as selective ablation of putative landmark cells. Ultimately these studies must lead on the one hand to an investigations of the molecular mechanisms underlying the preferential growth of pioneers over their chosen substrates and on the other hand to a study of the principles of spatial organization which generate these substrates at their appropriate locations — the fundamental unanswered question of developmental biology. □

Discovery of pre-galactic lithium

from Bernard Pagel

THE reality of the hot big bang is attested by galaxy redshifts, the 2.9K microwave background and evidence for evolution in the statistical properties of distant quasars. Indeed, if grand unified theories fulfill all their promises, then such basic facts as the existence of matter (rather than antimatter) and electric charge can also be taken as consequences of the big bang. These fundamental effects were imprinted on the Universe less than 10^{-35} seconds after it was born, while the last scattering of the microwave background took place about a million years later when protons combined with electrons and space became transparent. Galaxies and stars were presumably formed later still.

In an intermediate phase, when the Universe was about one second old and its temperature around 10^{10}K, neutrinos decoupled leaving an excess of protons over neutrons. During the next two minutes or so these combined in nuclear reactions to make deuterium, helium-3, helium-4 and lithium-7, production of heavier elements being aborted by the absence of stable nuclei at mass numbers 5 and 8. The resulting pre-galactic composition of cosmic matter, consisting chiefly of hydrogen and helium-4 in proportions of about 3:1 by mass, has since been modified by cycling of some of the material through stars. This has affected material in our neighbourhood by adding a mass fraction of 1 or 2 per cent of carbon and heavier elements and a similar amount of additional helium-4. Deuterium, on the other hand, is totally destroyed in matter cycled through stars, and helium-3 and lithium-7 can be both created and destroyed, so that the net effect of stellar evolution on these two species is rather uncertain.

A remarkable claim by Monique and Francois Spite, of the Meudon Observaory near Paris, that something at least very close to the pregalactic lithium abundance can be measured directly (see this issue of *Nature*, p 483), may now provide additional constraints on this view of the early Universe.

The pregalactic composition of cosmic matter depends on a number of parameters of cosmology and particle physics, notably the ratio of baryons to photons (or, equivalently, the present mean density of ordinary baryonic matter) and the number of lepton flavours, together with the net charge number and various lepton numbers that are believed to be zero or negligibly small. As a result, the determination of pregalactic abundance provides interesting constraints on these parameters and tests the consistency of the entire picture. For example, the presence of observable deuterium in the interstellar medium implies that the Universe cannot contain a sufficient density of ordinary matter to 'close' it, that is, eventually to halt the expansion by gravity, although it could be closed by non-baryonic matter such as massive neutrinos, if these exist. A still more severe upper limit to the density is provided by the observation that the mass-fraction of helium in emission-line galaxies of low oxygen abundance (in which the gas has accordingly undergone little recycling through stars) is below 25 per cent, which implies that the baryon/photon ratio (resulting from the primordial excess of matter over anti-matter) is below 4×10^{-10} or $\Omega_b < 0.03$ (assuming three neutrino flavours and a Hubble constant of 75 km s^{-1} Mpc^{-1}) where Ω_b is the fraction of the closure density supplied by ordinary baryonic matter. If, however, the density were less than about ⅓ of this upper limit, corresponding to a helium abundance of under 23 per cent, then the expected pre-galactic abundances of deuterium and helium-3 would become embarrassingly large. Thus a really accurate determination of the pregalactic helium abundance would provide a very severe test of the consistency of canonical big bang models, if only it could be carried out. Unfortunately, the prospects of finding the pregalactic helium abundance to better than 5 per cent are not very good.

What about lithium in all this? The 'cosmic' mass fraction of lithium-7, deduced from meteorites, is 5×10^{-9} and a similar amount is found in the atmospheres of the youngest stars. In older stars, however, and notably in the Sun itself, lithium is depleted because the surface layers are mixed in the course of time with

100 years ago

THE mines opened a short time since in China in the province of Chihli, with the special support and patronage of Li Hung Chang, have recently become the subject of much adventitious interest in Europe. It was believed that, with sufficient transport, one thousand tons a day could be raised for many years from the present pits, while it was said that fifty collieries of an equal size to the present one could be opened in or near Kaiping. The information, therefore, telegraphed by Reuter's agent in Shanghai that the further working of the mines had been peremptorily stopped by the Government, came with a shock to many interested in progress in China. It was stated that a censor in a memorial to the throne complained that the long galleries in the mines, and the smoke of the foreign machinery, disturbed the earth dragon, who in his turn disturbed the spirit of the Empress, who died some months ago, and who was buried about a hundred miles off. The irate spirit of the departed lady promptly took vengeance by afflicting the denizens of the palace in Peking with measles. The latter were, the censor is reported to have said, distintly traceable to the Kaiping mines, which interfered with the *fêng-shui*. The conclusion was obvious: the mines must be stopped. Such was the story told by the Tientsin correspondent of a Shanghai newspaper. The latest information from the East enables us to say that the mines are still working as usual, and there is not the slightest evidence that there is or has been any intention of interfering with them. It is even denied that such a memorial as that mentioned above has had any existence except in the imagination of a *gobemouche* at Tientsin. However this may be, it must be confessed that the petition has a Chinese ring about it, and that the method of argument is one sufficiently familiar to readers of the *Peking Gazette*.

From *Nature* **26**, 136, 8 June 1882

0028-0836/82/230456-02$01 00

deeper layers at a temperature of 2×10^6K where lithium nuclei are destroyed The degree of depletion in ordinary stars increases with age and with diminishing surface temperature because cooler stars have deeper outer convection zones A few highly evolved stars make fresh lithium, however, and yet more may be generated by cosmic-ray spallation in the interstellar medium, so extrapolation from present-day to pregalactic lithium abundance is a hazardous business

What Monique and François Spite have done is to estimate the lithium abundance of a sample of extreme subdwarfs These are old stars with extreme metal deficiency, typically a factor of 100 down on the Sun for carbon and heavier elements, so that the material from which they were formed could have undergone little previous cycling through stars Out of the five stars of differing surface temperature that they studied, the four hottest turned out to have one-tenth of the present-day lithium abundance — a strikingly large amount in view of the overall metal deficiency — and only in the coolest star was it undetectable, presumably because of depletion through convective mixing with deeper layers The authors argue that the constancy of lithium abundance in the four hotter stars indicates that none of these has been significantly affected by lithium depletion If they are right, then they have a value for the pregalactic lithium abundance, if not, then they still have an interesting lower limit

What does this new result tell us about the big bang? Unfortunately the predicted lithium abundance is a variable and generally fairly insensitive function of baryon density and, furthermore, it is rather uncertain For example, Olive and coworkers (*Astrophys J* **246**, 557, 1981) suggest an upward revision by a factor of 3 over the earlier calculations referred to by Spite and Spite, in this case the minimum possible value is minutely (25 per cent) greater than that observed, although it is striking that this value occurs at parameter values close to those deduced from helium and other light elements A fairly conservative view of the errors (especially with regard to possible depletion) suggests that lithium in subdwarfs provides an upper limit to the cosmological baryon density that is consistent with, but less stringent than that provided by helium What is exciting about the Spites' discovery is that lithium is there at all, and that its amount is not far from big bang predictions □

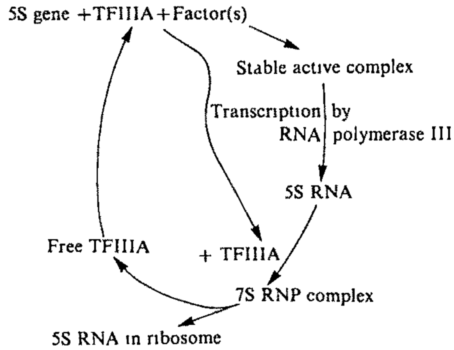
Stable gene expression *in vitro*

from H R Woodland

ONE characteristic of cell differentiation is its high degree of stability, and there is a suspicion among molecular biologists that this derives from a basic stability in the expression of genes involved in differentiation Our understanding of the issue is unlikely to improve beyond this point, however, until systems are developed which enable active genes to be reconstructed *in vitro* Bogenhagen, Warmington and Brown of the Carnegie Institution of Washington, together with R G Roeder's group at the University of Washington, may now have developed just such a system In a recent issue of *Cell*[1], they describe the construction of 5S gene protein complexes with the properties of stable gene expression or repression that have been suggested to occur in intact cells

As much is known about 5S gene transcription as for any other eukaryotic gene (see Korn's recent review in *Nature*[2]) 5S genes encode 5S RNA, a component of all ribosomes except those of animal mitochondria Like tRNA and a few other small RNAs, 5S RNA is produced by RNA polymerase III, a different enzyme from that which makes mRNA The unusual characteristics of this polymerase mean that the 5S genes differ in structure from genes encoding mRNA Surprisingly, the only part of the 5S gene actually essential for its transcription is residues 50–83 of the 120 nucleotides that are transcribed This region binds a 40,000 molecular weight protein, called TFIIIA by Roeder's group[3], which produces accurate transcription of the gene TFIIIA also binds to 5S RNA, forming a 7S ribonucleoprotein (RNP) particle This may provide a means of transcriptional regulation whereby the free protein stimulates 5S RNA synthesis, but is removed by the product of this synthesis (see the figure) A last important feature of 5S RNA, at least in *Xenopus laevis*, is that oocytes and somatic cells contain 5S RNAs of different sequence The main oocyte 5S RNA is encoded by 20,000 genes called 5S *ooc*, and that in somatic cells by a separate set of 400 genes called 5S *som*

Why do somatic cells contain different 5S RNAs? Selective transcription of the 5S *som* genes seems the cause In oocytes, some 5S *som* RNA is made, perhaps in proportion to the small number of 5S *som* genes, but the RNA seems not to enter ribosomes and is degraded[4]. Free 5S RNA is known to have a short lifetime in both oocytes and somatic cells[6-8] Unfortunately, the role of degradation in regulating 5S gene expression has never



Possible scheme of 5S RNA synthesis In a very young amphibian oocyte, 5S RNA is made in great excess of other ribosomal components and enters a 42S RNP particle, instead of a ribosome As the 42S RNP particle does not contain TFIIIA[10], the latter is released and can stimulate further 5S synthesis, just as in the normal cycle shown here

been accurately quantified in any system

The latest experiments from Brown's laboratory[1] use cell-free systems made from either oocytes or somatic cells If 5S DNAs of different types are added simultaneously to a cell-free system they compete for transcription[9] It has now been shown, however, that if two DNAs are added at different times, the first is transcribed in preference to the second[1] Indeed, if enough of the first DNA is added subsequent DNAs are not transcribed at all, no matter how much is added The first DNA seems to form a very stable, transcribable complex within a minute or two This is not an actual transcription complex, since maximal transcription is established much more slowly, thus agents other than the polymerase, but necessary for polymerase binding, must be involved in formation of the complex It might be guessed that TFIIIA is one such agent, but although 5S DNA may be bound to TFIIIA, this alone does not confer favoured transcription status upon it

Bogenhagen *et al* [1] were also able to make stable inactive 5S gene complexes Using a transcription system depleted of TFIIIA by antibody treatment, they showed that 5S DNA does not form the active complex unless further TFIIIA is added However, if histones were added instead of TFIIIA, a different complex was formed which could not then be reactivated with TFIIIA The possibility that this complex is an artefact is unlikely, since the transcription of tRNA genes is unaffected by added histones (tRNA genes do not require TFIIIA for transcription)

Bogenhagen *et al* [1] speculate that the stable complexes they have constructed *in vitro* have similar counterparts in cell-free systems This remains to be proved At least natural 5S DNA protein complexes show similar stability to those made in cell-free systems — chromatin added from somatic cells or oocytes to the same systems used to transcribe the pure 5S DNAs continues to express only those genes which were active in the intact cells from which it was derived This emphasizes that the cell-

H R Woodland is in the Department of Biological Sciences, University of Warwick, Coventry CV4 7AL

0028-0836/82/230457-02$01 00

free systems do not reprogramme chromatin, nor indeed do oocyte or somatic cell-derived systems discriminate significantly between 5S *ooc* and 5S *som* genes Why then are these genes expressed differently in oocytes and somatic cells? Bogenhagen *et al* [1] suggest that the activity of the 5S genes is determined by events during chromatin construction at DNA replication which establish an active or inactive structure that persists throughout the ensuing cell cycle The two states could be propagated through the next DNA replication unless hypothetical factors are present which change the state of the gene This hypothesis is consistent with many observations suggesting that DNA synthesis is necessary for changes in the differentiated phenotype of cells It does not fit, however, with Korn and Gurdon's[5] observation that the oocytes of certain *Xenopus* females can activate the oocyte genes of somatic nuclei in the absence of DNA replication

Bogenhagen *et al* [1] also suggest that what goes for 5S genes might also apply to genes involved in cell differentiation The dissimilarity of the transcription of the two sorts of genes by RNA polymerase III and RNA polymerase II respectively does not encourage heavy bets on this possibility Yet advances in this area certainly depend heavily on developing cell-free systems which accurately reproduce the gene regulation of intact cells There is no doubt that the new 5S systems show exciting possibilities in this direction, even if they do not yet solve the problems of cell differentiation □

Leg 84 of the Deep Sea Drilling Project

Subduction without accretion: Middle America Trench off Guatemala

from Jean Aubouin*, Roland Von Huene†, Miriam Baltuck‡, Robert Arnott§, Jacques Bourgois*, Mark Filewicz , Keith Kvenvolden†, Barry Leinert**, Tom McDonald‡‡, Kristin McDougall‡‡, Yujiro Ogawa§§, Elliot Taylor‡‡ and Barbara Winsborough

PRESENTED below are the first results from the recent visit of the drilling vessel *Glomar Challenger* to the southern Guatemalan segment of the Middle America Trench (Leg 84 of the Deep Sea Drilling Project/International Phase of Ocean Drilling, January–February 1982) The area, shown in Fig 1, had been selected for investigation because of several interesting problems that had been posed by earlier visits to the region In 1979, Legs 66 and 67 had produced contrasting results from the two halves of the Middle America Trench divided by the Tehuantepec Ridge — on Leg 66 ocean sediment was found to be accreting against the landward slope of the trench, while on Leg 67, off Guatemala, no accretion was found Leg 67 results come mainly from one site (494) on the landward slope of the trench where basement was reached [3], drilling at three other sites were abandoned when gas hydrates were unexpectedly recovered

Seabeam [4] and deep tow instruments were also used to survey the area examined by Leg 67 The original fabric of the Cocos Plate at the East Pacific Rise is delineated by magnetic anomalies which trend 20° from the direction of the trench axis As the Cocos Plate is flexed into the trench, it breaks into oblique extensional ridges and troughs paralleling the original fabric of the Cocos Plate, and the surface expression is one of collapse into the subduction zone

On the landward slope of the trench the structural picture is less clear Palaeogene and Cretaceous rocks were recovered at its base, suggesting non-accretion off Guatemala and showing that a tectonic history exists below the Neogene slope sediments More definite conclusions could not be drawn because only one penetration had been made below the Neogene slope deposits The recovery of visible gas hydrate made further drilling unsafe because the base of the gas-hydrated sediment had, at the time, not been defined in seismic records and it was feared that free gas might be trapped at the base of an impermeable hydrated section

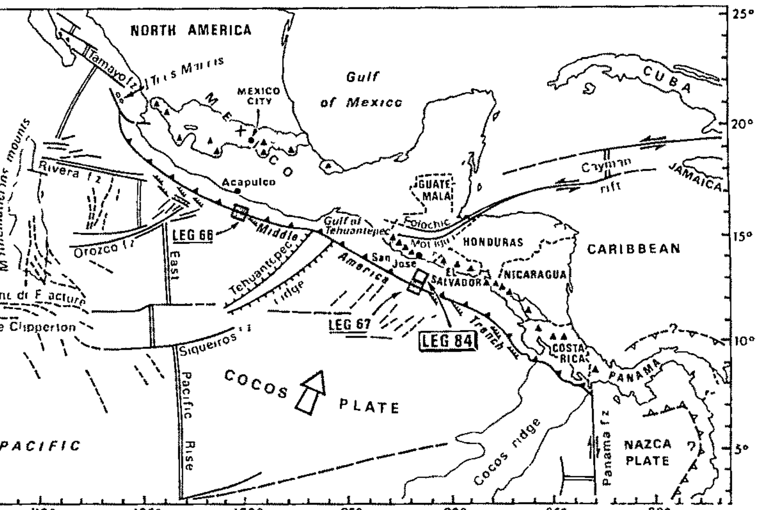

Fig 1 Sketch map of Middle America Trench

Leg 84 was recommended by the JOIDES advisory panels specifically to examine the tectonic and gas hydrate problems. Local base of gas hydrate reflections were found in a re-examination of predrilling site survey data and after enhancement and combination with refined temperature gradient information, the depth of the base of gas hydrate was established. Basements high above the base of gas hydrate were selected for drilling.

At the penetration sites (Fig. 2) basement was found to consist of ophiolitic rock covered by sediments of early Eocene (sites 569, 570), late Oligocene–early Miocene overlying late Cretaceous (567) and late Miocene (566) age. No age progression (younger rocks at the base to older at the top of the slope), as admitted over the supposed accreted complex off Mexico where only Neogene deposits were drilled, was found. The sites are distributed transverse to the margin and are laterally separated by as much as 100 km. Peridotite (harzburgite), gabbro, dolorite, basalt and much serpentine in various stages of decomposition were recovered. These rocks were of a metamorphic grade from low-temperature to greenschist facies and were tectonically juxtaposed without particular order. The Guatemalan margin is therefore underlain by tectonically disrupted ophiolitic rock.

The ophiolitic rock was tectonized and the tectonic complex was emplaced before the present arc-trench tectonic system. Clastics of ophiolitic rock were included in the unaltered slope sediment, particularly at the base of the slope where debris flows contain large blocks of serpentinized peridotite. Other studies[5-7] suggest the tectonic history includes three major periods:

(1) Ultramafic rock is thrust over the Jurassic–Cretaceous Nicoya complex[6] and is in turn overlain unconformably by Campanian sediments, as is evident on the Santa Elena Peninsula[8]. Initial tectonism of the Guatemalan ophiolitic rock could have started at this time, and the Cretaceous sediment at the base of the slope could correspond to the Campanian sediment cover.

(2) A strong Palaeocene uplift, documented in the Petrel well[9], may immediately pre-date the early Eocene sediment recovered at two sites.

(3) A strong Oligo–Miocene faulting left a sharp angular unconformity observed in seismic records across the edge of the shelf; the first thick hemipelagic slope mudstone deposits of the present tectonic system developed during and after this event.

There is nothing to indicate development of the present arc-trench system until the late Oligocene when the first substantial layers of volcanic ash are seen in the slope cover. The ophiolitic rock of the Guatemalan margin was certainly emplaced in pre-Eocene time and appears to be an extension of the continent of Central America. At the base of the slope

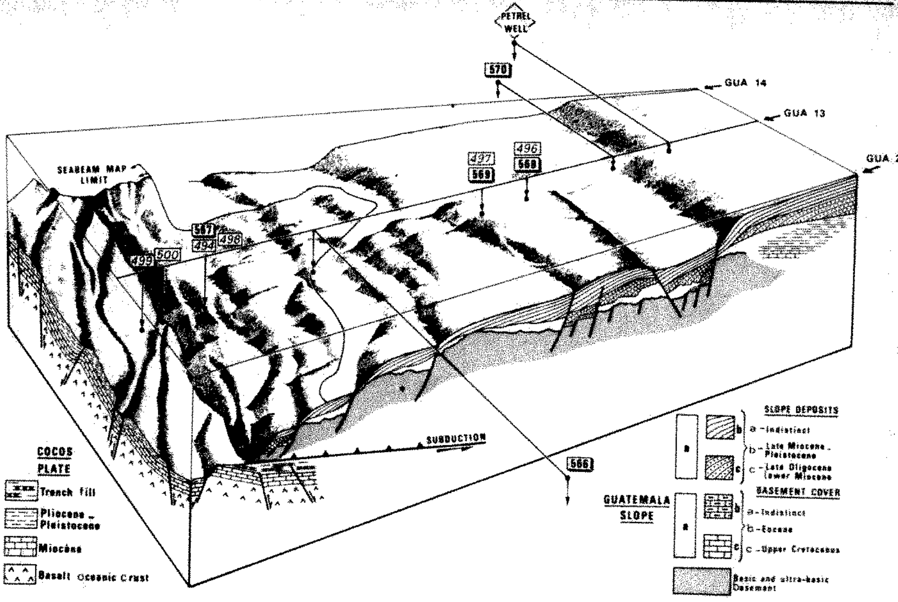

Fig. 2 Block diagram showing the convergent zone between Cocos Plate and Carribbean Plate in Leg 84 area. The morphology is reconstituted from *Jean Charcot* seabeam data and GUA 2, GUA 13 and GUA 14 seismic profiles of Texas University.

(Site 567) we came close to penetrating through the upper plate into the subduction zone. Here, Miocene to present oceanic and trench sediments are being subducted beneath the pre-Campanian ophiolitic rock at the front of the margin. Drilling ended when the hole collapsed, and the drill string became stuck. Collapse was accompanied by overpressured pore fluids — overpressure had also been observed at sites in top, mid and lower slope. Seismic records across the mid and upper slope sites show few compressional faults or folds in the slope sediment where the overpressures were observed. In fact, the most obvious structures on the transect are normal faults at the base of the slope. Elevated pore pressures are to be expected across the subduction zone, and such pore pressures help to explain the degree of decoupling required to subduct soft sediment beneath a mass of hard ophiolitic rock. High pore pressure appears to be very common in the Guatemalan convergent margin and occurs even in slope deposits that show few structures.

Many local unconformities and hiatuses were detected in sites drilled in slope deposits on the Guatemalan margin and indicate that as one depocentre is rapidly accumulating sediment, another may have lost its feeder channel and temporarily be in an interchannel or erosional area. Hollows and topographical flats from initial faulting of the surface of the ophiolitic mass are sites of ponded basins or early Miocene prograding sediment bodies. The sediment in these sequences locally contains more sand than is found in the sediment ponded in the trench axis. Sand was recovered in the channel areas, demonstrating again that the channels transport sand directly to the trench. The presence of a large amount of sand and rapid sediment accumulation is not a lithological criterion by which to distinguish between trench and slope deposits off Guatemala.

Slope deposits off Guatemala are now classic sites for gas hydrate[10] which was detected at all sites, except 567, and was recovered many times at 568, 570. The best recovery was at site 570 where a massive 3 m thick gas hydrate was cored, and samples were preserved in special pressure vessels for onshore studies. The gas hydrate was recognized: (1) visually, (2) by volumes of gas released during hydrate decomposition that greatly exceeded the volume of gas in gas-saturated water, (3) by composition — the hydrocarbon gases combined no molecules larger than isobutane, (4) by the decrease in chlorinity and salinity characteristic of the freshwater composition of gas hydrates, and (5) by sonic and density logs showing high velocities and corresponding low densities. These are the first demonstrated log responses of cored gas hydrates in oceanic sediment and provide the first measurements of their *in situ* sonic velocity and density.

Gas hydrates were found dispersed in very fine-grained sediments; associated with porous, coarse-grained sediments; occupying fractures; and as a massive unit. Geophysical records off Guatemala do not show strata corresponding to the massive gas hydrate or any other gas-hydrated horizon; only the base of gas hydrate reflecion is laterally continous, and this reflection was observed at many places on the slope, namely at one of the sites occupied (568).

Inorganic geochemical studies on Leg 84 confirm the proposed relationship between low values of salinity and chlorinity and the occurrence of gas hydrates. In all cases where gas hydrates were observed on Leg 84, values of salinity and chlorinity were lower than in sediments where gas hydrates were absent.

Most gas hydrates found were composed of gases from microbial and early diagenetic processes. However, at two sites

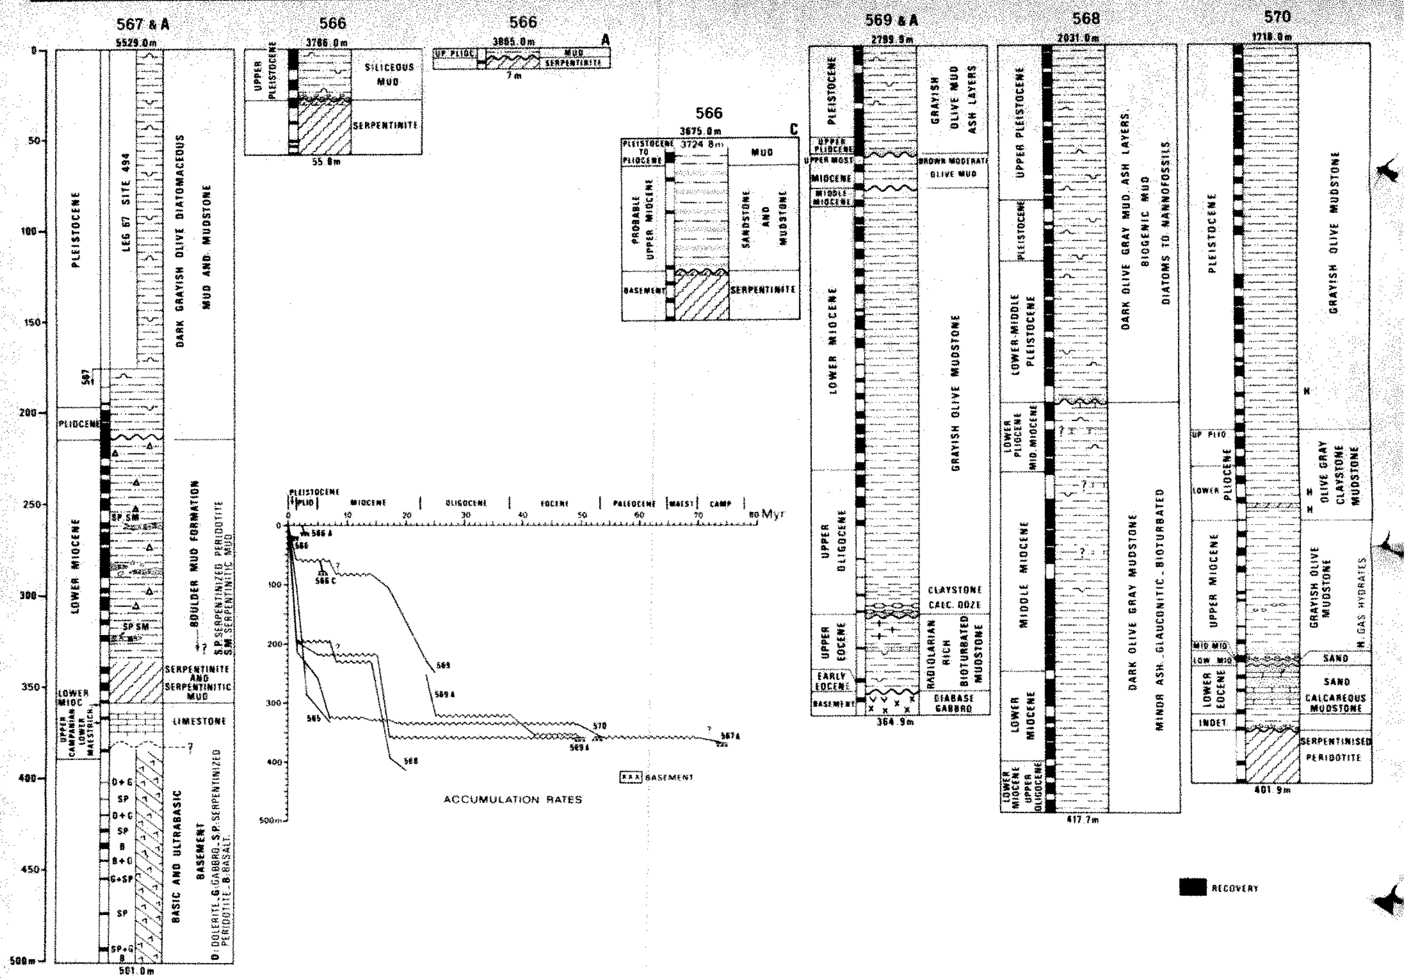

Fig. 3 Simplified stratigraphical columns summarizing the lithostratigraphy, biostratigraphy and recovery of Leg 84 drill sites.

(566 and 570) the gases found associated with serpentinite were probably a product of the thermal breakdown of organic matter because they contained very high concentrations of hydrocarbon gases, particularly of ethane relative to methane, and hydrocarbons at least as large as hexane and heptane.

Conclusions

(1) The DSDP/IPOD Guatemalan transect across the Middle America trench has defined a non-accretionary convergent margin; Neogene subduction has not resulted in the development of an accreted complex; rather, a mass of tectonized ophiolitic rock now faces the subducting Cocos Plate (Fig.3). The ophiolitic rock was emplaced before Eocene time in a previous tectonic system: at the trench the Cocos Plate is of Miocene age.

(2) A horst and graben topography gives the Cocos Plate the appearance of collapsing into the trench, and the adjacent base of the Guatemalan margin is also normally faulted. However, given the 10 cm yr^{-1} plate convergence rate, this extensional topography must be surficial and secondary. The topography of extension in a fundamentally compressional environment can be explained on the seaward slope of the trench by flexure of the Cocos Plate; on the landward slope of the trench it may be explained by a high degree of decoupling across the subduction zone. Decoupling is required to subduct sediment on the lower Cocos Plate beneath the ophiolitic upper plate rather than accreting it. A classical mechanism for such decoupling is overpressured pore fluid such as that measured only a short distance above the Middle America subduction zone. Elevated pore pressure was measured not only in the vicinity of the subduction zone but also in slope sediment across the transect, indicating a general overpressure condition throughout much of the margin.

(3) Beneath the cover of slope sediment, the basement of the Guatemalan margin is an extension of the Central American continent.

(4) The major results of Leg 84 were achieved by drilling below the present slope sediment and into basement. Accretionary complexes may be defined by their geometry in seismic reflection records, but results from most of the convergent margins drilled during the IPOD programme indicate that the accretion observed in seismic records may belong to previous tectonic systems; accretionary periods may alternate with non-accretionary periods. Thus, a seismic record alone may be insufficient to establish the tectonic history or the present tectonic system in a convergent margin. Unless the accretionary complex is sampled, its time of emplacement and relation to the present tectonic system is uncertain.

(5) Gas hydrates are probably dispersed throughout many marine sediment sequences that lie in the zone of gas hydrate stability; they can be detected by seismic techniques when bottom-simulating reflectors appear on seismic records. The occurrence of visible gas hydrates in cores is in part a function of effective porosity and perhaps permeability. Off Guatemala gas hydrate is found finely dispersed in mudstone, as a solid in fractures, in the pore space of sandy ash layers, and in massive form, filling voids of unknown origin. □

REVIEW ARTICLE

Radar research on thunderstorms and lightning

W. David Rust & Richard J. Doviak

National Severe Storms Laboratory, National Oceanic and Atmospheric Administration, Norman, Oklahoma 73069, USA

Weather radars can resolve many phenomena related to thunderstorms. Echoes from clear air, water and ice condensate, and ionized lightning channels can all be identified. Radial velocity data from two Doppler-radars are synthesized to show a storm mesocyclone with updraft speeds as large as 40 m s^{-1}, moist boundary layer air flowing into the storm, and outflow into the upper troposphere. Maximum wind speeds in tornadoes can be remotely measured using Doppler spectra obtained with a high PRF radar. Doppler radars can detect thunderstorm gusts even when they are in the clear air many tens of kilometres away from the storm, and radar detection of the ionized channels caused by lightning opens new avenues into thunderstorm research.

EVERY year, starting in early spring in the southern states of the USA and ending in mid-summer in the southern provinces of Canada, severe local storms sweep across the Great Plains of North America bringing tornadoes, hail, damaging gusts, and lightning, as well as beneficial rains and cooling outflows. These storms, each a few tens of kilometres in diameter, ingest warm moist air trapped in the first kilometre or two of the atmosphere, convert moisture to rain and sometimes hail, and vent air heated by condensation into the cold upper (9–13 km) troposphere.

Researchers have been observing stormy weather over the past few decades with various instruments. One of the most significant of these is the Doppler weather radar. Radar is the only remote sensing instrument able to expose the internal structure of thunderstorms veiled by clouds that give little evidence of the enclosed hazards. Atmospheric research with radars in the USA is principally supported by: (1) the National Science Foundation, which supports universities directly and through the National Center for Atmospheric Research, (2) the National Oceanic and Atmospheric Administration (NOAA), which maintains and operates a network of weather radars for storm hazard warnings and which contains the Environmental Research Laboratories that support weather radar research having potential operational application, and (3) the Department of Defense, which supports weather radar research through its Air Force Geophysics Laboratory. The French[1] have a small but well organized Doppler weather radar research programme, and the Soviets[2] have long used Doppler radars in weather research. The Canadians[3,4] have a strong research programme to determine precipitation characteristics (such as shape, size, and ice or water) using radars with polarization diversity and dual wavelengths. Recently, the British[5] have shown how dual polarization radar can better identify precipitation type and improve rainfall rate estimates. Research on rainfall and hailfall accumulations, the foundation for many years of weather radar research, continues in the USA[6,7], Switzerland[8], Japan[9], and other countries[10–13]. Recently, aeronomists in the USA[14,15] and Germany[16] have focused large area (for example, 10,000 m^2), long-wavelength (6 m) Doppler radar antennas into the troposphere to study the air motions in cloudless skies. Researchers have also used short-wavelength (10 cm) Doppler weather radars to map winds in the clear air prestorm environment and have obtained results suggesting improvements in prediction of storm location and severity[17,18].

Although lightning is necessary in thunderstorms, only recently have there been coordinated studies to undertake simultaneous measurements of the storm's electrical properties, its precipitation intensity, and its wind fields. One such coordinated effort has been the Thunderstorm Research International Program[19] in which experiments have been conducted in Florida and New Mexico in the USA. Initial results of these and other experiments show correlations between lightning and winds inside the storm[20,21]. Not only does lightning seem to be linked to storm dynamics in the highly convective spring and summer thunderstorms, but it also seems related to the dynamics in weaker winter storms. The recent observations by Brook *et al.*[22] show a correlation between the occurrence of lightning that transfers positive charge to earth and the vertical shear of horizontal wind in the winter thunderstorms along the Hokuriku coast of Japan.

There are many research organizations investigating various aspects of weather phenomena, but at NOAA's National Severe Storms Laboratory (NSSL), located in Oklahoma in the heart of the Great Plains, observations and research are focused on the interactions between storm electricity, precipitation, and wind in severe thunderstorms using: (1) two 10-cm wavelength pulsed Doppler weather radars powerful enough to sense the evolving wind fields in the prestorm environment; (2) the USA's tallest meteorologically instrumented tower; (3) a network of surface-based electrical and meteorological sensors; (4) a unique passive network of radio receivers to map lightning inside clouds and to locate the strike point of cloud-to-gound flashes; and (5) a system to guide instrumented aircraft in their penetration of the intense and turbulent storms.

The continued study of storm electricity, precipitation, and dynamics with recently developed remote sensing instruments could improve our understanding of how thunderstorms organize themselves. Improved predictions and warnings of hazards should result. We now summarize aspects of the use of radar to observe remotely the hazardous phenomena of thunderstorms.

Doppler weather radar

As its beam sweeps through the storm, the weather radar maps the distribution of precipitation by measuring reflectivity factor Z (the product of the number of drops per m^3 and the average sixth power of their diameter expressed in mm (ref. 23)) and generates a three-dimensional 'photograph' of reflectivity fields, typically in 3–5 min. Transmitted radar pulses also reflect from ionized paths created by lightning within the radar beam. Furthermore, radar can detect echoes returned from the small irregularities of the air's temperature and humidity in the optically clear atmosphere[24]. Irregularities of centimetre size and temperature variations as small as 10^{-3} °C produce reflectivity detectable by radar, although invisible to the naked eye. However, the eye can see the scintillation of stars caused by these temperature fluctuations. Echoes from such targets in the first kilometre of the clear atmosphere can be seen in Fig. 1*b*.

Doppler radar adds information through its ability to measure target speeds. Doviak *et al.*[24] have reviewed the principles of

Doppler weather radar, and we highlight those to help interpret the data we present. The motions of targets towards or away from the radar (that is, radial velocities) cause minute shifts (~0.01 p.p.m.) in the microwave frequency of echoes in the same manner as a passing train causes shifts in the observed pitch of its whistle. Because there are usually many millions of targets moving at different velocities, the Doppler radar actually measures a spectrum of radial speeds within its resolution volume, defined by the beamwidth and the pulse length of the transmitted radiation. The resolution volume is an inherent characteristic of the radar for zero antenna scan rate. Because echoes from several tens of transmitted pulses are required to determine the Doppler spectrum, the volume contributing to the spectrum is larger than the resolution volume[25] if the beam scans while receiving echoes. This larger volume is defined as the measurement volume. The width of the radial velocity distribution within the measurement volume can be $<1\ \mathrm{m\ s^{-1}}$ when there is no wind shear or turbulence, or as much as $100\ \mathrm{m\ s^{-1}}$ when a tornado is contained within the volume. The average velocity v and the variance σ_v^2 of the radial velocity distribution are the first and second moments of the Doppler spectrum.

Because the Doppler radar measures only the component of target velocity in the direction of the radar, three or more radars must map Doppler speeds nearly simultaneously from different directions to synthesize the three components of velocity. However, the three components of wind are connected by the mass continuity equation so that only two spaced radars are sufficient to estimate the wind field[26]. Because ice crystals and water drops fall through the air, estimates of their fall speeds relative to the air (terminal velocities) need to be made when these are the tracers of wind. (Note that velocities relative to the ground are fall velocities.) Terminal velocity estimates are usually based on the reflectivity of the hydrometers[27]; larger ones have higher terminal velocities and reflectivities. Refractive index irregularities and lightning channels have zero terminal velocities.

Observations

Storm structure is well illustrated when data from a single radar are displayed on a range height indicator (RHI) that gives vertical cross-sections of Z, v, and σ_v. Figure 1*a*, *b* shows respectively, Z (scaled in decibel units, dBZ) and v, in cross-sections along a 347° azimuth, for a severe thunderstorm. Visible in the Z field (*a*) is an anvil of cloud particles extending to the left (SSE) at ~10 km AGL (above ground level). More of the anvil is evident in the velocity display (*b*) for which the signal-to-noise ratio (SNR) threshold has been reduced to show the motion of the weakly reflective particles, which are probably ice crystals. Storm overhang and strong reflectivity gradients below 2 km AGL on the storm's south side suggest strong inflow into the storm. If we assume that the hydrometers are liquid and have the Marshall–Palmer[28] exponential dropsize distribution often used by radar meteorologists, then the 20 dBZ contour near the ground corresponds to a rainfall rate $<1\ \mathrm{mm\ h^{-1}}$ and 30, 40 and 50 dBZ to ~3, 10 and $50\ \mathrm{mm\ h^{-1}}$, respectively. Often the high reflectivity regions (>50 dBZ) extending to the ground contain wet hail, which causes errors in the estimate of rainfall rate. Melting ice crystals mixed with rain in the region (melting layer) between the freezing temperatures above and warmer temperatures below can also cause a significant error in rainfall rate estimates.

The Doppler velocity field in Fig. 1*b* depicts motions to the right and away (positive velocity) from the radar as well as motion towards (negative velocity) the radar. The storm outflow, assisted by northwesterly winds outside the storm, carried cloud particles in the anvil causing it to grow southeastward towards the radar. In the anvil, air velocities were more negative than $-27\ \mathrm{m\ s^{-1}}$, the Nyquist limit[24] of the radar, so they appear as high positive values (but less than $+27\ \mathrm{m\ s^{-1}}$) and are seen as patches of lightest red embedded in regions of lightest green. The momentum of updraft air carried condensate into the lower stratosphere where negative buoyancy forced air downward and outward around the updraft. This latter motion is evident in Fig. 1*b* above the anvil on the storm's southern side where we see the highest radial velocities.

The velocity data in Fig. 1*b* above the upper edge of the boundary of the reflectivity field shown in Fig. 1*a* are due to antenna sidelobes receiving echoes from the high reflectivity regions when the main beam lobe is pointed above the storm (due to reception of signals from directions away from the antenna axis at angular distances larger than the beamwidth). These falsely mapped velocities do not portray the true wind there. Antenna sidelobes constitute one of the more important limitations to expanding the utility of Doppler radars. However, if there are no strong echoes at a given range in the main or sidelobes, then the Doppler radar can accurately sense the velocities in weak echo regions in the main beam at that range. For example, weakly reflecting targets drifting with the flow in the clear air boundary layer (low altitude, red region in Fig. 1*b* between ranges of 50 and 60 km) trace the air moving into the storm.

Although radial velocity fields from one radar exhibit many interesting storm features, they cannot unambiguously depict the wind. Figure 2*a* shows a horizontal cross-section of a tornadic storm that formed in central Oklahoma[29] on 2 May, 1979. The three components of wind were obtained from radial velocity measurements made by two radars spaced 70 km apart, a reflectivity–terminal velocity relation, and integration of the mass continuity equation using suitable boundary conditions at the ground and the cloud top[30]. The large circulation of air seen in Fig. 2*a* is a thunderstorm cyclone. Because thunderstorm cyclones are much smaller than extra tropical ones or tropical cyclones, including hurricanes, these circulations are called mesocyclones. Not all thunderstorms develop mesocyclones, but when they do so, they have the potential to generate large and long-lived tornadoes as did this one. In all the cases observed, large tornadoes have been preceded by mesocyclones. Mesocyclones have diameters ranging from a few to ~10 km and can extend in height from near the ground to near the tropopause. Tornadoes are smaller scale vortices imbedded within the mesocyclone, and if their centres do not coincide (as in Fig. 2*a*), the tornado circulates around the mesocyclone centre forming a trochoidal path on the ground as the mesocyclone and tornado are translated by the moving storm[31]. Note that the small scale tornado vortex is not resolved in Fig. 2*a*.

The inflow of air from the south-east in the first 2 km AGL, and updrafts as large as $40\ \mathrm{m\ s^{-1}}$ can be seen in Fig. 2*b*. Inflow air lacking precipitation targets is also detected by radar as shown in Fig. 1*b*. Large gradients of reflectivity mark the region of inbound air, and strong outflow occurs in the anvil at 12 km AGL. These are features similar to those seen in the single radar data fields (Fig. 1*a*, *b*). Although the cross-section in Fig. 2*b* shows mostly updrafts, other regions of the storm have downdrafts. The chilled downdrafts are sometimes so

§ Lead time between issuing of warning and tornado occurrence.

strong and enduring that they form cooled air masses that extend many kilometres beyond the storm cloud.

Observed winds compared with model predictions

High-speed, high-capacity computers allow us to model numerically thunderstorm evolution. As computers become faster and less expensive and models more computationally efficient, it even becomes feasible to use prestorm environmental parameters (vertical profiles of temperature, moisture and wind) for improved predictions of weather events. Figure 3 shows a comparison of a numerically modelled storm formed in an environment similar to that of an observed storm[32] in which wind at 4 km AGL is from the SSW (199°) at 25 m s^{-1}. Winds are relative to storm motion (14 m s^{-1} at 192° for the model; 18 m s^{-1} at 193° for the observed storm). The heavy contour in Fig. 3*a* corresponds to a reflectivity factor of 38 dB*Z*, assuming the Marshall–Palmer dropsize distribution. Seen in both the modelled and observed storms are the updrafts and downdrafts with reasonable agreement in shape, location and intensity. The updraft blocks the dry environmental air at 4 km and diverts it around the storm whose circulation causes higher speed dry air to intrude into the storm's east side. There the fast-moving dry air deflects and evaporates the condensate, thus forming a notch-like feature in the reflectivity contour, seen in both the model and observations.

Tornado observations

When a tornado is contained within the radar's resolution volume, the Doppler velocity spectrum becomes very broad[33]. When radar targets have small terminal velocities, the Doppler spectra can be analysed to determine the flow of air around the tornado[34,35]. The only scanning of a large tornado (Fig. 4*a*) with a pulsed Doppler radar operating with a Nyquist interval sufficiently large (±91 m s^{-1}) to measure unambiguously the high tornadic wind speeds was in Spring 1981 at NSSL. The Nyquist interval, $\pm\lambda/4T_s$, is determined by radar wavelength λ and the period T_s between transmitted pulses. Targets moving at speeds higher than the Nyquist limits produce signals that are not sampled often enough to resolve unambiguously the Doppler shift. The contour in Fig. 4*a* shows the approximate location and cross-section of 16 consecutive (in range) measurement volumes within which targets produced the 16 Doppler spectra shown in Fig. 4*b*. Each spectrum gives the distribution of velocities within one of the 16 measurement volumes, and each volume has a range extent of ~200 m. These spectra were recorded within a minute of the time of the tornado photograph in Fig. 4*a*. Because the antenna was scanning in azimuth while data were collected to form these spectra, the measurement volume has an azimuthal dimension of 1.5°, although the beamwidth is 0.8° (ref. 25). The 16 volumes are aligned along the

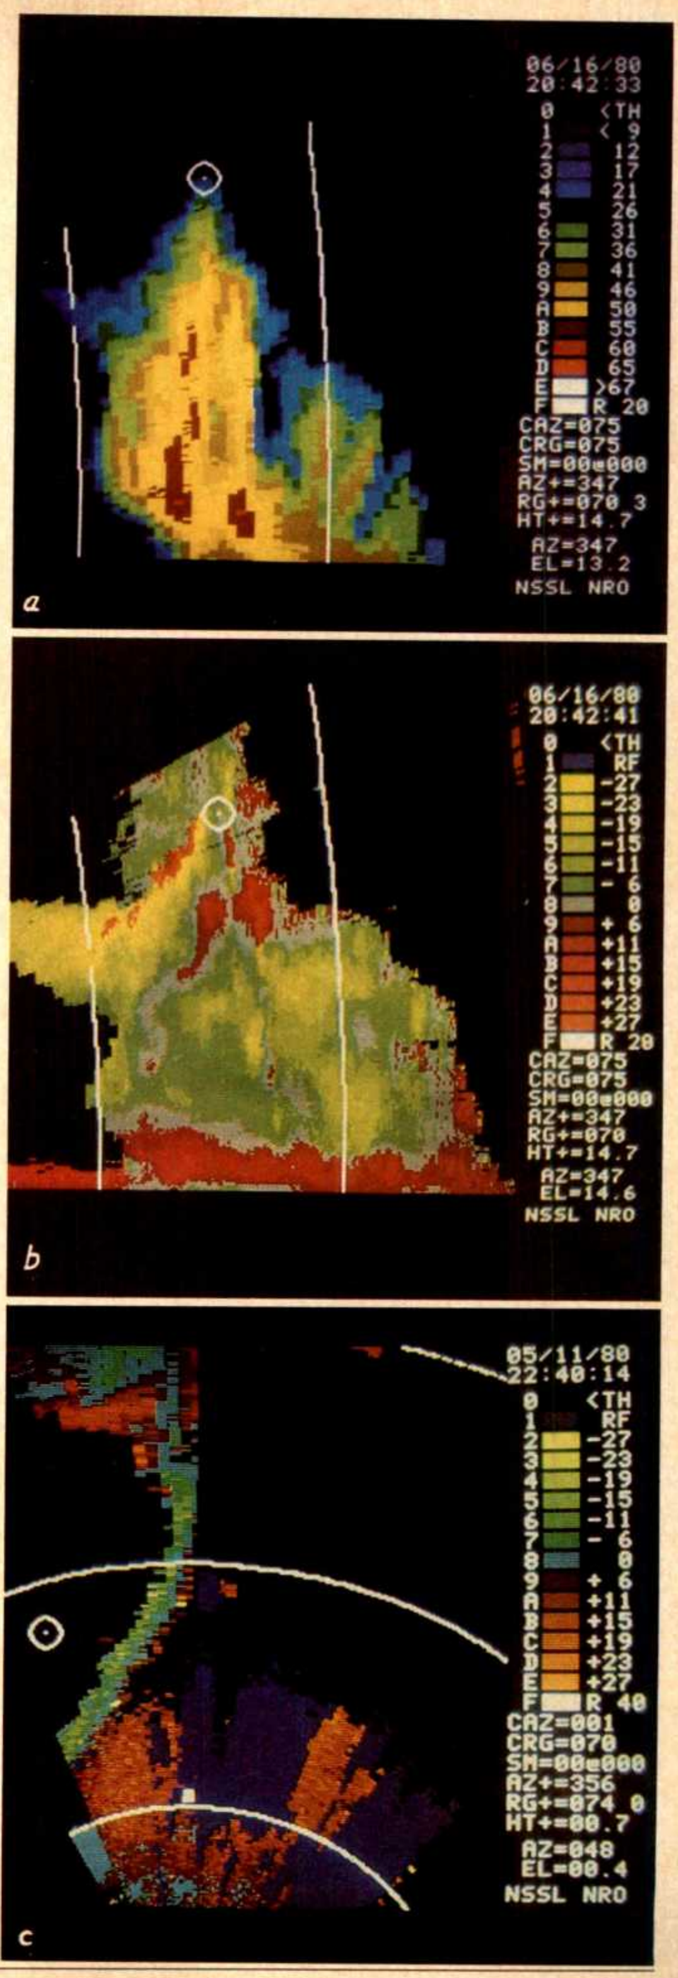

Fig. 1 *a*, Vertical cross-section of reflectivity factor *Z*, a measure of precipitation intensity, through a severe storm that occurred in central Oklahoma on 16 June 1980. The storm top (indicated by dot in white circle) is at 14.7 km AGL. The two shades of blue indicate median values of $10 \log_{10} Z$ (dB*Z*) equal to 17 and 21; the three shades of green correspond to 26, 31 and 36 dB*Z*; the three of yellow to 41, 46 and 50 dB*Z*; and the two of red to 55 and 60 dB*Z*. The relation between dB*Z* values and rainfall rate is given in the text. The radar location is to the left, and the vertical arcs are at 60 and 80 km from the radar. *b*, Radial velocity field in the same vertical section as *a*. Red (green) coloured areas are radial velocities away from (towards) the radar. The shades from dark to light correspond to median radial velocities of 6, 11, 15, 19, 23 and 27 m s^{-1}. The grey hue is for a median value of 0 m s^{-1}. Differences in storm outline from that in *a* are discussed in the text. *c*, Radar depiction of radial velocities in a bow gust line produced by thunderstorm outflow at ground level. Colour code is the same as in *b*. This is an azimuthal sweep through the gust at a constant elevation angle of 0.4°, and the arcs are at 40 and 80 km range.

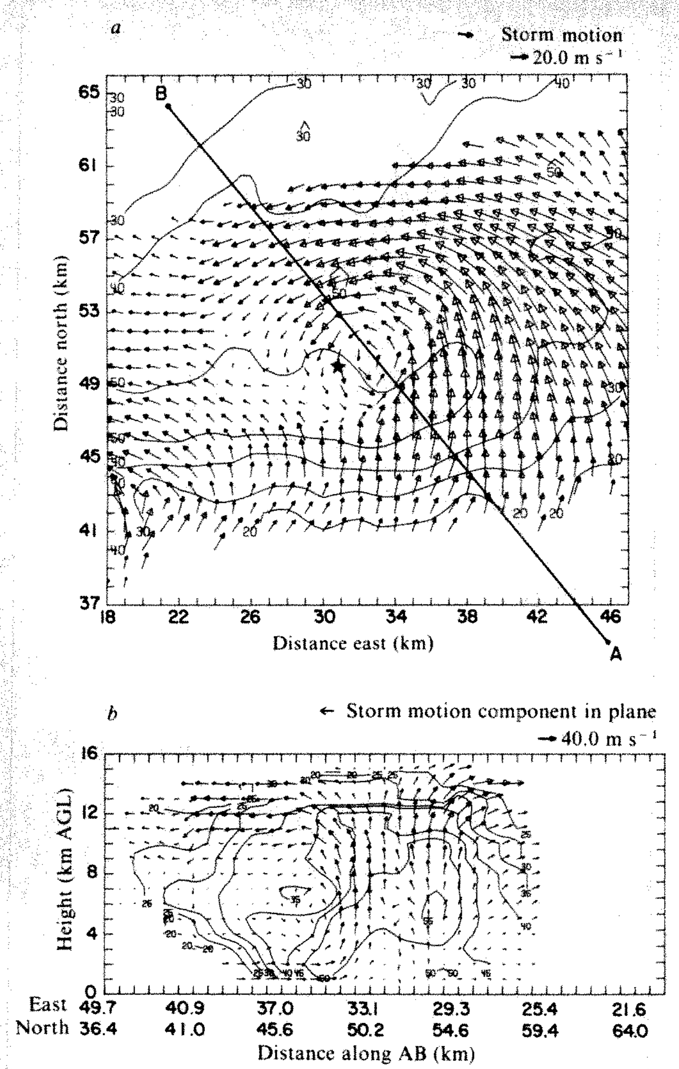

Fig. 2 Contours of reflectivity factor in dBZ and the wind field in a horizontal cross-section at 2 km AGL (a) and a vertical cross-section (b) of a tornadic thunderstorm. Winds are in the coordinate system moving with the storm. Storm motion speed and direction are shown. Line AB in a is the location of the vertical cross-section. Distances are from a radar at Roman Nose State Park, Oklahoma[29]. ★, The tornado location in a. The arrow of indicated velocity at top right of each plot gives speed which is proportional to arrow length (E. Brandes and B. Johnson, personal communication).

beam, but only two or three of these cross the tornado's circle of maximum wind. In Fig. 4b the widest spectra denote the location of the tornado. Maximum tornado wind speeds can be estimated from these data. At this time the radar-measured maximum winds were ~90 m s^{-1}. Acquiring *in situ* data in and around the tornado is very difficult, but Doppler radar provides a remote and relatively safe method of surveying storms for tornadoes.

Although in principle two or more Doppler radars are required to depict circulations inside storms, a single Doppler radar can indicate circulations, such as mesocyclones, that have nearly circular symmetry. The circulation signature of large mesocyclones shows itself remarkably well on colour displays (see cover of ref. 36). Because mesocyclones are often several kilometres in diameter (see Fig. 2a), their circulations can be resolved to ranges of ~200 km with radars having beam widths <1°.

A test was conducted in Oklahoma to determine how tornado warnings are improved over the present non-Doppler warning system when Doppler information alone is used to forecast tornadoes. Table 1 compares several measures of effectiveness of tornado warning using Doppler radar alone with present techniques which rely heavily on visual sightings. The critical success index (CSI)[37] gives credit for a high probability of detection and low false alarm rate, with a CSI of 1.0 being perfect.

Doppler radar can increase the average lead time before tornado occurrence by 20 min, thus offering the population a longer time to take cover if warnings are communicated properly. Although the probability of detection at the instant of issuance of warning is not significantly improved, the false alarm rate is significantly decreased with Doppler radar. Therefore, Doppler radar can reduce the overwarning inherent in the present system even while giving longer lead times, and warning areas may be reduced substantially by precise location of the storms containing mesocyclones.

Gust fronts

A gust front is the leading edge of cool air produced when a raincooled downdraft turns into an outward moving, ground-based flow. The front is marked by shifts (shear) in the wind, both in the vertical and horizontal directions. A gust front can propagate in the clear air many tens of kilometres away from the thunderstorm that caused it and yet harbour shear forces that can be destructive to aircraft, especially when a flight crew is unaware of its presence. The wind behind the front is usually turbulent and attached to the storm's downdraft[38]. But in some cases, as shown in Fig. 1c, the outflow air can detach itself from the storm and propagate away from it. Gust fronts often appear as thin lines on radar displays Fig. 1c, and reflectivity is so weak (<10 dBZ) that some radars fail to detect it. However, moderately sensitive Doppler weather radars can sense reflectivities as low as −10 dBZ at ranges <60 km.

Figure 1c shows the Doppler velocity field of a gust produced by a thunderstorm, which can be partially seen at the top of the figure. The radar beam elevation was fixed at 0.4° while the radar scanned in azimuth from 330° to 45°. Note the abrupt change in radial velocity across the gust line. The wind on the radar side (south-east) of the line shows a component away from the radar, and just beyond the line, towards the radar. The region of approaching velocities along the gust is rather narrow. The air flow immediately behind the 4-km wide band of approaching air is again southerly, although it is not evident in Fig. 1c because the SNR threshold eliminated the weaker echoes behind the gust. The dark blue area near the 40 km range arc indicates regions where the velocity data are contaminated with echoes from distant (>150 km) storms along the same bearing. A time sequence of radar images of the thunderstorm and gust suggests that this outflow propagated more than 80 km with a relatively constant velocity of 13 m s^{-1}. Fortunately, the gust passed the 444-m tall KTVY television tower, instrumented by NSSL, so that *in situ* measurements of the wind and temperature were obtained.

The vertical profiles of the wind and temperature in a south-east to north-west cross-section obtained from a composite of radar and tower data are shown in Fig. 5. The data show this solitary gust to be a cylindrical pool of cool air that propagates southeastward. This highly localized pool of steadily moving cool air appears to be detached from the storm and propagates in a stable boundary layer with little mixing of its air with the environment so that the air behind the line quickly returns to ambient conditions. This solitary gust seems to have a remarkably long lifetime (>1 h) as judged from time lapse photography.

Turbulence

Evident in Figs 2 and 5 (and in the visual images of cumulus clouds) are small scale eddies, perturbations in the larger scale circulations of storm winds. Radars with finer resolution than the nearly 2 km resolution of Fig. 2 and *in situ* point measurements made with aircraft often show small scale thunderstorm

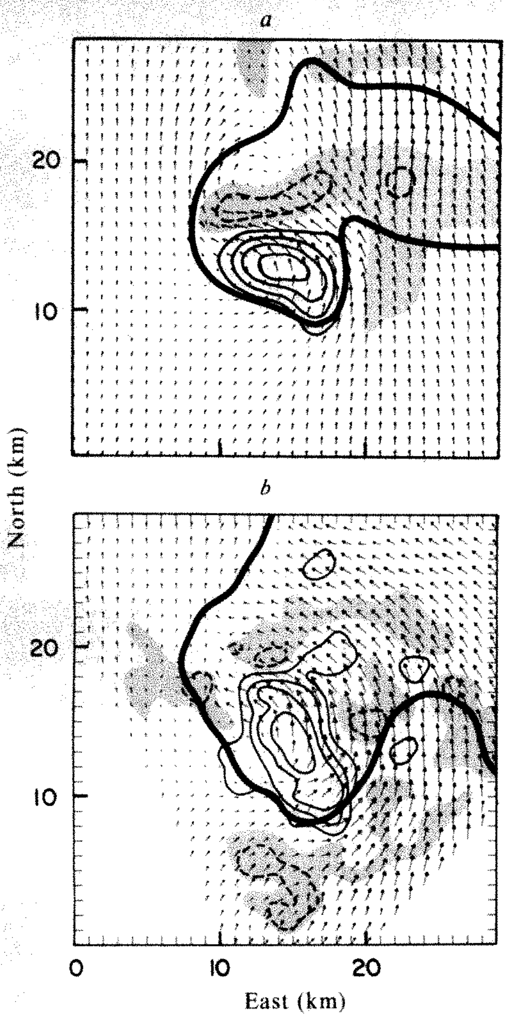

Fig. 3 Horizontal cross-section of modelled storm winds (*a*) and winds synthesized from observed Doppler velocities (*b*) in a plane at 4 km AGL (ref. 32). Updraft velocities (solid lines) and downdraft velocities (dashed lines) are contoured in 5 m s^{-1} increments. Shaded areas are downdraft regions stronger than -1 m s^{-1}. The heavy solid contour in *a* encloses a region of liquid water concentration >0.5 g kg^{-1}. In *b* the heavy contour is a 30 dB*Z* reflectivity factor. Wind vectors are scaled such that one grid interval is 20 m s^{-1}.

wind to be chaotic. If these turbulent eddies are intense, they can be destructive to aircraft.

The width, σ_v, of the Doppler velocity spectrum is normally a measure of turbulence within the measurement volume, although shear, antenna scan rate, and differential fall speeds contribute to a lesser degree to the measured value[24,39]. Although an aircraft can record turbulence in narrow volumes along its flight path, and a radar resolves it within its usually much larger measurement volume, Bohne[40] has shown good correlation between levels of turbulence estimated from aircraft and radar. Analysis of a larger amount of data by Lee[41] suggests a strong correlation between σ_v and *in situ* aircraft measurements of turbulence. His data show that when aircraft-measured gust velocities exceed 6 m s^{-1} (moderate or severe turbulence), σ_v exceeds 5 m s^{-1} within 1 km of the radar measurement volume. However, not all storm regions of large σ_v produced turbulence detected by aircraft. Furthermore, in over 50 thunderstorm flights when σ_v was <4 m s^{-1}, the aircraft experienced only light turbulence.

Only meagre results relate radar-estimated turbulence to storm wind fields; nevertheless, present evidence suggests that the most intense turbulence in a tornadic thunderstorm occurs along the edges of high speed (≥ 20 m s^{-1}) updrafts[42]. The most intense turbulence is usually found in the midlevels of the storm where there is large shear between updrafts and downdrafts[43].

Rainfall measurements

Although radar estimates of rainfall rate R obtained from Z are typically in error by a factor of up to two, radar has the advantage of surveying remotely vast areas and making millions of measurements in minutes. A sufficiently dense network of rain gauges can measure the rainfall more accurately and reliably. However, no matter how accurate the gauges are for point measurements (typically 5–10%), their usefulness for determining the rainfall integrated over a large area is limited by gauge density and the spatial variability in the rainfall[44]. The cost of a rain gauge network to match the radar's capabilities

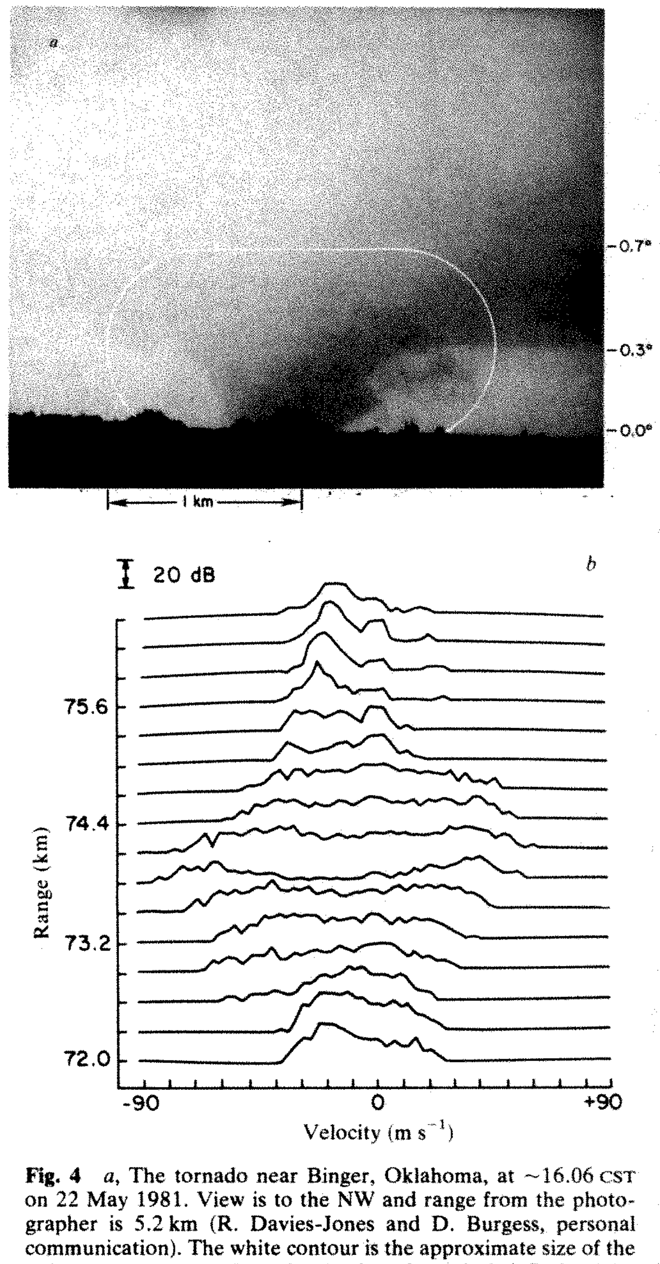

Fig. 4 *a*, The tornado near Binger, Oklahoma, at ~16.06 CST on 22 May 1981. View is to the NW and range from the photographer is 5.2 km (R. Davies-Jones and D. Burgess, personal communication). The white contour is the approximate size of the radar measurement volume for the data shown in *b*. *b*, Reflectivity spectral densities (in dB units) versus Doppler (radial) velocity at 16 range locations in the tornado's circulation. Beam elevation angle is 0.3°. The nearly horizontal lines at each end of the spectra are thresholds at 10 dB above the receiver noise level and correspond to a reflectivity spectral density of ~3.4 mm^6 m^{-3} m^{-1} s. The vertical scale is 20 dB per division (L. Hennington and D. Zrnic', personal communication).

in spatial continuity and rates of data sent to a central location would be prohibitive. Therefore, radar and widely-spaced rain gauge data are combined to produce rainfall maps. Inherent in this procedure are the assumptions that, despite the possible error in absolute radar measurement of R, the radar accurately measures the spatial variability of R and a valid calibration can be made between gauge and radar measurements at each gauge location. With these assumptions such rainfall maps approach the point accuracy of a dense gauge network[45,46].

The distribution of dropsize, $N(D)$, is of central importance in determining R. Operational weather radars measure the single parameter Z, and meteorologists often estimate R by using an assumed exponential dropsize distribution (see ref. 28) in which only one parameter is estimated from Z. In general, however, specification of $N(D)$ requires knowledge of several independent parameters to describe it, so that accurate estimates of R and Z can be made. It has been suggested that when $N(D)$ is described by a two-parameter distribution, pairs of independent measurements of two remotely sensed properties, such as attenuation and reflectivity, can be used for a better estimation of R (ref. 47).

A dual polarization radar[48] can use echo intensity information contained in two orthogonally polarized waves to estimate both parameters of a two-parameter $N(D)$. The basis for the dual polarization scheme is the observation that drops, falling at their terminal velocities, are not spherical but have an oblate spheroidal shape, so that we expect larger echo power for horizontally polarized waves. It can be shown that the ratio Z_H/Z_V of reflectivities obtained with horizontally and vertically polarized waves is an accurate measure of the spatial variability of R, even if the absolute radar calibration is in error, if the assumption of exponential dropsize is valid. Then rain gauges, even though sparsely spaced, can be used to scale the radar estimates of R. Although results given by Seliga *et al.*[49] suggest that a dual polarization radar can give better estimates of rainfall rate, more research is needed to evaluate the technique for operational applications.

Because the ratio Z_H/Z_V is related to the shape of the scatterers, polarization analysis can also be used to identify precipitation type (rain, hail, graupel, and so on) when this ratio and absolute measurements of Z are categorized into levels expected for various types of hydrometers[5].

Lightning studies using radar

Lightning flashes occur as either cloud-to-ground (CG) or intracloud (IC). A CG flash is comprised of one or more return strokes, which have large electrical currents in the channel between the cloud and ground, while all flashes not reaching the ground are termed IC. (See ref. 50 for a general description of lightning and its measurement.) Both IC and CG flashes create ionized channels that carry electrical currents. Backscattering from these ionized channels is sufficient to produce radar echoes.

Radar detection of lightning has been known for many years[51–58]. Although some early studies included estimates of values for lightning parameters such as electron density, it was not until 1972 that a theory of lightning echoes from return stroke channels was proposed[59]. Since then, new measurement techniques and theories have been developed to help unravel the complexities of lightning echoes.

Characteristics of lightning echoes

In a few early studies of lightning echoes, attempts were made to relate the echoes to known lightning processes by comparing the sferics from lightning (the transient electromagnetic field radiated by a flash) with the radar echoes of the same flashes[57,60]. More recently, coincident measurements of lightning echoes and electrostatic field changes, which allow reasonably conclusive identification of flash type and inter-flash events, showed that lightning echoes from a CG flash often have sudden increases in amplitude associated with return strokes followed by a decay to pre-flash levels[61] (Fig. 6). This feature has also been noted during some interstroke intervals. The radar echoes from an IC flash usually have a relatively broad peak with variations superimposed, which may be seen in Fig. 6*b* during the first part (0.6–1.15 s) of the flash. The electric field changes, (R in Fig. 6) are typical of return strokes. This flash was independently verified by a lightning strike location system as a CG with at least eight return strokes. Note that abrupt increases in the lightning echoes in a particular range interval ΔR may not always coincide with the return stroke field change.

Comparison of lightning echoes with electric field changes suggests that a continuing discharge process often keeps the channels ionized[62,63]. We define the duration of lightning echoes as the time interval from the instant the echoes are first discernible until they decay back to the pre-discharge amplitude. This duration forms a lightning echo event. Figure 6 shows at least nine echo events. Typical lightning echo events have durations of ~200–300 ms with extreme values of 10 ms and 3 s having been observed.

The rise time (the time for the radar received signal to reach peak amplitude) of a lightning echo event is generally a few tens of milliseconds. Although it was first thought that the rise time indicates increasing current flow in the channel[57], more recent analysis[64] shows that observed rise times agree well with ones determined theoretically, when the lightning is modelled as an ionized channel or streamer propagating across the antenna beam at a rate of $\sim 100\ \mathrm{km\ s^{-1}}$. Propagation speeds of this order of magnitude for streamers within clouds have been inferred by several investigators, using different measurement techniques[65,66]. When streamers propagate radially along the beam, their echoes can be seen developing in contiguous resolution volumes. Radar observations of several thousand lightning flashes in Oklahoma storms have yielded a maximum propagation speed of $\sim 250\ \mathrm{km\ s^{-1}}$, and streamer propagation speeds of $>100\ \mathrm{km\ s^{-1}}$ have been measured within small storms[62].

The radar cross-section, RCS, of lightning has been estimated both theoretically and experimentally. The lightning RCS depends on two factors: (1) the size and number of reflecting

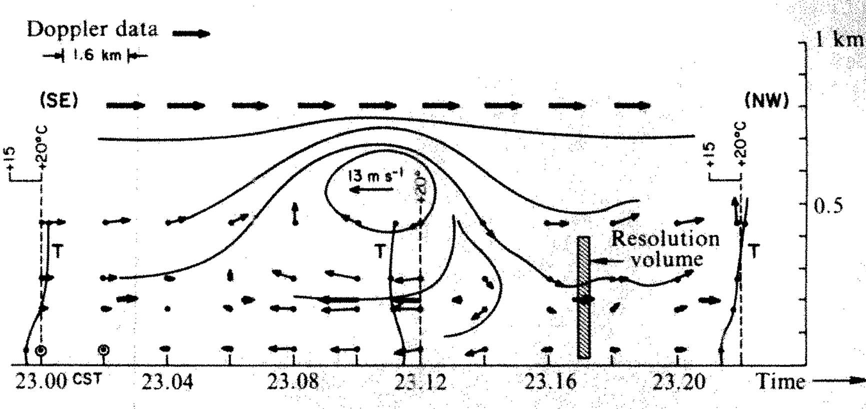

Fig. 5 SE–NW cross-section of a gust. Lightly traced arrows are the tower measured winds projected onto this plane, bold arrows the Doppler velocity. T, temperature profiles. The hatched area shows the radar's resolution volume cross-section in the plane of the beam axis.

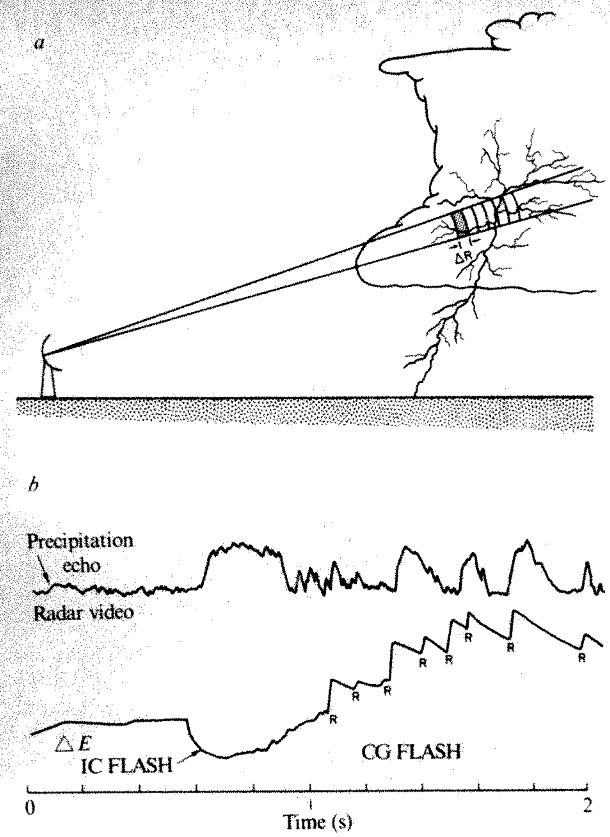

Fig. 6 Depiction of a technique (*a*) for observing lightning and an example (*b*) of lightning echoes for a long flash that began as an IC and then became a CG. The radar antenna typically is held at a fixed position to acquire lightning echoes. The stippled region in *a*, ΔR, represents one of the radar's resolution volumes in which the time variation of echo intensity may be studied. Top trace of *b* is time history of lightning echo intensity in a resolution volume at 86 km and 4 km altitude. Although depicted as a continuous line, the trace is actually a series of points separated in time by the period T_s ($\simeq$1 ms) between transmitted pulses. Precipitation echo denotes pre-flash radar echo intensities due to precipitation. The bottom trace is the electrostatic field change at the radar site due to the same flash. (Reprinted from ref. 21.)

lightning channel elements within the radar resolution volume and their orientations relative to the incident wave, and (2) the channel plasma characteristics. The initial theoretical work was principally done by Dawson[59], who assumed that only those ionized channels perpendicular to the beam axis contributed significantly to lightning echoes, and Divinsky[67], who considered the return echoes irrespective of channel orientation. Both treated the limiting cases of low density and overdense plasma (the plasma is considered overdense when the radar signals are reflected from it as if it were a metallic conductor). More recently Mazur[64] estimated the RCS as a function of channel orientation relative to the incident wave and any level of electron density and temperature by treating lightning elements as dielectric cylinders of finite length. Experimentally determined estimates of the lightning RCS reported by Mazur[64], Holmes *et al.*[62], and Zrnic' *et al.*[63] are reasonably consistent. Holmes *et al.*[62] conclude that the in-cloud portion of their flashes, which were at altitudes above 6 km, had channels with diameters <2 cm and electron densities of $\sim 10^{16}$ m^{-3}.

Lightning and storm structure

The fact that radars of wavelength $\geqslant$10 cm can easily locate lightning, even in intense precipitation, out to ~300 km makes them useful in the study of lightning relative to storm structure. The use of Doppler radar to observe lightning is a promising new area of research.

A phenomenon of long-standing interest and controversy is the 'rain gush', which is a dramatic increase in rainfall soon after lightning. The controversy has arisen as a result of different interpretations of the gush: one is that lightning causes the rapid growth of precipitation[68], another is that the precipitation, in electrostatic levitation before the flash[69,70], is merely released by the change in the electric field caused by the flash. Other interpretations have also been suggested.

Recently two radars have been used by Szymanski *et al.*[71] to search for a relationship between rain gushes and lightning. A 3-cm wavelength radar was used to observe precipitation reflectivity while an 11-cm wavelength radar was used to record the location of lightning echoes. They report that of more than 150 flashes observed by radar, only one flash, which occurred in very low precipitation reflectivities, seemed to cause precipitation growth in the volume around the lightning. Further such observations with radar are needed to provide more definitive information concerning the fundamental question of electrical effects on precipitation.

Zrnic' *et al.*[63] found, as had Szymanski *et al.*[71], that lightning in heavy precipitation usually causes no discernible change in precipitation reflectivity. However, Zrnic' *et al.* did find that lightning altered precipitation reflectivity of low Z and suggested that these were due to changes in orientation brought about by electrostatic field changes in these regions. These changes occurred within 0.1–0.5 s after the flash began. McCormick and Hendry[3] give convincing evidence that both aerodynamic forces and the storm's electric field control the orientation of ice crystals.

We have combined measurements of precipitation, using our 10-cm wavelength Doppler radar, and lightning echoes, using our 23-cm wavelength radar, to study the coevolving lightning and precipitation structure of large storms. In a squall line (that is, storm cells along a line) on 21 June 1980, over 1,000 lightning flashes were observed during a 44-min period. The storm cells were aligned nearly radially from the co-located radars, and lightning flashes from several cells were recorded. For this one squall line, the following were noted[64]: although lightning is observed throughout the storm, most of the lightning occurs close to the leading edge (relative to storm movement) of the heavy precipitation; the incidence of long lightning flashes that propagate between growing and dissipating cells increases as the precipitation echo intensity decreases in the dissipating cell.

The length of lightning flashes determined from the radial extent of lightning echoes varies greatly. Holmes *et al.*[62] report lengths up to 2 km in small, isolated mountain thunderstorms. Ligda's[52] photographs show lightning with lengths up to ~160 km in large storms. Most lightning that we observe in Oklahoma is several tens of kilometres long, and we have

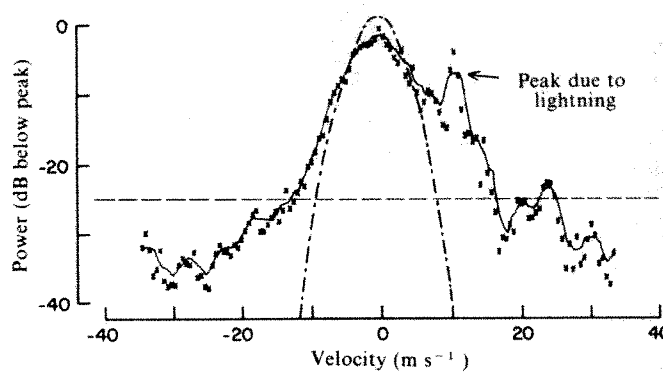

Fig. 7 Reflectivity spectral density for vertical fall velocities from precipitation and lightning at 7.1 km. The dash-dotted curve is the estimated true fall speed spectrum. The solid curve is a five-point running average of the data (×), which were obtained by averaging 12 spectra. Powers below the dashed line and the peak at 24 m s^{-1} are considered to be unreliable, so the intersection of this line and the observed spectrum yields the assumed, reliable maximum fall velocity of ~14 m s^{-1}.

observed lengths in excess of 100 km. These very long flashes have occurred in severe storms or along a line of storms.

Lightning often appears visually to occur in closely-spaced sequences, suggesting that the first flash somehow causes others. Mazur[64] has studied this phenomenon with radar. He observed lightning events characterized by a time interval of <200 ms between them and with a separation in the range of only a few kilometres. He has recorded these in squall lines both in the East Georgia region of the USSR and in the Great Plains of the USA. Mazur termed these 'associated discharges' because of the apparent association between the seemingly separate lightning flashes. It is, of course, possible that different branches of the same flash propagated by chance into the beam to give the observed apparent association. However, Mazur's analysis of lightning in an intense storm showed that this possibility was <5%. From this, he concluded that there may be processes that result in one flash being initiated by another.

Zrnic' *et al.*[63] have used a vertically pointing, 10-cm wavelength Doppler radar to study interactions between lightning and precipitation. Figure 7 shows an example of the reflectivity spectral density of lightning and precipitation observed simultaneously by Doppler radar. Reflectivity spectra obtained with vertically pointed radars have been used to determine the drop size distributions[72,73]. Unless the vertical air velocity and turbulence are estimated with precision better than $1\ \mathrm{m\,s^{-1}}$, large errors in drop size distribution will result. Although several methods have been proposed, none will provide correct values of vertical air motion[74]. If lightning produces ionized channels that permeate the measurement volume, these channels should be perfect tracers of the updraft and turbulence because they have zero terminal velocity.

A subjectively estimated true reflectivity spectrum for the hydrometers is also plotted on Fig. 7 to show how the spectrum depends on velocity. The true spectrum has an upper speed limit equal to the mean fall speed of the smallest detectable drops. Departures of the observed spectrum from the true is caused by turbulence, window broadening (a signal processing effect), possibly returns received via sidelobes, or other non-meteorological effects. Assuming that the ionized channels drift with the wind, Zrnic *et al.*[63] estimated the updraft velocity to be $10\ \mathrm{m\,s^{-1}}$, and so the maximum reliable terminal velocity estimate for the largest hydrometer is $\sim 24\ \mathrm{m\,s^{-1}}$. Such a high velocity was attributed to hail, which indeed fell in the vicinity of the radar. Although this newly tested Doppler radar technique shows potential to determine true updraft velocity and to estimate the radar volume-averaged drop size distribution, much more research is required to ascertain the accuracy and utility of this method.

Concluding remarks

The usefulness of weather radar as a remote probe of large and often severe thunderstorms continues to expand. When used in combination with other sensors, it offers us the opportunity to learn more about the complex interrelations between wind, water, and electricity in storms. Much of this understanding can then, in turn, be applied to the many weather-related problems that affect numerous aspects of our daily lives.

We thank our scientific colleagues, many of whom we could not cite, for their contributions to our understanding of thunderstorms. We thank the staff of NSSL, whose diligent work enabled us to accomplish our research. We particularly acknowledge many stimulating discussions with Vladislav Mazur. Our participation in this work was supported in part by the Atmospheric Science Program of the United States Office of Naval Research, the Severe Storms and Local Weather Research Office of NASA, and the Federal Aviation Administration of the US.

Tectonic subsidence, flexure and global changes of sea level

A. B. Watts

Lamont-Doherty Geological Observatory and Department of Geological Sciences, Columbia University, Palisades, New York 10964, USA

Tectonic models for the evolution of passive continental margins predict that following rifting, sediments should progressively onlap basement at the edge of a margin as the lithosphere cools and increases its flexural rigidity with age. The pattern of modelled onlap is strikingly similar to that used by Vail and colleagues to estimate sea-level rise through geological time. This similarity suggests that major portions of stratigraphical sequences at margins may have a tectonic, rather than eustatic, control. The patterns of onlap used by Vail and colleagues may be widespread, however, because several widely separated passive margins rifted at similar times, but they are unlikely to be worldwide.

THE distribution of seas through geological time is the result of two principal factors: global or eustatic changes of sea level and tectonic movements of the Earth's crust[1]. One or both of these factors may cause shorelines to shift and sedimentary facies to change. It may be expected that a relative rise in sea level, due either to a global rise in sea level or to crustal subsidence, would produce a transgressive stratigraphical sequence, while a relative fall of sea level, due either to a global fall in sea level or to crustal uplift, would produce a regressive sequence. The occurrence of a transgressive or regressive sequence at a particular locality in a sedimentary basin, however, is controlled by the rate of sediment influx and the rate and direction of change in the relative position of sea level and the sea floor[2]. It appears that global changes in sea level, due to changes in the volume of land ice or mid-ocean ridge crests, proceeded rapidly enough to explain some of the transgressive and regressive sequences at the edges of epeiric seas during the geological past. But there has been considerable debate[3] on the origin of the transgressive and regressive sequences that occurred during periods of no extensive land ice and relatively constant ridge crest volumes.

Sloss and Speed[4] argued that the major control on stratigraphical sequences in the continental interiors[5] were tectonic movements. They recognized three main episodes or 'modes' during the development of stratigraphical sequences in the continental interiors: 'oscillatory', in which land areas were subject to differential uplift and subsidence; 'emergent', in which land areas were progressively uplifted; and 'submergent', in which land areas progressively subsided. Sloss and Speed[4] noted a similar timing of these modes between widely spaced continents and argued for a synchronous tectonic control over broad regions.

Vail *et al.*[6,7], on the other hand, argued that the major control of sedimentary sequences in continental interiors and margins was global changes of sea level. They recognized several depositional cycles during the development of a stratigraphical sequence, each of which was bounded by surfaces of discontinuity. By identifying these surfaces, using characteristic patterns of seismic reflectors of 'onlap' and 'offlap', they constructed cycle charts at individual localities. Vail *et al.*[6] noted that similar cycles could be recognized at localities in widely separated margins and argued for a eustatic control. They used estimates of the amounts of onlap and offlap to construct a global sea-level curve for the Phanerozoic that was characterized by several short-term fluctuations superimposed on a broad long-term change. Vail *et al.*[7] used the pattern of onlap and offlap to infer sea-level rise and fall respectively. By calibrating their 'global' curve with other estimates of long-term sea-level changes[8,9] they argued that the short-term fluctuations could have magnitudes of up to a few hundred metres[10].

Pitman[9] pointed out that the occurrence of a transgressive or regressive sequence at the edge of a gently sloping shore depends on the rates of change of tectonic movements and global sea level. For example, a transgressive sequence could result from a sea-level fall, if the rate of subsidence of a basin exceeds the rate of sea-level fall. Pitman[9] showed that a major transgression during the Eocene in the North American and African margins could result simply from the interaction of changes in the rates of long-term sea-level fall with the steady, normal subsidence of these margins.

Vail and Todd[11] therefore modified the original statements[7] that coastal onlap and offlap could be directly equated to sea-level rise and fall. Their amended global sea-level curve for the Jurassic, however, was strikingly similar to the original curve, the main difference being the less abrupt sea-level falls.

The nature of the control of stratigraphical sequences has subsequently been widely debated. Hallam[12] argued that a tectonic control on the scale proposed by Sloss and Speed[4] was unlikely, as there was no satisfactory mechanism to explain why widely separated continents would be affected by tectonic movements at similar times. He suggested[13] that the main control on stratigraphical sequences were global changes of sea level and constructed a curve for the Jurassic, similar in overall shape to the Vail *et al.*[6] curve. But as Donovan and Jones[3] have pointed out, without a satisfactory mechanism, the

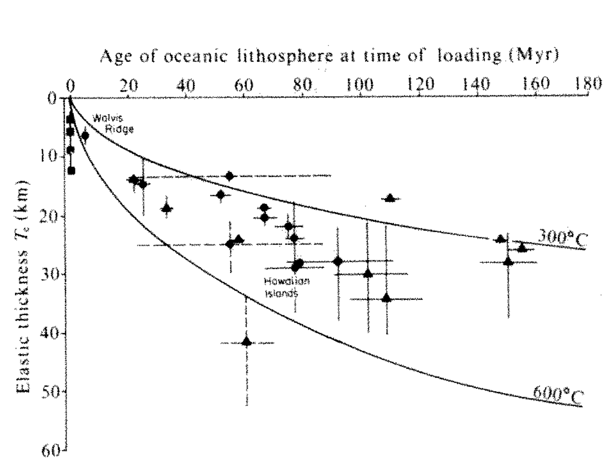

Fig. 1 Plot of elastic thickness T_e against age of the oceanic lithosphere at the time it was loaded[48]. The elastic thickness is determined from observations of the flexural rigidity and assumes Young's modulus = 10^{12} dyn cm^{-2} and Poisson's ratio = 0.25. ●, Seamounts and oceanic islands; ▲, deep-sea trench–outer rise systems; ■, ridge crests; ◆, river delta. Solid lines indicate the 300 °C and 600 °C oceanic isotherms based on the cooling plate model[49].

0028-0836/82/230469—06$01.00

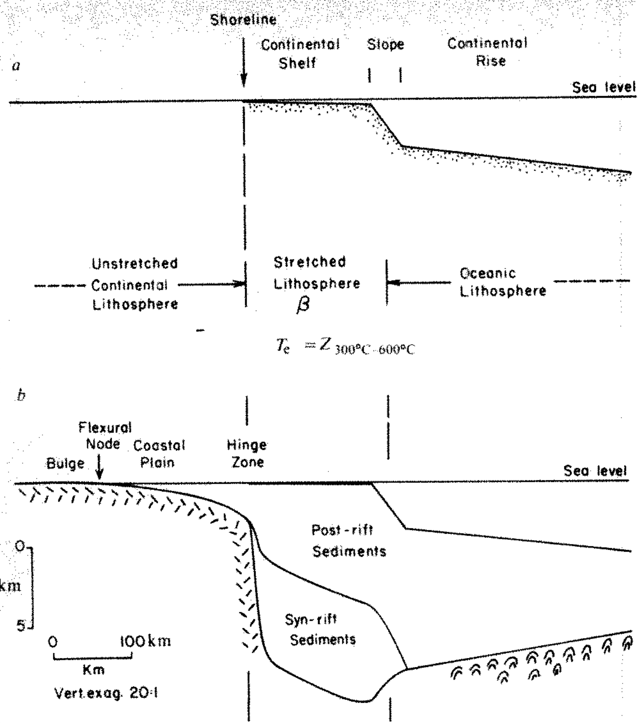

Fig. 2 Thermal and mechanical model for the tectonic evolution of a passive continental margin. *a*, Initial conditions. The tectonic subsidence of the margin is due to thermal contraction following heating and thinning of the lithosphere and crust at the time of rifting. Sediments are assumed rapidly to infill continental shelf, slope and rise regions and to maintain a constant bathymetric profile through time. *b*, Cooling and flexure. The sediments represent a load on the cooling lithosphere which responds by flexure. Sediments that form early in margin history load a relatively weak lithosphere while sediments that form later in its history load a strong lithosphere. The sediments that infill the initial subsidence are referred to as syn-rift while the sediments that infill the thermal subsidence are referred to as post-rift[31]. The model calculations assume an initial lithospheric thickness of 125 km, an initial crustal thickness of 31.2 km, a coefficient of volume expansion of 3.4×10^{-5} °C^{-1}, a mantle temperature of 1,333 °C and initial densities of 2.8 and 3.33 g cm^{-3} for the crust and lithosphere respectively. A uniform density of 2.5 g cm^{3} is assumed for the sediment infill.

large amplitude sea-level changes inferred by Vail *et al.*[6] and Hallam[12] must also remain in doubt. Bally[14] suggested, in fact, that the effects of global sea-level changes are subordinate to tectonics and that the major control on stratigraphical sequences are widespread and correlatable tectonic events associated with major plate reorganizations.

There is little doubt, however, that the sea-level curve of Vail *et al.*[6] represents an important synthesis of high-quality stratigraphical data that apparently has been useful in correlation studies and petroleum exploration. The outstanding question is the interpretation of these curves and whether they represent global sea-level changes or widespread tectonic events. Unfortunately, many of the data used by Vail *et al.*[6] are not generally available so it is difficult to determine whether they have satisfactorily separated eustatic from tectonic effects. This study uses recently developed models for the tectonic evolution of passive margins[15,16] to estimate how tectonics has contributed to stratigraphical sequences.

Tectonic subsidence at passive margins

The knowledge of the tectonic evolution of passive margins has progressed rapidly during the past decade. Backstripping studies[17–21], using data from commercial exploratory and COST-type wells, have shown that the principal factors affecting the post-rift subsidence of passive margins are thermal contraction and sedimentary loading. Factors such as chemical and mechanical compaction, palaeobathymetry, amount of sediment influx and long-term changes in sea level all contribute to the subsidence but their combined effects are small compared with thermal contraction and sediment loading. By correcting the well data for the effects of sedimentary loading it has, therefore, been possible to estimate the form of the thermal contraction and how it may vary across a margin.

Most modelling studies now assume that thermal contraction at passive margins arises from heating and thinning of the crust and lithosphere at the time of intial rifting[22,23]. The main differences between the various models is the manner by which the heating and thinning occurs. Sleep[22] proposed that the thinning was caused by uplift and subaerial erosion while McKenzie[23] proposed that it was caused by a passive, uniform extension of the crust and lithosphere.

There is good observational evidence for crustal extension during the early rifting history of passive margins, particularly at the sediment-starved margins of the eastern Atlantic and portions of the margin off eastern North America. For example, de Charpal *et al.*[24] have mapped listric faults and tilted fault blocks in northern Biscay, and Given[25] and Schlee[26] have mapped graben systems off Nova Scotia and New England. The amount of extension cannot easily be estimated from fault geometry, but seismic refraction data are consistent with a stretching factor[23] of $\beta = 2–3$ over distances of 100–200 km in northern Biscay[27,28].

The stretching model[23] has also been applied to the thickly sedimented margins of the western Mediterranean off southern France[21] and portions of the margin off eastern North America[29,30]. The main difficulty is the lack of information at these margins on the thickness and depositional environment of the sediments formed during rifting and, the tectonic fabric of the underlying basement rocks. For example, the relative proportion of syn-rift to post-rift sediments, an important constraint in the stretching model[31], is not precisely known at these margins. The available evidence[29,30] suggest a stretching factor in the range $\beta = 1.5–6.0$. Unfortunately, there is too little seismic refraction data to constrain these estimates satisfactorily but geoid data are consistent with large amounts of stretching ($\beta = 3–4$) over distances of 100–200 km along portions of these margins (ref. 20 and M. S. Steckler, personal communication).

The model of McKenzie[23] therefore appears to give a general explanation of the available geological and geophysical data at passive margins. Some problems still remain, however, the most important of which are: the discrepancies between estimates of stretching based on fault geometry and deep crustal seismic refraction data[28], the occurrence of seaward-dipping reflectors of possible subaerial volcanic origin at some margins[32] and the relative role of passive and active heating in the thermal evolution of a margin[21].

Flexure

The response of the lithosphere to sediment loads at a passive margin has been modelled using either an Airy or flexure model of isostasy[17,18]. Seismic reflection profiles indicate that active faulting accompanies the early stages of rifting[24–26]. This suggests that an Airy model, in which sediments are locally compensated, is most applicable early in margin evolution. The presence of gently dipping post-rift sediments and a broad coastal plain, however, suggests the flexure model becomes more important later in margin evolution.

The actual lithospheric response to sediment loads is difficult to determine at a passive margin because sediments are continually added to it during long periods of time. The best evidence has come from studies of seamounts and oceanic islands, as they formed during relatively short time periods (1–1.5 Myr). These studies show that the flexural rigidity and the equivalent elastic thickness of oceanic lithosphere, T_e, increases with the age of the lithosphere at the time it was loaded (Fig. 1). Loads formed on young oceanic lithosphere, such as the Walvis ridge, are associated with small values of T_e while loads formed on old oceanic lithosphere, such as the

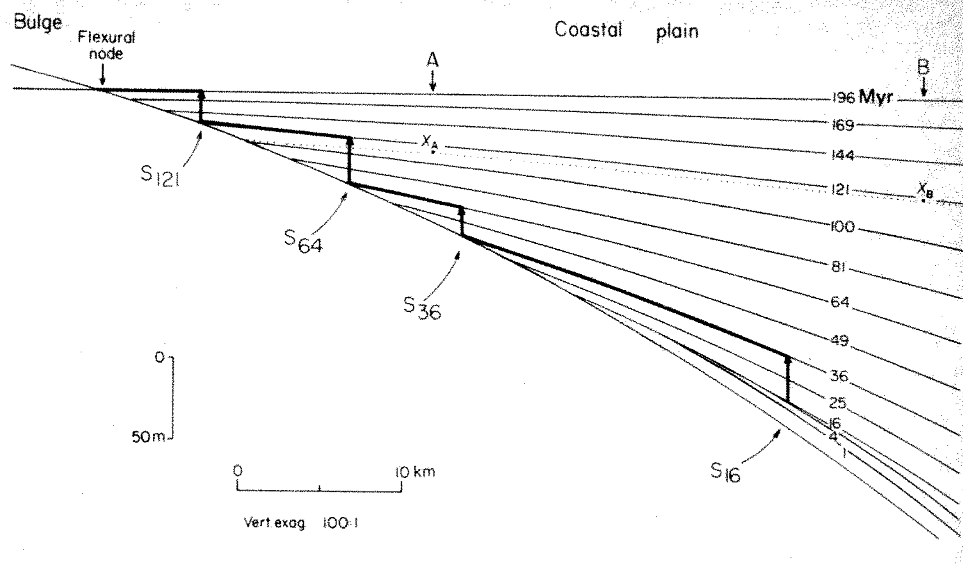

Fig. 3 Coastal plain stratigraphy calculated using the thermal and mechanical model in Fig. 2. The model calculations assume $\beta = 3.0$ and $T_e = Z_{450}$ °C. Solid lines represent individual stratigraphical horizons at different times following rifting. The effects on the stratigraphy of compaction have not been included. The heavy solid lines illustrate the procedure used by Vail *et al.*[7] and this study to estimate the vertical component of coastal onlap. The dotted line indicates the equilibrium shoreline where the rate of change of long-term sea-level fall[9] equals the subsidence rate. Because the coastal plain sediments subside at a slower rate than long-term sea-level rises or falls, there is a tendency, depending on the rate of sediment influx, for transgression below the dotted line (enhancing the effects of flexure) and regression above the line (competing with flexure).

Hawaiian islands, are associated with large values. Figure 1 shows there is good general agreement between T_e and the depth, Z, to the 300–600 °C oceanic isotherms. Thus, flexure studies in the ocean basins suggest that as the oceanic lithosphere increases in age and cools, it becomes more rigid in its response to loads.

Because the lithosphere at passive margins is extensively heated during rifting[22,23], it should therefore become progressively more rigid in its response to sediment loads as it cools following rifting. Sediments formed soon after rifting would be expected to load a relatively hot and weak lithosphere while later sediments would load a relatively cool and strong lithosphere. A flexure model, in which the rigidity of the lithosphere increases with time, explains certain tectonic–stratigraphical features of well sedimented passive margins such as an outer stratigraphical high, a hinge zone and a coastal plain in which younger sediments progressively onlap basement[33].

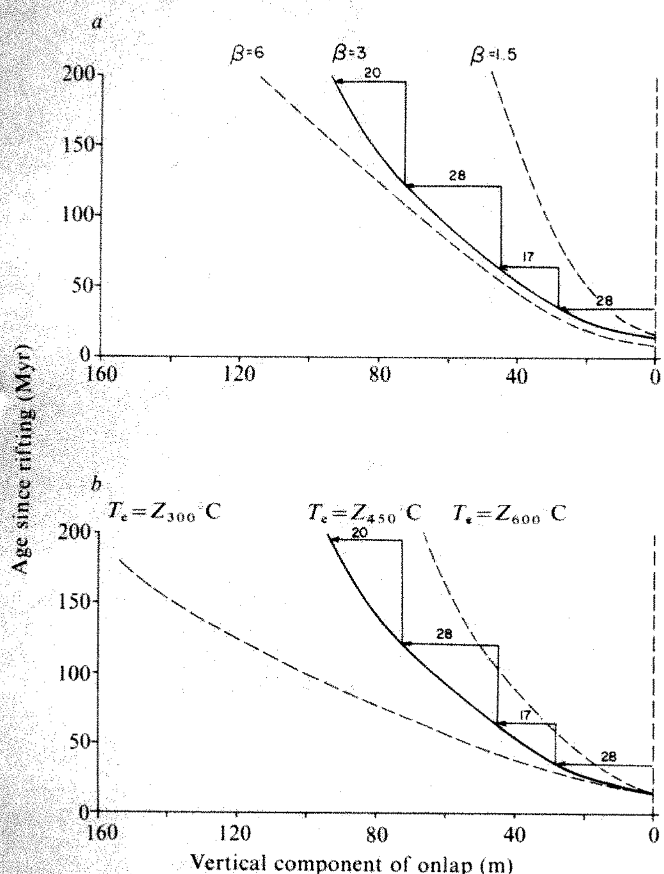

Fig. 4 The vertical component of coastal onlap estimated from the thermal and mechanical model in Figs 2 and 3. Solid lines indicate the individual measured increments of coastal onlap and the heavy solid lines indicate the smoothed change in onlap following rifting. *a*, $T_e = Z_{450}$ °C and β variable. *b*, $\beta = 3.0$ and T_e variable.

Thermal and mechanical models

Thermal and mechanical models have now been constructed[15,16,34] for the stratigraphy of passive margins that combine the effects of thermal contraction and sedimentary loading. In these models, thermal contraction occurs following crustal and lithospheric extension at the time of rifting while sedimentary loading occurs by flexure of a progressively more rigid basement following rifting. Since T_e is a strong function of temperature (Fig. 1), thermal and mechanical effects can be coupled. Thus, T_e can be calculated as a function of time and position following rifting.

Figure 2 shows a simple model for the tectonic evolution of a passive margin that formed by crustal and lithospheric extension at the time of rifting. The region of extension is limited to beneath the shelf and slope and to have a magnitude ($\beta = 3$) and horizontal extent (175 km), similar to present day margins. Sediments are assumed to infill uniformly the cooling margin, maintaining a constant bathymetric profile with time. The model includes the effects of lateral heat conduction across the stretched region and flexure that varies as a function of time and position ($T_e = Z_{450}$ °C).

Figure 3 shows the stratigraphy predicted by the thermal and mechanical model at the edge of the margin. The solid lines indicate stratigraphical horizons at equal increments of the square root of time since rifting. Figure 3 shows that there is initially a significant onlap of sediments onto the basement, due to the abrupt transition in the stretching model from fault-controlled Airy-type subsidence to flexural controlled subsidence. Soon after rifting, the pattern of onlap is abruptly terminated because lateral heat flow from the stretched region to unstretched continental lithosphere causes the coastal plain to remain emergent[15,16]. Beginning about 16 Myr after rifting, however, flexure overcomes the effects of lateral heat flow and younger sediments progressively onlap the basement, due to its increase in flexural rigidity with age.

The model in Fig. 3 is simplified as it assumes an abrupt increase in β across the hinge zone and a sediment influx that

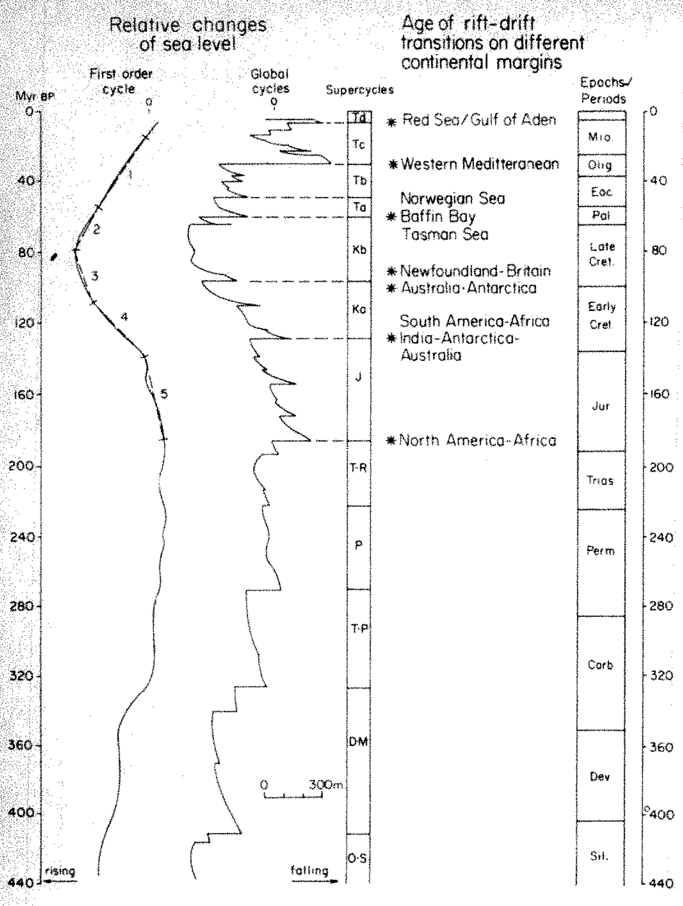

Fig. 5 Global cycles of relative changes of sea level since the Devonian[6] compared with the age of the rift–drift transition at different continental margins[48]. The numbered dashed lines on the 'first-order cycle' are construction lines used to estimate the rates of change of sea-level rise and fall in Fig. 6.

uniformly infills shelf, slope and rise regions. Although there is little information on how β varies across a hinge zone, it seems likely that it would change more smoothly than assumed in the model. An abrupt change in β maximizes the lateral effect of heat flow across the hinge zone so the coastal plain would remain emergent for a longer time following rifting. However, a more gradual transition in β across the hinge zone only slightly decreases the pattern of onlap in Fig. 3. The pattern of onlap would be expected to change if sediments by-passed shelf regions due, for example, to vigorous submarine erosion[26]. A prolonged absence of shelf loading would cause the flexural node (Fig. 2*b*) to migrate seaward towards loaded slope and rise regions, resulting in offlap in the coastal plain. Changes in the pattern of sediment influx seem unlikely, however, to compete with the modelled onlap in Fig. 3 unless it, like flexure, varies systematically during margin evolution.

The model studies therefore suggest that coastal onlap is a characteristic feature of stratigraphical sequences at a cooling margin. This result is important since measurements of the amount of onlap at present day and ancient passive margins is the principal means by which Vail *et al.*[6,7] estimate sea-level changes through time. The models in Figs 2 and 3 have been constructed assuming no sea-level changes through time. Thus, by measuring the amount of onlap in the models we can estimate the contributions of tectonics to stratigraphical sequences.

Vail *et al.*[7] measured onlap by estimating the 'coastal aggradation', or 'vertical component of onlap', in a stratigraphical sequence. Beginning with the lowest point of onlap in a sequence, they successively summed each increment of onlap until the highest point of onlap is reached. Figure 3 illustrates, on the modelled stratigraphy, the procedure used by Vail *et al.*[7]. Starting with S_{16}, the lowest point of onlap in the sequence, the first increment of onlap is 28 m and the time interval is 16–36 Myr. Successive increments of 17, 28 and 20 m give a total amount of onlap for the sequence of 93 m. Figure 4 shows the largest amount of onlap (100–160 m) occurs for the greatest amount of stretching and weakest plate, while the smallest amount (45–65 m) occurs for the least stretching and strongest plate. The form of the onlap is similar in each model, generally following the shape of an exponential curve, with an initial rapid increase followed by a more gentle increase.

Although they did not detail their method, Vail *et al.*[7] used coastal onlap to estimate sea-level rise through time. They used a modal average of three or more correlative cycles of onlap from different continents to construct a global sea-level curve for the Phanerozoic. But, as Fig. 4 shows, coastal onlap is a characteristic feature of the tectonic evolution of a cooling passive margin and does not require sea-level changes to produce it. Therefore, if the model predictions are correct, some correlation should exist between the beginning of major cycles of onlap in the Vail *et al.*[6] curve and the age of the rift–drift transition in passive margins, formed as a result of continental break-up.

Figure 5 shows there is an excellent visual correlation between the beginning of the supercycles of Vail *et al.*[6] and the age of the rift–drift transition at margins formed by the breakup of the Pangea supercontinent. There is a striking similarity between the form of the modelled onlap and individual supercycles (Fig. 5). This similarity suggests, therefore, that major portions of the Vail *et al.*[6] curve may have a tectonic, rather than eustatic, control.

Vail *et al.*[6], however, terminate their supercycles by rapid sea-level falls (Fig. 5). The tectonic models predict regressive sequences early in the development of a margin (Fig. 3) but, they do not predict them at higher levels in a stratigraphical sequence. Therefore, if the magnitudes of the sea-level falls deduced by Vail *et al.*[6] are correct then, factors other than flexure must be invoked to explain them.

There is some doubt that Vail *et al.*[6] have correctly estimated the amount of sea-level fall from stratigraphical sequences[14,35]. The main problem is that they determine sea-level fall by measuring the vertical component of onlap between the highest point of onlap in an underlying sequence directly to the lowest point of onlap in an overlying sequence. Because the record is largely removed by erosion during a sea-level fall, they cannot use the 'incremental method' that was used to measure onlap. Thus, the effects of tectonics during the sea-level fall are not satisfactorily accounted for.

There is good evidence[36], however, for major periods of regression in the geological record, although their origin is in some doubt. For example, Grasty[37] has related major regressive events to crustal thickening associated with orogeny while Ager[36] has related them to long-term changes in global sea level, due to changes in mid-ocean ridge crest volumes.

The effects of long-term changes in sea level[9,6] on the modelled stratigraphy are illustrated in Fig. 6. The open triangles (Fig. 6) indicate the age since rifting when the rate of sea-level fall equals the rate of model subsidence and the shoreline would stabilize. For small times following rifting the seas would rise faster than the model subsides, causing a transgression, while for longer times the seas would fall faster, causing a regression. The actual effect of long-term sea-level changes depends, however, on the relative rates of sediment influx and subsidence[2]. For the modelled stratigraphy in Fig. 3, a transgressive sequence would be expected to develop soon after rifting, enhancing the pattern of onlap produced by flexure, while for later times a regressive sequence would develop, competing with flexure. The timing of the resulting seaward shift in onlap would depend on position, but for the model in Fig. 3 it occurs about 112–117 Myr following rifting.

The model predictions are difficult to compare with the Vail *et al.*[6] curve as this curve represents the summation of several shifts in the pattern of onlap from different positions in widely

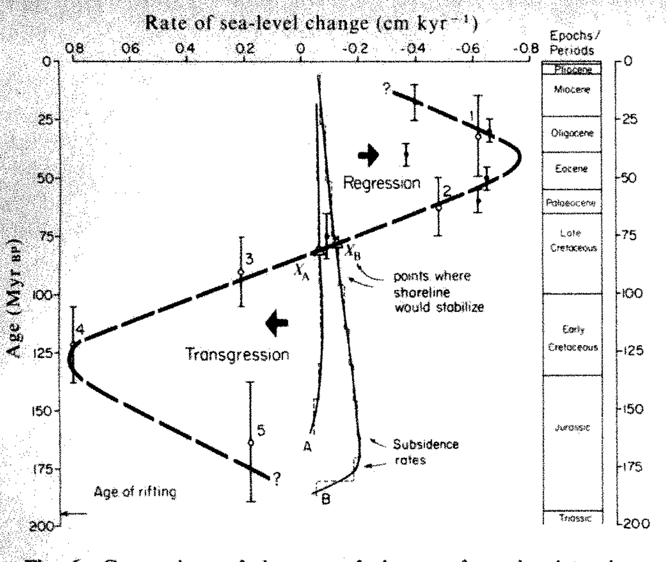

Fig. 6 Comparison of the rate of change of sea level to the subsidence rate at two points (A, B) in the thermal and mechanical model in Fig. 3. The rate of change of sea level is based on the long-term sea-level curve of Pitman[9] and the first-order cycle of Vail *et al.*[6]. ●, Based on Table 2 of ref. 9; ○, a straight line fit to the first-order cycle of Vail *et al.*[6] (Fig. 5). △, The time in Myr BP that the rate of sea-level fall equals the rate of subsidence and the shoreline, in the absence of other effects, would be in equilibrium.

spaced margins. There is evidence though, from published geological cross-sections of the US Atlantic coastal plain[38], of a progressive onlap of Jurassic to early Cretaceous sediments onto basement that is terminated by a seaward shift in the overall pattern of onlap about 120 Myr after rifting. Thus, the model in Fig. 3 seems to agree with the overall stratigraphy of this relatively old margin.

The tectonic models are still unable, however, to explain the widespread rapid short-term falls of sea level in the Vail *et al.*[6] curve. Thus, without a satisfactory mechanism, the origin of these falls remains in doubt.

Discussion

The model studies suggest that tectonics is an important control on the development of stratigraphical sequences at passive margins. Flexure produces patterns of onlap, remarkably similar in form to those used by Vail *et al.*[7] to infer sea-level rise. Although Vail *et al.*[7] attempted to remove tectonic effects by summing increments of coastal onlap in a sequence, they did not correct for flexural effects that vary as a function of time and position. They considered only a limited role for tectonics that was generally equivalent to assuming sedimentary loading occurs by flexure of a lithosphere of uniform flexural rigidity.

As has already been pointed out, however, flexure cannot explain all the occurrences of onlap in stratigraphical sequences; neither can it explain the occurrence of offlap at high levels in stratigraphical sequences. The Cenomanian and Callovian transgressive sequences[36] extended too far into the interiors of the continents to be explained by flexure, so other factors, such as long-term changes in global sea level due to changes in mid-ocean ridge crests, are required to explain them. Similarly, the Oligocene regressive sequences of the eastern US[35], western Australia[39], and the northern North Sea[6] cannot be explained by flexure. These relatively old margins were subsiding at relatively slow rates during the Oligocene so the relatively rapid long-term fall in global sea level[9] since 85 Myr BP may have contributed to these sequences. Furthermore, flexure cannot explain transgressive sequences such as the Hettangian[40] of south-west Britain, which were too far north to have been affected by the Tethys passive margin[41], or regressive sequences such as the Oligocene of southern Africa[42]. Tectonics, but not necessarily flexure, may have contributed to these sequences[40,42].

Figure 7 shows the overall pattern of stratigraphical sequences predicted by the tectonic models for different age margins. Following rifting each margin would be expected to show its own pattern of onlap as it cools and becomes progressively more rigid with age. But as each margin increases in age, there is a greater tendency to be affected by long-term changes in sea level. For example, the fall in long-term sea level from 85 to 15 Myr BP (ref. 9) would cause a shift in the pattern of onlap at approximately similar times in each margin. The patterns of onlap would also be affected, of course, by the rise in sea level before 85 Myr, but this would only enhance the effect of flexure. Figure 7 shows that although there is a similarity in the timing of the shift in onlap at each margin, the overall pattern of onlap is strikingly different between each margin. The models predict, in fact, that there would be little correlation in patterns of onlap between margins unless they rifted at similar times. Thus patterns of onlap, of the type used by Vail *et al.*[7] may be widespread, because many widely spaced margins rifted at similar times, but they are unlikely to be worldwide.

Unfortunately, there is presently too little stratigraphical data available to test the model predictions in Fig. 7. Vail *et al.*[7] only published a few sea-level curves from separate localities and most of these extend for the duration of only one supercycle. However, Todd and Mitchum[43] published sea-level curves for Texas Gulf Coast and West Africa; localities associated with the rifting of North America from Africa at ~196 Myr BP (ref. 44). Although it is not possible to compare their curves directly with the model predictions, both curves show a steady increase in the amount of onlap during the Jurassic. The main difference is that the models do not predict the short-term falls in sea level, the largest being in the Valanginian (125–130 Myr BP). As Todd and Mitchum[43] pointed out, however, a restricted Valanginian sequence can only be inferred from seismic profiles in the Gulf Coast.

This article has focused on the nature of the control on stratigraphical sequences in present day passive margins but tectonics, in the form of lithospheric flexure, may also have been a major control in the continental interiors. For example, Vail *et al.*[6] constructed a sea-level curve for the Devonian and Cambrian; presumably based on data from the Michigan basin and the western and eastern US orogenic belts. They show a

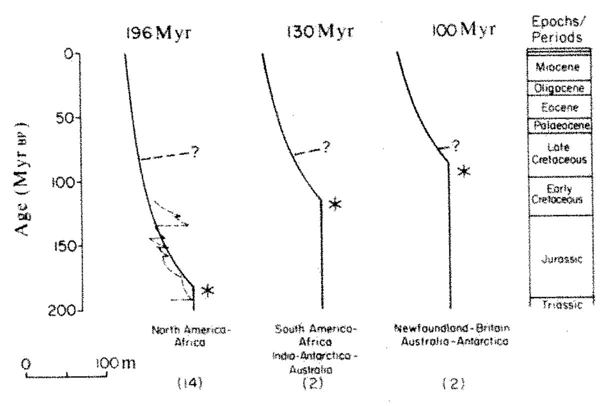

Fig. 7 The pattern of onlap predicted for passive margins of different ages. The heavy solid line represents the pattern of onlap predicted from the thermal and mechanical models with $\beta = 3$ and $T_e = Z_{450}$ °C. The heavy dashed line indicates the shift in the pattern of onlap caused by a fall in long-term sea level since 85 Myr BP. The actual shift in the pattern would vary across a margin. The fine dashed line indicates the sea-level curve for the Texas Gulf Coast based on Todd and Mitchum[44]. This curve has not been calibrated[44] and is shown for comparison only. There is a significant difference in the patterns of onlap between each margin because they rifted at separate times. The numbers in parentheses indicate the number of localities that Vail *et al.*[6] apparently used in each margin. Because they used a modal average of patterns of onlap from individual localities, the pattern of onlap from the North America–Africa margin should dominate their global sea-level curve.

prominent pattern of onlap for each of these periods which they interpreted as a sea-level rise. The increase in width of the Michigan basin during Devonian[45] can be explained[46], however, by an increase in flexural rigidity of the lithosphere with age, and does not require sea-level changes to produce it. Furthermore, the apparent progressive onlap of sediments onto the western and eastern margins of the North American craton during the Cambrian[47] can be explained by flexure, although the large horizontal extent of the Albertan may require long-term sea-level changes in addition.

This is not to imply that a completely satisfactory model exists yet for the tectonic evolution of sedimentary basins in present day and ancient passive margins. There is too little seismic reflection and refraction data at present day margins that satisfactorily constrains the deep crustal structure implied by the thermal models. The occurrence of coastal onlap at a passive margin, however, is the consequence of the cooling of the lithosphere following rifting and does not depend on a particular type of thermal model. The actual separation of tectonic effects from stratigraphical sequences remains a difficult problem that will require careful studies of seismic, geological and palaeontological data from localities in widely separated margins. The problem is important for future consideration, however, as it has major implications for tectonics, lithospheric mechanics, correlative stratigraphy and the thermal history of the Earth.

Human EJ bladder carcinoma oncogene is homologue of Harvey sarcoma virus *ras* gene

Luis F. Parada, Clifford J. Tabin, Chiaho Shih & Robert A. Weinberg

Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Examination of homologies between retroviral oncogenes and transforming sequences defined by transfection reveals that the human bladder carcinoma (EJ) oncogene is homologous to the Harvey sarcoma virus oncogene (ras). *Structural analysis limits the region of homology to a 3.0-kilobase* SacI *fragment of the EJ oncogene. Both EJ and* ras *DNA probes detect similar transcripts in transfectants derived from bladder carcinoma cell lines.*

TWO groups of cellular oncogenes have been discovered during the past decade. The first consists of genes that were characterized by virtue of their association with retroviruses. The prototype of this class is the *src* gene of avian sarcoma virus. Several experiments have indicated that this gene was acquired from the chicken genome by an avian retrovirus, and has been exploited by the chimaeric virus to transform cells[1,2]. Once incorporated into the viral genome, expression of the *src* gene is driven by viral controlling elements and is no longer responsive to control mechanisms that governed its expression while in the cellular chromosome. In addition to the *src* gene, this group includes at least 12 other gene sequences, each associated with a different chimaeric retrovirus[3,4]. These genes are conserved over great evolutionary distances[2,5] implying that they mediate essential cellular or organismic functions.

A second class of cellular transforming genes has been detected by the experimental route of DNA transfection. Recent reports have indicated that the DNAs of some non-virally induced tumour cell lines can induce transformation when applied to mouse fibroblast monolayers. These tumour cell lines are derived from chemically induced animal tumours[6–9] and from human tumours of spontaneous origin[7,10–12].

The two classes of oncogenes have many properties in common, the most striking of which is the apparent origin of both types of genes from normally benign, cellular genetic elements. Because of this and other parallels, we undertook a search to determine whether the two groups of genes shared any members in common. Such overlap would have far-reaching consequences for our understanding of the mechanisms of viral and non-viral carcinogenesis.

Detection of homologies by nucleic acid hybridization

The search for relatedness between the two groups of genes depended on detection of nucleic acid sequence homologies between individual members of each group. One group consisted of a series of seven retrovirus-associated *onc* genes known to be unrelated or only distantly related to one another[4]. The other group studied was a collection of seven tumour oncogenes that had been defined by transfection[7,10]. Nucleic acid sequence probes have been derived for the retrovirus-associated genes, whereas only a few of the transfection-derived genes have been isolated in the form of molecular clones. We therefore used the virus-derived *onc* probes to survey the DNAs of cells which had acquired, via transfection, copies of the second class of genes. The survey was performed using the Southern gel–filter transfer procedure[13]. Virus-derived *onc* probes were from several sources (see Table 1).

We used each retrovirus-related *onc* probe to search for novel cross-reacting fragments in each of several transfectants. For example, an analysis using the v-*abl* probe is shown in Fig. 1: lane *a* represents the endogenous mouse sequences detected in the DNA of untransfected NIH 3T3 cells by the v-*abl* sequence probe. These 'background' bands of 28, 10 and 6 kilobases (kb) were also found in the DNAs of all transfectants (Fig. 1, lanes *b*, *d–g* and *i*). Figure 1*c* shows detection of the human homologue of the v-*abl* probe; lanes *d–g* show an analysis of DNAs of mouse cells transfected with four different human oncogenes. None of the DNAs contains any fragments beyond those present in the untransfected mouse control (lane *a*). We concluded that none of these transfected cells acquired the human homologue of the v-*abl* sequence. From a similar analysis in lanes *h* and *i*, we concluded that the rabbit bladder carcinoma oncogene is also not related to the *abl* gene. A more equivocal interpretation came from analysis of the DNA of a mouse cell transfected with a mouse fibroblast oncogene (Fig. 1*a*, *b*). Due to the lack of species-specific fragment markers, we were unable to rule out the identity of the *abl* and fibroblast oncogene. However, knowledge of their restriction enzyme cleavage sites excludes identity[14,15].

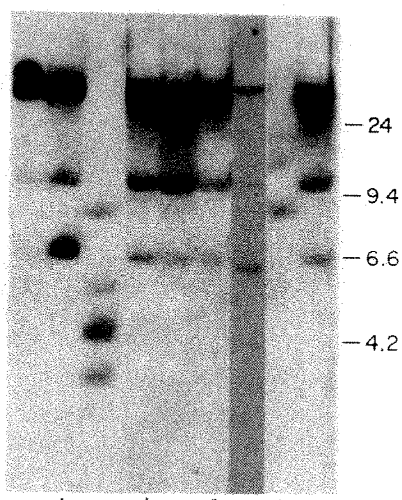

Fig. 1 Southern blot analysis of digested cellular DNAs from various transfectants probed with v-*abl* specific probe (see Table 1). 10 μg of each DNA were digested with endonuclease *Eco*RI, fractionated by electrophoresis through a 1% agarose gel and transferred to nitrocellulose paper[13]. The filters were incubated with 5×10^6 c.p.m. of nick-translated[39] ^{32}P-labelled Abelson virus specific probe. The DNAs analysed were from the following cell lines: *a*, NIH 3T3; *b*, Y5-1; *c*, HeLa; *d*, A5-2; *e*, SH-1-1; *f*, SW-2-1; *g*, EJ-6-1; *h*, rabbit embryo fibroblast; *i*, RBC-1. Lanes *a–f* and *h*, *i* are from one filter; *g* is from a different filter. The transfected cell lines are described in Table 2. Migration of *Hin*dIII-digested λ DNA fragments are shown at the right (in kilobase pairs, kbp).

Figure 2 shows a further Southern blot analysis of DNAs that were prepared from several cell lines derived by transfection of NIH 3T3 cells with DNAs of human tumour cell lines. The probe used was the rat cellular homologue of Harvey sarcoma virus, c-Ha-*ras*1, given by R. Ellis and E. Scolnick[16,17]. A novel fragment of 9.5 kb was found in the DNA of a mouse cell transfected with DNA of the EJ human bladder carcinoma cell line (Fig. 2*c*). In contrast, no novel fragments were present in the transfectants derived from other tumour cell lines (Fig. 2*d–g*).

Of the seven *onc* probes used in this survey, only one detected the presence of novel DNA fragments in transfection-derived cell lines. The results of this comparative oncogene survey are summarized in Table 2. Below we consider the relationship between the c-Ha-*ras*1 gene and the human bladder carcinoma gene suggested by Fig. 2.

Homology of the two oncogene DNAs

A series of tests was performed to further substantiate the relationship between the EJ bladder oncogene and the c-*ras* oncogene. Figure 3*A* shows that nine cell lines derived by transfection of EJ bladder carcinoma DNA have all acquired novel DNA fragments reactive with the c-Ha-*ras*1 probe. DNA from untransfected mouse cells (Fig. 3*A*, lane *a*) does not exhibit any of these novel fragments. The *Bam*HI-digested DNAs of the various transfectants exhibit differently sized novel fragments because of rearrangements occurring during the transfection process. Note that the oncogene of the T24 human bladder carcinoma is closely related to that of the EJ bladder carcinoma[18,19]. Figure 3*A*, lane *m*, indicates that a mouse transfectant carrying the T24 oncogene also contains in its DNA a novel acquired fragment reactive with the probe.

To further define the linkage between the EJ oncogene and the c-Ha-*ras*1 homologous sequences, we analysed the DNAs of three EJ transfectants derived by transfer of *Bam*HI-cleaved DNA (Fig. 3*B*). The donors of these DNAs were secondary transfectants derived previously by two serial passages of the bladder carcinoma oncogene. As endonuclease *Bam*HI does

The oncogene probes shown are described in Table 1. The transfected cell lines listed are of the following origins: Y5-1-1 is derived from two serial passages of the oncogenic DNA from a 3-methylcholanthrene-induced mouse fibroblast cell line, MCA-16 (refs 6, 33); EJ-6-1 is a secondary transfected cell line derived from DNA of a human bladder carcinoma cell line, EJ[7]; A5-2 is a primary transfected cell line derived from human lung carcinoma cell line, A549 (ref. 34); SH-1-1 is a secondary transfected cell line derived from DNA from human neuroblastoma cell line, SK-N-SH (J. Føgh, personal communication); SW-2-1 is a secondary transfected cell line derived from human colon carcinoma cell line, SW-480 (refs 10, 35); HL60-1-9 is a secondary transfected cell line derived from human leukaemia cell line, HL60 (refs 10, 36); B104-1-1 is a secondary transfected cell line derived from rat neuroblastoma cell line, B104 (refs 7, 37); RBC-1 is a primary transfected cell line derived from rabbit bladder carcinoma cell line, RBC[7,38]. + Indicates hybridization of the probe to novel bands in addition to hybridization with NIH 3T3 cellular sequences; – indicates a well controlled negative correlation. * Apparent negative correlation that is not based on species-specific DNA fragment sizes that distinguish donor DNAs from resident chromosomal DNAs of the recipient cells. NT, not tested.

not inactivate the EJ oncogene[18], the transfection of *Bam*HI-cleaved secondary DNA ensured that almost the only human fragment present in resulting tertiary transfectants was the 6.6-kb *Bam*HI fragment bearing the EJ oncogene. The three DNAs of the tertiary transfectants were analysed after *Eco*RI cleavage as it was thought they might have lost some *Bam*HI sites during the second transfection. The DNAs of the three transfectants (Fig. 3*B*, lanes *a–c*) all showed acquired fragments reactive with the c-Ha-*ras*1 probe. This demonstrated that the linkage between the EJ oncogene and the c-Ha-*ras*1 homologous sequences could not be broken by *Bam*HI cleavage.

A further comparison between the genes depended on the fact that the EJ bladder carcinoma oncogene was one that we have recently isolated as a molecular clone[18]. The EJ human bladder oncogene has been cloned as a biologically active *Eco*RI fragment of 16 kb carried by a Charon 4A λ phage vector and termed Φ631. A biologically active 6.6-kb *Bam*HI fragment subclone has been inserted into plasmid vector pBR322 and termed pEJ6.6. All endonucleases shown to cleave within this 6.6 kb insert (Fig. 4) inactivate the focus-inducing activity of this DNA (ref. 18 and C. Shih, unpublished results).

Using the EJ 6.6-kb *Bam*HI fragment and the c-Ha-ras1 oncogene clone as sequence probes, we analysed the DNA fragments homologous to these genes in normal human DNA. Both probes detected a 6.6-kb *Bam*HI fragment (Fig. 3*A*, *C*, lanes *b*) and a 23-kb *Eco*RI fragment (Fig. 3*B*, *D*, lanes *b*) in

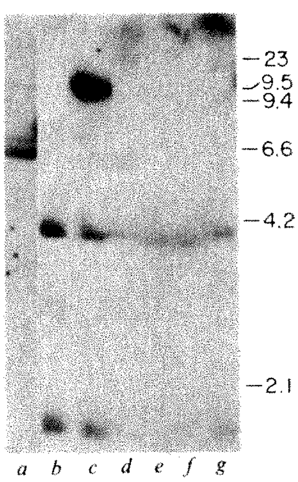

Fig. 2 Southern blot analysis of DNA from transfected cells with rat cellular *ras* probe (c-Ha-*ras*1). ^{32}P-labelled c-Ha-*ras*1 DNA was prepared as described in Fig. 1 legend and incubated with a filter carrying *Bam*HI-digested DNAs from the following cell lines: *a*, HeLa; *b*, NIH 3T3; *c*, EJ-6-1; *d*, A5-2; *e*, SH-1-1; *f*, SW-2-1; *g*, HL-60-9. Lanes *b–g* are from the same filter. The cell lines are described in Table 2.

human DNA (see also ref. 20). Furthermore, the EJ bladder oncogene probe detected the same novel fragments in transfected mouse lines (Fig. 3*C*, lanes *c–k*) that were previously detected using the c-Ha-*ras*1 probe (Fig. 3*A*, lanes *c–k*).

Endonuclease-cleaved Φ631 DNA was immobilized on a cellulose nitrate filter and probed with the c-Ha-*ras*1 sequences. Figure 4*a* indicates that homology between c-Ha-*ras*1 and the EJ clone is limited to the 6.6-kb *Bam*HI fragment of the bladder carcinoma oncogene; lane *b* further reduces the domain of homology between the two oncogenes to a 3.0-kb *Sac*I fragment within the 6.6-kb *Bam*HI fragment. Figure 4*f–i* shows a similar experiment to that of lanes *b–e* but in this case BS-9, a v-Ha-*ras* probe, was used (provided by Drs D. Lowy and E. Scolnick). BS-9 is a *ras* specific subclone of the Harvey sarcoma virus genome[21] and is ~450 base pairs (bp) long. This probe includes the 5′ half of the v-*ras* gene. Comparison of left and right panels of Fig. 4 confirms that the viral probe and c-Ha-*ras*1 cross-hybridize with identical fragments of the EJ oncogene DNA. Double digests (Fig. 4*g*, *i*) with *Sac*I+*Kpn*I or *Sac*I+*Xba*I indicate that the v-Ha-*ras* homology straddles the *Kpn*I and *Xba*I cleavage sites indicated at the top of Fig. 4. Most of the reactivity of the c-Ha-*ras*1 probe lies in the larger of the two fragments created by these digests (Fig. 4*c*, *e*). The deduced alignments between the EJ oncogene and the v-Ha-*ras* and c-Ha-*ras*1 probes are shown at the top of Fig. 4. The direction of transcription, deduced from the results of the present study and previous data[16,17], is from right to left on the map.

Taken together, these results indicate that the EJ bladder oncogene is closely linked to the human homologue of the rat c-Ha-*ras*1 sequences. Although the limits of the c-Ha-*ras*1 structural sequences have been well defined[16,17,20], the corresponding sequences of the EJ gene have not yet been mapped. Thus, the data above cannot exclude the possibility that the two genetic elements were adjacent to one another rather than congruent.

Analysis of transcripts homologous to the clones

The transcripts encoded by these genes were analysed to further establish their relationship to one another. We examined the RNAs of transfected cells for molecules reactive with the two oncogene probes. As shown in Fig. 5, the two probes each detected transcripts of 1.2 and 5.1 kb in both the parental tumour cell line and in EJ- and T24-transfected mouse cell lines (see also ref. 22). These transcripts were not detected in untransfected NIH 3T3 cells. Thus, introduction of the EJ oncogene into mouse cells results in synthesis of RNAs that are homologous with the rat c-Ha-*ras*1 gene. As discussed below, these data support a congruency between the functionally active region of the EJ gene and that of the c-*ras* gene.

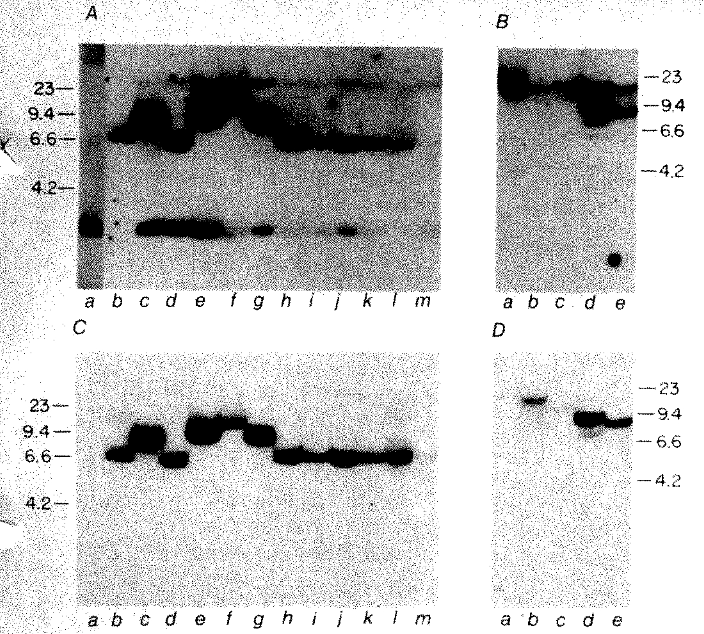

Fig. 3 Analysis of DNAs from EJ and T24 transfectants using the c-Ha-*ras*1 and EJ oncogene probes. DNAs were digested with endonuclease *Bam*HI (*A*, *C*) or *Eco*RI (*B*, *D*) and analysed as described in Fig. 1 legend. The filters shown *A* and *B* were incubated with 5×10^6 c.p.m. of c-Ha-*ras*1 DNA probe (2×10^8 c.p.m. μg^{-1}) and exposed for autoradiography for 16 h. The adsorbed ^{32}P-labelled probe was removed from the filters by washing in 0.1 M NaOH, 0.5 M NaCl, 1.0 mM EDTA. The washed filters were exposed to film for 48 h to verify that all the radioactive signal had been removed (not shown). The filters were then incubated with 5×10^6 c.p.m. of nick-translated pEJ6.6 DNA (6×10^7 c.p.m. μg^{-1}). *C* and *D* represent autoradiography after 16 h. The DNAs analysed in panels *A* and *C* were from the following cell lines: *a*, NIH 3T3; *b*, HeLa; *c*, EJ-6-1; *d*, EJ-2-R1; *e*, EJ-2-R5; *f*, E-4-R4-B; *g*, EJ-6-1; *h*, EJ-6-2-R; *i*, EJ-6-3; *j*, EJ-1-2; *k*, EJ-3-2; *l*, T-24 human cells[19]; *m*, T24-8-5. *B* and *D* display DNAs from: *a*, NIH cells; *b*, HeLa cells; *c*, EJ-6-2 (*Bam*)-1 cells; *d*, EJ-6-2(*Bam*)-2 cells; *e*, EJ-4(*Bam*)-1 cells. In *A* and *C*, lanes *c–f* and *h–k* represent DNA from cell lines that were derived from independent serial transfections of the EJ tumour cell oncogene; lanes *g* and *c* are duplicates. Lane 1 contains DNA from human bladder carcinoma cell line T24. Lane *m* contains DNA from a secondary transfectant of T24. Lanes *c–e* of *B* and *D* show an analysis of DNAs from tertiary transfectants induced by exposure to *Bam*HI-cleaved secondary transfectant DNA.

Discussion

The present data strongly suggest an evolutionary homology between the EJ human bladder carcinoma oncogene and the rat c-Ha-*ras*1 gene. We now consider the experimental basis for this conclusion and its implications.

The relatedness between the EJ and c-Ha-*ras*1 genes was first noted when we demonstrated that a cell acquiring the EJ oncogene also carried a novel DNA fragment reactive with the c-Ha-*ras*1 probe. As the linkage between the c-Ha-*ras*1 homologous sequence and the EJ oncogene was not broken by endonuclease *Bam*HI, we concluded that the two genetic elements lay within the same 6.6-kb *Bam*HI-generated fragment. These data alone were consistent with the two elements being either physically adjacent or congruent with one another. To resolve this ambiguity, we analysed the transcripts encoded by the two oncogenes. The EJ parental tumour and its derived transfectants, all express 5.1- and 1.2-kb transcripts that react with the oncogene probe. The fact that these transcripts are also present in cells transfected with *Bam*HI-cleaved DNA (data not shown) implies that the entire transcriptional unit of the 5.1-kb RNA is found within the confines of the 6.6-kb *Bam*HI-generated fragment (Fig. 3*B*, *D*).

It could be argued that the transcripts detected in transfected mouse cells are of murine origin. In this case, their synthesis would be induced indirectly in the mouse cells by the acquired human oncogene rather than being encoded directly by the human gene. We consider this unlikely, as the rat c-Ha-*ras*1 probe used had a three-fold higher specific radioactivity than the human EJ probe, but yielded a 3–4-fold lower signal intensity on autoradiography (Fig. 5). This must reflect the relatively lower affinity of the rat probe for human transcripts present in the EJ transfectants. Thus, we conclude that the two probes both detect RNAs transcribed largely, if not entirely, from the human EJ oncogene template.

A similar, if not identical, pair of transcripts has been found by colleagues working with the c-Ha-*ras*1 gene and its RNAs[22]. As both the EJ and c-Ha-*ras*1 homologous 5.1-kb transcriptional units lie within the 6.6-kb *Bam*HI fragment, we conclude that the two genes are congruent with one another rather than adjacent. Consistent with this structural homology is a functional analogy in that both genes are able to induce fibroblast transformation.

The *ras* genes encode proteins of molecular weight 21,000 (ref. 23). Immunoprecipitation of metabolically labelled lysates of transfected cells has detected a protein of this size (R. Finkelstein and R.A.W., unpublished observations). However, the association of this protein with the bladder oncogene will only be well established after its detailed peptide structure has been analysed. Knowledge of the function of this protein may elucidate the important steps in human bladder carcinogenesis.

This p21 polypeptide represents a strong candidate for the protein mediating transformation of a human tumour cell. It is

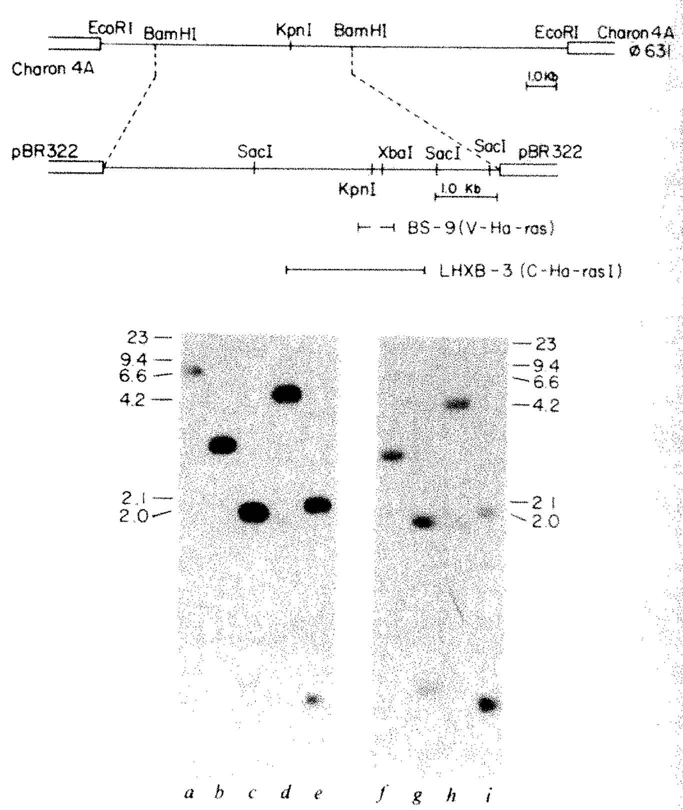

Fig. 4 Alignment of c-Ha-*ras*1 and of v-Ha-*ras* (BS-9) with the physical map of the EJ oncogene. DNA from the EJ–Charon 4A clone Φ631 was digested with several restriction enzymes. DNA (0.5 μg) was loaded onto each lane before electrophoresis and blot transfer. Identical nitrocellulose filters were prepared and incubated with ^{32}P-labelled DNA of c-Ha-*ras*1 (lanes *a–e*) or with HaSV subclone BS-9 (lanes *f–i*). Φ631 DNA was cleaved with *Bam*HI (*a*); *Bam*HI + *Sac*I (*b*, *f*); *Sac*I + *Kpn*I (*c*, *g*); *Bam*HI + *Xba*I (*d*, *h*); *Sac*I + *Xba*I (*e*, *i*). The alignment shown is accurate to within 200 nucleotides.

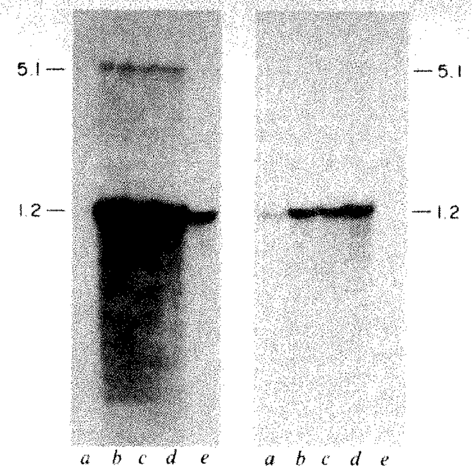

Fig. 5 Cellular polyadenylated RNAs analysed using pEJ6.6 and c-Ha-*ras*1 ^{32}P-labelled probes. In the left-hand panel, nick-translated c-Ha-*ras*1 DNA (2×10^{8} c.p.m. μg^{-1}) was used to probe RNA isolated from the following cell lines: *a*, NIH 3T3; *b*, T24-8-1 (a secondary transfectant derived from T24 human cell line); *c*, EJ-4(R1)-2; *d*, EJ-6-2; *e*, EJ human bladder. In the right-hand panel, nick-translated pEJ6.6 (6.6×10^{7} c.p.m. μg^{-1}) was used to probe the following cell lines:*a*, EJ; *b*, EJ-6-2; *c*, EJ-4(R1)-2; *d*, T24-8-1; *e*, NIH 3T3. The polyadenylated RNAs were prepared by the technique of Varmus *et al.*[40]. The RNA was then fractionated by electrophoresis through formaldehyde-containing gels and transferred to nitrocellulose (B. Seed and D. Goldberg, in preparation). ^{32}P-labelled probes, prepared as described in Fig. 1 legend, were annealed to the immobilized RNAs[41]. Bands which represent sequences homologous to the probes were visualized by autoradiography. Molecular weights were determined by comparison with markers obtained from *in vitro* run-off transcription of the adenovirus late promoter[42] and are shown in kilobases.

one of the first proteins implicated directly in the oncogenic conversion of a cell following its transformation by non-viral agents, and has been localized at the inner surface of the plasma membrane in Harvey sarcoma virus (HaSV)-transformed cells[24]. If this localization applies also to the EJ bladder carcinoma cells, then the transforming protein of these cells, the p21, should not display extracellular antigenic determinants. In this case, any tumour-specific surface antigens displayed by the bladder carcinoma cell should be encoded by genetic elements other than the oncogene itself.

The present work has several other implications. Perhaps the most apparent is that a single proto-oncogene can be activated by different molecular processes. The c-Ha-*ras*1 oncogene of the rat became activated via its affiliation with retrovirus sequences, forming the chimaeric Harvey sarcoma virus[21,25]. As demonstrated in the accompanying article[26], the human c-Ha-*ras*1 gene is also capable of oncogenic activation after it becomes linked *in vitro* to retrovirus promoter sequences. The mode of activation of the EJ oncogene is different, but not yet understood. Presently evidence suggests that the EJ oncogene and its normal human allelic counterpart sequence are indistinguishable by restriction enzyme site mapping[18]. It is possible that its activation depends on minor structural alterations, such as point mutations.

The relatedness between the EJ oncogene and that of a transforming retrovirus represents an advance in our understanding of the molecular basis of human bladder carcinoma. This stems from the fact that the structure and function of the *ras* genes and their gene products have been extensively studied[16–18,20–23].

We have been unable to demonstrate other homologies between retrovirus *onc* genes and the transfection-derived tumour genes, but this may merely reflect the small repertoire of tumour genes presently available in cloned form. As other genes become available for study, additional connections will probably be found.

Two paradoxes seem to be raised by the unexpected association of a rat sarcoma oncogene with a human bladder oncogene. First, this work implies the ability of the c-Ha-*ras*1 gene to act in unrelated tissue environments. The rat gene, when carried in Harvey sarcoma virus, can induce sarcomas and erythroleukaemias[27] while its human counterpart is now implicated in the genesis of bladder carcinomas[10–12,18,19] We consider it possible that the *ras* oncogene of either species is capable of transforming a wide range of target tissues, only a small portion of which has been studied experimentally.

Second, we have suggested that the precursor of the EJ oncogene, now identified as c-Ha-*ras*1, represents a preferred target for activation during bladder carcinogenesis[18]. It seems unlikely that the bladder urothelium was the site of acquisition of the *ras* gene during the events that let to the creation of the chimaeric HaSV genome. The two routes of oncogene activation must involve different molecular mechanisms which probably occur at different sites in the organism. Each mode of activation may be favoured by different predisposing factors present in different tissues. For example, in the bladder, the c-Ha-*ras*1 gene may be in a configuration particularly susceptible to mutational activation whereas in certain other tissues it may be expressed in a manner favouring the recombinational events that lead to creation of chimaeric retroviruses.

We thank our colleagues for providing the *onc* probes used in this study. This research was supported by US National Cancer Institute grants CA17537 and CA26717 to R.A.W.

Tumorigenic transformation of mammalian cells induced by a normal human gene homologous to the oncogene of Harvey murine sarcoma virus

Esther H. Chang*†, Mark E. Furth‡, Edward M. Scolnick‡ & Douglas R. Lowy*

* Dermatology Branch and ‡ Laboratory of Tumor Virus Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

A normal human gene homologous to the p21 ras *oncogene of Harvey murine sarcoma virus induced oncogenic transformation and high p21* ras *levels in murine fibroblasts when this gene was ligated to a control element (the long terminal repeat) from a murine or feline retrovirus. These results indicate that high levels of a gene product encoded by a normal human oncogene can induce tumorigenic transformation.*

TRANSFORMING retroviruses have been isolated from diverse sources, including birds, rodents and non-human primates (for review see ref. 1). The *in vivo* tumorigenicity of these viruses has been correlated with their ability to induce focal transformation of tissue culture cells. These infected cells are fully transformed by the criteria of anchorage-independent growth *in vitro* and tumorigenicity in animals. As viral DNA genomes and subgenomic viral DNA fragments can induce similar transformation in mouse NIH 3T3 fibroblasts[2,3], this assay has been used to define the viral sequences required for focal transformation. Two components are essential: the viral transforming oncogene (v-*onc*) and the viral long terminal repeat (LTR), a control element which permits transcription of the v-*onc* gene[4,5].

More than ten v-*onc* genes have been described, each of which has been found to be transduced from a closely related, evolutionarily conserved, cellular oncogene (collectively called c-*onc*; reviewed in ref. 6). Using v-*onc* DNAs as probes and antibodies directed against v-*onc*-specified proteins, RNA and protein expression of some c-*onc* genes has been detected in normal cells. However, the level of v-*onc* expression in virally transformed cells is usually higher than that of c-*onc* expression in normal cells, suggesting that elevated levels of c-*onc* gene expression might induce oncogenic transformation. This prediction has recently been proven at least for two rodent c-*onc* genes: c-*mos*[7,8], the mouse sequences from which v-*mos* of Moloney murine sarcoma virus (Mo-MuSV) was derived, and c-Ha-*ras*1 (ref. 9), a rat gene closely related to the transforming gene (v-Ha-*ras*) of the rat-derived Harvey (Ha) MuSV. The gene product of v-Ha-*ras* is a protein (p21) of molecular weight 21,000 (p21), and low levels of an immunologically cross-reacting non-viral p21 have been found in normal cells from various vertebrate species[10]. While v-Ha-*ras* contains no intervening sequences (IVS) within the p21 coding sequences, rat c-Ha-*ras*1 has three IVS between its four exons. In contrast to most other c-*onc* genes, mouse c-*mos* does not contain intervening sequences, and transcription of this gene in normal cells has not been observed[8,11]. Nonetheless, both rat c-Ha-*ras*1 and mouse c-*mos* DNAs were capable of inducing cellular transformation of mouse NIH 3T3 cells, provided that a viral LTR was ligated upstream from the cellular *onc* gene. Transformation was associated with high RNA levels of c-Ha-*ras* or c-*mos*, respectively, and in the case of c-Ha-*ras*, high levels of p21.

† Present address: Department of Pathology, Uniformed Services University of the Health Sciences, Bethesda, Maryland 20014, USA.

Given the evolutionary conservation of c-Ha-*ras*1 (refs 12, 13), we have sought to determine whether its counterpart in normal human cells has oncogenic potential similar to that of rat c-Ha-*ras*1. If the rat and human genes behaved similarly, it would suggest that the capacity of this oncogene to induce transformation was a property of this gene in any species. As part of our studies of *ras* genes, we have recently detected and cloned from normal human DNA four genes which share homology with v-*ras*[13]. The *ras* sequence in one of these human genes (called human c-Ha-*ras*1) was closely related to v-Ha-*ras* and had a structure very similar to that of rat c-Ha-*ras*1. We have now found that this human gene can induce oncogenic transformation of NIH 3T3 cells when an LTR is present upstream. The transformants form tumours in nude mice and

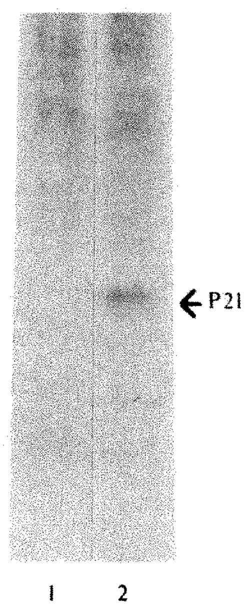

Fig. 1 Immunoprecipitation of endogenous p21 from normal human cells. WI-38 human fibroblasts were metabolically labelled with ^{35}S-methionine for 18 h and lysates were prepared and immunoprecipitated (5×10^6 c.p.m. of TCA-precipitable counts) by a monoclonal antibody as described elsewhere[15,35]. Dissolved immunoprecipitates were then electrophoresed on a 10.5% SDS-polyacrylamide gel. Lane 1, anti-α-tubulin antibody; lane 2, v-Ha-*ras* p21-specific antibody (Y13-238). This monoclonal antibody was also used in Figs 4, 6.

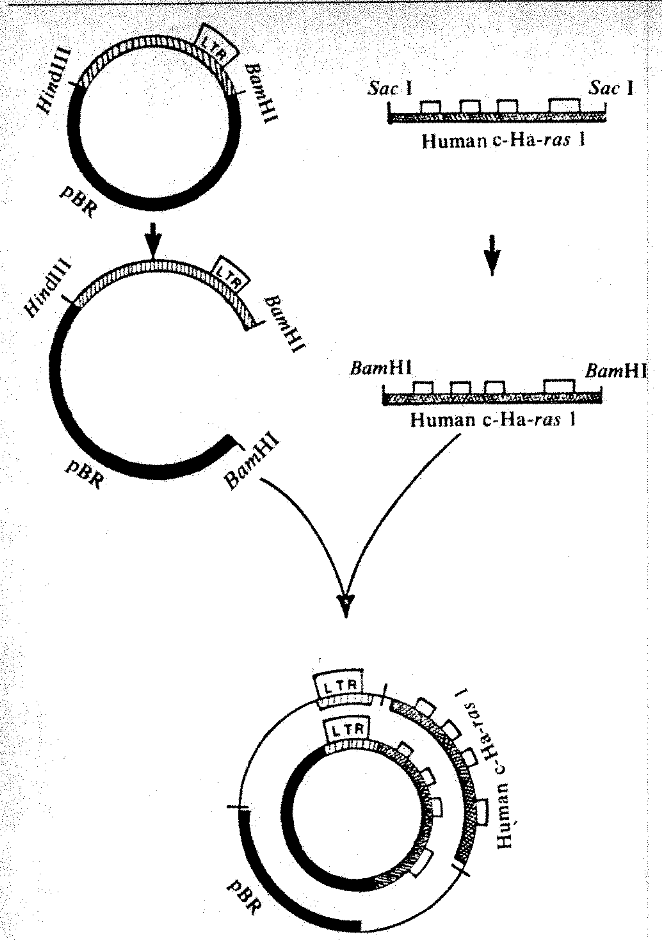

Fig. 2 Schematic representation of the construction of the Ha-MuSV LTR–human c-Ha-*ras1* recombinant. To ligate an LTR upstream from the human c-Ha-*ras1* gene, we constructed a chimaeric recombinant plasmid between the 2.9-kb *SacI* fragment of human c-Ha-*ras1* and a pBR322 clone which already contained the Ha-MuSV LTR. This *SacI* fragment contains all the c-Ha-*ras1* sequences which hybridized to v-Ha-*ras*[12]. The pBR322 LTR clone chosen for this construction (clone P-14) contains a 2.5-kb *HindIII/BamHI* fragment of Ha-MuSV DNA; these sequences, which are derived from a circularly permuted molecule of Ha-MuSV[18], span the region from a *HindIII* site in the 3' end of the Ha-MuSV DNA to the LTR and include 0.3 kb of 5' sequences beyond it to a *BamHI* site; they do not include v-Ha-*ras* sequences. To facilitate insertion of the c-Ha-*ras1 SacI* fragment at the unique *BamHI* site in clone P-14, an attempt was made, as shown in the figure, to add *BamHI* oligonucleotide linkers (Collaborative Research) to the *SacI* ends, after the termini were made flush with DNA polymerase I (Klenow). This change in the ends of the 2.9-kb c-Ha-*ras1* fragment was, however, apparently not achieved because when DNAs from two clones (6-2 and 6-9) which hybridized to a Ha-*ras* probe were analysed, they contained deletions around the inserted sites as shown in the inner circular DNA at the bottom of the figure, instead of the predicted *BamHI* insert shown in the outer circular DNA. There was also a deletion in the 3' sequence of the Ha-MuSV DNA upstream from the LTR. The deletions were 1.4 kb in the 3' sequences of Ha-MuSV DNA, 0.3 kb at the junction between the Ha-MuSV and human c-Ha-*ras1* sequences, and 1.8 kb at the junction between pBR322 and human c-Ha-*ras1*; 1.7 kb of this latter deletion was contained in pBR322 sequences. Despite these deletions, the viral LTR and the region of c-Ha-*ras1* homologous to v-Ha-*ras* were both intact and joined in a single cloned molecule. pBR322 DNA is represented by solid shading, Ha-MuSV DNA by diagonal shading, and human c-Ha-*ras1* DNA by cross-hatching. The open rectangles in c-Ha-*ras1*, which is shown left-to-right in the 5'–3' orientation, represent the exons in the gene.

contain high levels of a p21 which is similar to that specified by the rat gene.

Normal human cells contain low levels of p21

We have recently reported that p21 *ras* is a gene family which consists of at least two prototypic gene types[14]: those closely related to *ras* of Ha-MuSV (Ha-*ras*) and those closely related to *ras* of Kirsten (Ki) MuSV. Ki-MuSV is a rat-derived virus whose v-*ras* encodes a p21 which is immunologically related to the Harvey p21. Of the four human *ras* genes we have detected[13], human c-Ha-*ras1* contains three IVS, as does rat c-Ha-*ras1*, and it is closely related to v-Ha-*ras*. Two of the other human *ras* genes are more closely related to v-Ki-*ras*, and one is distantly related to v-Ha-*ras*.

Because p21 *ras* is a gene family consisting of at least Harvey and Kirsten type genes, it is not clear which of these genes encode the low p21 levels detected in normal cells. The p21 in rodent fibroblasts have recently been found to be predominantly of the Kirsten type[15]. This analysis was made possible by the isolation of a panel of eight monoclonal antibodies to v-Ha-*ras* p21 (ref. 15), the specificities of which have been defined by the viral forms of p21: some recognize Harvey viral p21 but not Kirsten viral p21, whereas others detect both the Harvey and Kirsten forms of p21. In rodents, the type specificity of these monoclonal antibodies apparently also extends to p21 species encoded by Harvey and Kirsten type c-*ras* genes[15,16].

To determine whether human cells contain Harvey type p21, as defined above by the monoclonal antibodies, ^{35}S-methionine-labelled extracts of normal human diploid fibroblasts (WI-38 cells) were immunoprecipitated with a v-Ha-*ras* p21-specific monoclonal antibody. In contrast to rodent fibroblasts[15], a distinct 21K band was detected with this antibody (Fig. 1). This result suggests that these human cells contain significant levels of Ha-*ras* p21.

LTR activation of human c-Ha-*ras1* transforming activity

The two previously cloned c-*onc* retroviral homologues, mouse c-*mos* and rat c-Ha-*ras1*, which have been shown to possess oncogenic potential, were both inactive by themselves when assayed for their ability to transform NIH 3T3 cells[7–9]. To demonstrate their capacity to induce morphological transformation, it was necessary to ligate a viral LTR upstream from the

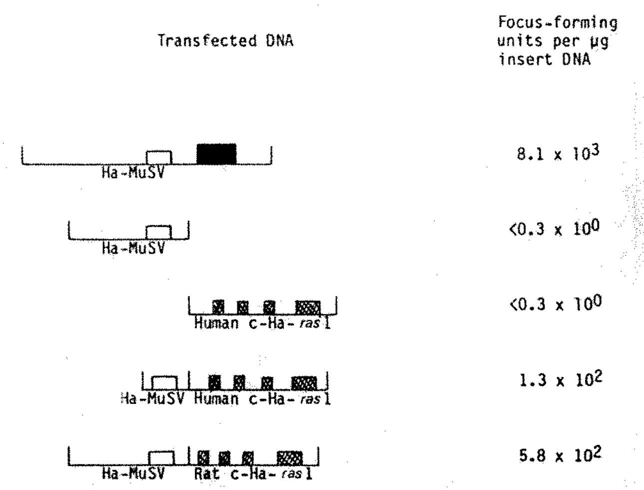

Fig. 3 Transformation induced by the normal Harvey *ras* oncogene. DNAs were precipitated with calcium chloride[36] and 0.2 ml was added to 35-mm dishes seeded on the previous day with 2.25×10^5 NIH 3T3 cells. Calf thymus DNA (25 µg ml^{-1}) was used as carrier. Each DNA insert shown was cloned in pBR322; 0.1 or 0.2 µg of insert DNA was used per dish. The DNAs were added without digestion by a restriction endonuclease. The cells were treated as described elsewhere[2], except that DM50 was not used. Foci were counted 16 days later. The viral LTR is represented by an open rectangle, v-Ha-*ras* by a solid rectangle, and the exons of c-Ha-*ras1* (defined by their homology to v-Ha-*ras*) by cross-hatched rectangles. Ha-MuSV DNA was genomic clone H-1, which is a 5.4-kb circularly permuted copy of the viral DNA genome[5,37]; Ha-MuSV LTR DNA was clone P-14, described in Fig. 2 legend; human c-Ha-*ras1* DNA contained the 2.9-kb *SacI* fragment also described in Fig. 2 legend. In other experiments, a 6.6-kb *BamHI* fragment of c-Ha-*ras1* which contained this 2.9-kb *SacI* fragment also failed to induce foci. Ha-MuSV LTR–human c-Ha-*ras1* DNA was clone 6-2 (clone 6-9 gave similar results in other experiments) described in Fig. 2 legend. Ha-MuSV LTR–rat c-Ha-*ras1* DNA was clone P-14 into which a 2.3-kb fragment of rat c-Ha-*ras1* had been inserted (by M. Haiken, R. Ellis and E.H.C.) at the *BamHI* site. This 2.3-kb fragment of rat c-Ha-*ras1* extends from *EcoRI* to *XbaI* in clone LHBE[9]; these sites were converted (by R. Ellis) to *BamHI* by adding oligonucleotide linkers and cloned at the *BamHI* site in pBR322 (this latter clone is called LXBE).

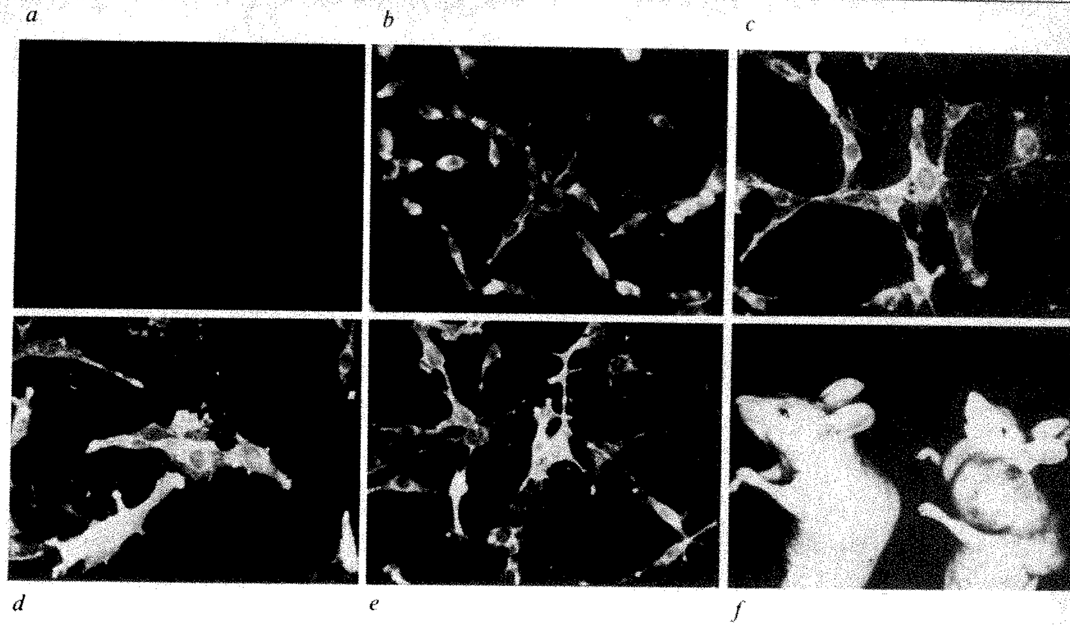

Fig. 4 Detection by immunofluorescent staining of p21 in NIH 3T3 cells transformed by Harvey v-*ras* and c-*ras* genes; tumour formation of human c-*ras* transformants. *a–e*, NIH 3T3 cells and derivatives transformed by Harvey v-*ras* or c-*ras* genes were tested for expression of p21 by indirect immunofluorescent staining with a monoclonal antibody specific for Harvey *ras* p21: *a*, NIH 3T3 cells; *b*, clonal line transformed by Ha-MuSV (viral non-producer Ha821); *c*, clonal line transformed by rat c-Ha-*ras*1 ligated to LTR of Ha-MuSV 9; *d*, focus of cells transformed by human c-Ha-*ras*1 ligated to LTR of Ha-MuSV (clone 6-2); *e*, focus of cells transformed by human c-Ha-*ras*1 ligated to LTR of FeSV. Trypsinized cells were grown on 8-spot printed glass slides (Roboz Surgical) pretreated with 0.1% gelatin, for 18 h at 37 °C in Dulbecco's modified essential medium (DMEM)+10% fetal calf serum. After washing with phosphate-buffered saline (PBS), the cells were fixed by incubation at 25 °C for 10 min in 3.7% formaldehyde in PBS, followed by incubation in absolute methanol at −10 °C for 4 min. The slides were rinsed briefly in acetone (−10 °C) and air-dried. The fixed cells were incubated at 37 °C for 45 min with monoclonal antibody Y13-238 (ref. 15). The antibody was concentrated and partially purified from culture supernatants of cells grown in serum-free medium, and was used at a final concentration of ~20 μg ml^{-1} in PBS with 0.4% (w/v) bovine serum albumin (BSA). After washing with PBS, the cells were incubated at 37 °C for 45 min with rhodamine-labelled antibodies against rat IgG, prepared in goats (Cappel Laboratories). The fluorescent antibody was affinity-purified on a column of rat IgG by Dr Jurgen Wheland, NCI, and was used at a concentration of 125 μg ml^{-1} in PBS with 0.4% BSA. The slides were washed extensively with PBS, mounted under coverslips (no. 1) with Elvanol (DuPont), and observed using a Zeiss microscope equipped with epifluorescent optics. The cells were photographed under UV light using a ×40 Planapochromat objective. Photographs were matched for times of exposure and development, except that the development time for *a* was reduced to enhance the low level of background staining; at matched development this panel would be completely black. Controls of normal and transformed cells stained after incubation with normal rat serum or irrelevant monoclonal antibodies are indistinguishable from *a* (data not shown). Final magnification is ×105. *f*, On the left is a nude mouse showing no evidence of a tumour, 3 weeks after subcutaneous inoculation with 2×10^6 NIH 3T3 cells; on the right is a nude mouse having a large tumour at the site where the mouse was inoculated 3 weeks previously with 5×10^5 cells from a focus transformed by clone 6-2 (human c-Ha-*ras*1 ligated to the LTR of Ha-MuSV). In this experiment none of five mice inoculated with 2×10^6 NIH 3T3 cells developed tumours after 10 weeks, whereas all of five mice inoculated with cells from the lines shown in *b–e* developed palpable tumours within 2 weeks.

5′ end of the gene. Similarly, attempts to induce cellular transformation with the human c-*ras* genes without an LTR have been unsuccessful. In our initial attempts to transform cells with the c-*ras* genes, we have focused on human c-Ha-*ras*1, which preliminary molecular hybridization data have suggested is transcriptionally active in normal human fibroblasts (E.H.C. *et al.*, unpublished data).

We therefore constructed a chimaeric plasmid containing the LTR of Ha-MuSV upstream from human c-Ha-*ras*1 (see Fig. 2). This chimaeric DNA induced focal transformation of NIH 3T3 cells in all of four separate experiments. While the foci induced by Ha-MuSV DNA were usually first detected about seven days after addition of the DNA to the cells, the foci induced by human c-Ha-*ras*1 were generally detected about nine days after addition of the DNA; this short delay has also been observed for rat c-Ha-*ras*1. The results of a typical experiment are shown in Fig. 3. The number of foci induced by a chimaeric plasmid containing an LTR upstream from rat c-Ha-*ras*1 was an order of magnitude lower than that induced by a circularly permuted full-length Ha-MuSV DNA genome. The clone containing human c-Ha-*ras*1 induced only about one-fifth as many foci as did the rat c-Ha-*ras*1 clone. The higher efficiency of transformation by the chimaeric plasmid containing rat c-Ha-*ras*1 may be due to the fact that it carries almost 2 kilobases (kb) more non-*ras* Ha-MuSV sequences upstream from the LTR than were present in the chimaeric plasmid with human c-Ha-*ras*1; deletion of these sequences has previously been associated with a lower efficiency of transformation by Ha-MuSV DNA[5,17]. In further experiments, three independent foci were also obtained in the NIH 3T3 cells when the human c-Ha-*ras*1 fragment (a 2.9)-kb *Sac*I fragment[13]) was ligated without cloning to a 1.4-kb *Sac*I fragment which contained the cloned LTR of the Gardner–Arnstein strain of feline sarcoma virus (FeSV)[18].

In addition to being phenotypically transformed, the cells transformed by human or rat c-Ha-*ras*1 were also tumorigenic for nude mice: palpable tumours developed in less than two weeks in mice inoculated with 5×10^5 transformed cells, whereas no tumours were evident in the 10 weeks following inoculation with 2×10^6 control cells (see Fig. 4*f*).

Human gene transformants contain the LTR and human c-Ha-*ras*1

To determine the presence of the cloned DNA in the transformed NIH 3T3 cells, genomic DNA from transformants was analysed for the presence of LTR and human c-Ha-*ras*1 sequences. Genomic DNAs were digested with restriction endonuclease, and fragments were fractionated by agarose gel electrophoresis, transferred to nitrocellulose paper, and hybridized with ^{32}P-labelled LTR and human c-Ha-*ras*1 probes (Fig. 5). Hybridization to the *ras* probe of *Eco*RI-digested genomic DNA from a transformant yielded two major new fragments of 7.6 and 5.8 kb (Fig. 5*a*, lane 3)—this indicated that the transformant contained additional *ras* sequences. These new fragments were presumably human c-Ha-*ras*1, since at the exposure in the autoradiogram shown in Fig. 5, the probe detected the 25-kb *Eco*RI fragment in human genomic DNA previously identified as containing c-Ha-*ras*1 (ref. 13; Fig. 5*a*, lane 1) and did not reveal endogenous mouse *ras* fragments in the NIH 3T3 cells (Fig. 5*a*, lane 2). The LTR was presumptively identified as being linked to both of these fragments, as hybridization of *Eco*RI-digested DNA from the transformant to the LTR probe detected, in addition to multiple copies of endogenous LTR fragments, two novel fragments which co-migrated with the two fragments identified using the *ras* probe (Fig. 5*b*). The 5.8-kb *Eco*RI fragment is similar in size to the input cloned DNA, suggesting that some of the copies might still be intact circular episomes or integrated in tandem.

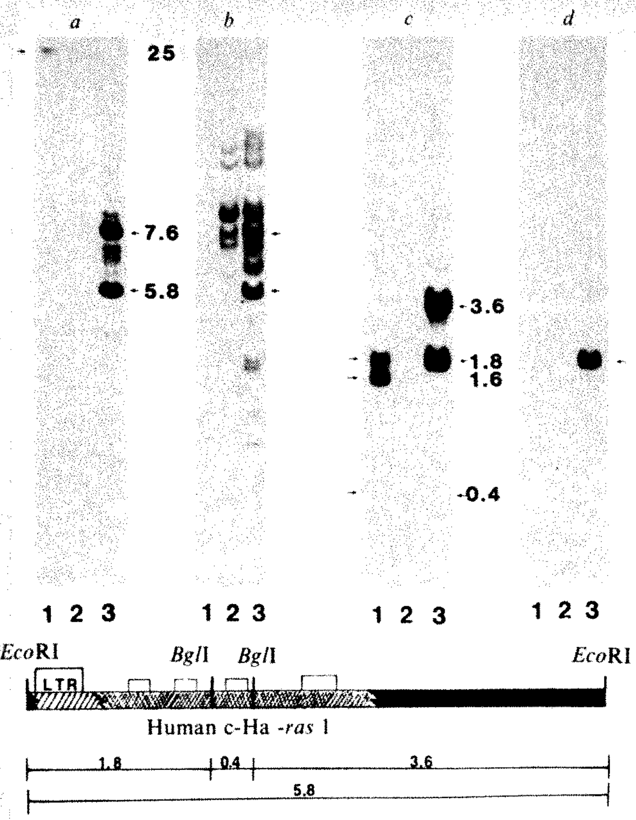

Fig. 5 Southern blot analysis of restriction endonuclease-digested high-molecular weight cellular DNA. Restriction endonuclease-digested genomic DNA was electrophoresed in 0.6% agarose gels, transferred to nitrocellulose filters, and hybridized to c-Ha-*ras* or LTR ^{32}P-labelled probes in 4×SSC, 0.2% of *Escherichia coli*, BSA, PVP, 0.1% SDS and 50 μg μl^{-1} of low-molecular weight salmon testes DNA at 65 °C for 36–48 h (ref. 37). Filters were then washed in 0.1×SSC and 0.1% SDS for 1 h with four changes and in 0.1×SSC for 1 h with two changes at 65 °C. *a*, *b*, All lanes contain *Eco*RI-digested genomic DNAs; *c*, *d*, all lanes contain *Eco*RI/*Bgl*I-digested genomic DNAs. For each panel, lane 1 is human placenta; lane 2, NIH 3T3; lane 3, 6-2 clone (LTR–human c-Ha-*ras*1)-transformed NIH/3T3. The ^{32}P-labelled probes used for hybridization were: human c-Ha-*ras*1, *Sac*I–*Sac*I 2.9-kb insert for *a* and *c*; Ha-MuSV LTR 0.65-kb insert for *b* and *d*. The schematic drawing at the bottom represents the linear molecule resulting from *Eco*RI digestion of the chimaeric plasmid 6-2 or 6-9, described in Fig. 2 legend. Ha-MuSV (non-*ras*) sequences are indicated by shading with diagonal lines, human c-Ha-*ras*1 sequences by cross-hatching, and pBR322 sequences by solid shading. Open rectangles in c-Ha-*ras*1 represent exons.

The linkage of the LTR and human c-Ha-*ras*1 sequences in the DNA of the transformants was confirmed by *Eco*RI+*Bgl*I digestion of the genomic DNAs. This double digestion cleaves the pBR–LTR–human c-Ha-*ras*1 cloned DNA into three fragments: a 1.8-kb fragment containing LTR and some *ras* sequences, a 0.4-kb *ras*-containing fragment, and a 3.6-kb fragment which includes *ras* and pBR sequences (see schematic drawing in lower part of Fig. 5). The 1.8-kb fragment was detected with the LTR and the *ras* probes (Fig. 5*c*, *d*, lane 3), indicating that the LTR and *ras* fragments were linked to each other. The predicted 3.6-kb fragment was also easily detected with the *ras* probe, and the 0.4-kb fragment, not seen at this exposure, was detected in longer autoradiographic exposures. These results indicate that the cloned DNA is intact in the transformed cells. Similar results have also been obtained with genomic DNA from two other foci induced by the cloned DNA (data not shown).

Transformed cells contain high levels of Ha-*ras* p21

Having demonstrated that the LTR and c-*ras* sequences were intact, it was important to determine that the transformed cells contained high levels of Harvey type p21. Immunofluorescent staining of the transformants with a Harvey-specific monoclonal p21 antibody yielded positive results (Fig. 4). While the normal mouse cells were not detectably stained by the antibody, cells transformed by v-Ha-*ras*, rat c-Ha-*ras*1 and human c-Ha-*ras*1 (with FeSV or Ha-MuSV LTR) all gave a similar pattern of intense staining consistent with the membrane fluorescence previously reported for v-Ha-*ras*-transformed cells[19].

The transformants were also analysed by immunoprecipitation for Ha-*ras* p21. When ^{35}S-methionine-labelled extracts of the transformants were reacted with a Harvey p21 monoclonal antibody, high levels of p21 were precipitated (Fig. 6). This was observed both for cells transformed by the chimaeric Ha-MuSV LTR–human c-Ha-*ras*1 plasmid and for a transformant induced by ligation of the FeSV LTR to human c-Ha-*ras*1. The p21 in the cells transformed by the human gene resembled that obtained from cells transformed by rat c-Ha-*ras*1. While the p21 encoded by v-Ha-*ras* consists of two forms, as shown by the double band in the autoradiogram (Fig. 6*b*), the p21 of the cells transformed by either c-Ha-*ras*1 gene contain only a single detectable form of p21. Further details on the biochemical comparison of v-*ras* p21 and c-*ras* p21 will be published elsewhere.

Significance of c-Ha-*ras*-induced transformation

The *ras* multigene family consists of at least two types of p21 genes that were first identified with *ras* probes derived from Harvey and Kirsten murine sarcoma viruses. Two other transforming retroviruses have also transduced c-*ras* sequences: the BALB (B) MuSV, isolated from a BALB mouse[20,21], and the rat MuSV, isolated from rat cells in tissue culture[22,23]. These two viruses have both transduced a Harvey type c-*ras* gene[13,21,23]. While the oncogenic potential of the LTR-activated cloned c-*ras* genes have been demonstrated here only for NIH 3T3 cells, the *ras*-containing retroviruses can transform a wide variety of other cell types from humans and other species, including primary and epithelial cells.

Previous studies have shown that two rodent c-*onc* genes homologous to v-*onc* from a transforming retrovirus can induce oncogenic transformation, when activated by a retroviral LTR leading to their high level expression. The present studies

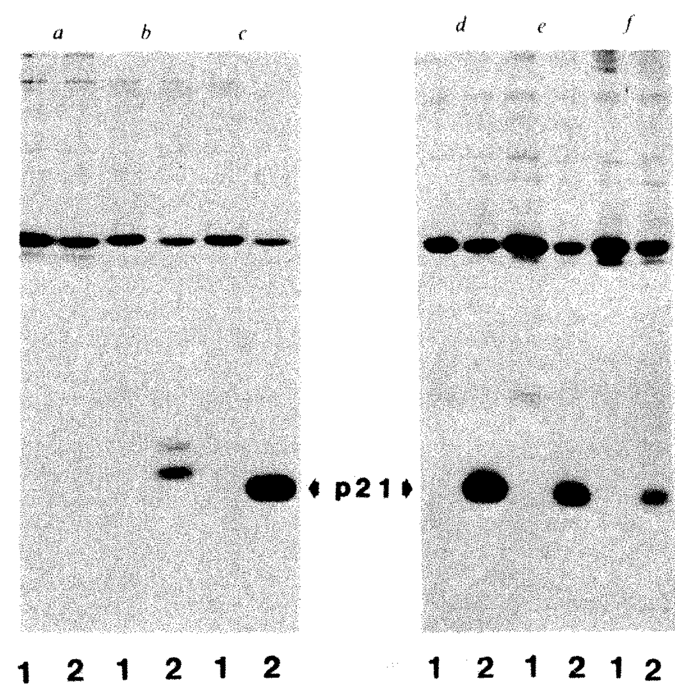

Fig. 6 Gel electrophoresis of immunoprecipitates of p21 in normal c-Ha-*ras*1-transfected NIH/3T3 cells. Cells were labelled with ^{35}S-methionine at 37 °C for 16 h and extracts were prepared and immunoprecipitated as described elsewhere[15,35]. Lane 1, no antibody; lane 2, anti-Harvey p21 monoclonal antibody (Y13-238). *a*, Uninfected NIH/3T3 cells; *b*, Ha-MuSV-transformed cells (Ha 821); *c*, rat c-Ha-*ras*1-transformed cells. *d*–*f*, Human c-Ha-*ras*1-transformed cells: *d*, ligated to FeSV LTR; *e*, clone 6-2; *f*, clone 6-9.

extend this finding to a human c-*onc*, a species from which a transforming retrovirus has not yet been isolated. These results suggest that such transformation may be a general feature of c-Ha-*ras*1 genes. It should also be stressed that these rodent and human genes have been cloned from normal cellular DNA, and they have not by themselves induced focal transformation of NIH 3T3 cells.

Given the tumorigenic properties of these activated normal genes, it seems reasonable to speculate that other cellular oncogenes may possess analogous tumorigenic potential, and that normal transcriptional control mechanisms prevent these genes from being continuously expressed at high levels. These and other examples of LTR-mediated activation of a cellular oncogene[8,9,24–26] suggest that a constitutive change in the transcriptional control of an oncogene could represent an important mechanism in the pathogenesis of some cancers. Such changes in oncogene expression might be induced either by viral or other mechanisms, such as somatic mutation or recombination. In this regard, it has recently been reported that, in contrast to the very low transforming potential of genomic DNA from normal cells, genomic DNA from some human malignancies is able by itself to induce oncogenic transformation of NIH 3T3 cells[27–29]. These transforming sequences from a bladder carcinoma have recently been molecularly cloned and have retained their oncogenicity[30–32]. As reported in the accompanying paper[33], this cloned gene has now been identified as human c-Ha-*ras*1. Similar observations have also been made by others[32,34]. Because the normal c-Ha-*ras*1 gene and the human tumour c-Ha-*ras*1 gene are now available, it should be possible to localize the alterations in the normal gene that are responsible for the dramatic change in biological activity of the gene isolated from the bladder tumour. This analysis may help to elucidate the molecular basis of neoplastic transformation in a human cancer.

We thank Drs Ronald W. Ellis and Thomas Y. Shih for helpful discussions; Mr Jerome Goodwin, Ms Shirley Yu and Ms Marilyn R. Lander; and Ms Barbara Fleurdelys for technical assistance. Lithium abundance at the formation of the Galaxy

M. Spite & F. Spite

Observatoire de Paris-Meudon, Section d'Astrophysique, 92190 Meudon, France

The observed abundance of lithium in population I stars (young stars)[1] seems to have been stable during the past 5×10^9 yr (ref. 2). This stability has been used previously[1,3] to estimate the abundance of lithium at the time of formation of the Galaxy and at pre-galactic times[1,3]. But because the basis for this estimate was not completely satisfactory, we have made new observations, aiming at a better determination of the lithium abundance at the time of formation of the Galaxy. The newly observed stars are extreme population II dwarfs (very old, very metal-poor stars). Their lithium abundance turned out to be significantly lower than the abundance in population I stars. If attributed to the big bang, this lithium abundance suggests a rather low baryonic density of the Universe, which in turn favours, under some assumptions, an open Universe[3]. Finally, we suggest that the good agreement between the abundance of ^{7}Li and the deuterium ^{2}H abundance[3] supports the standard model of the big bang.

The new Canadian, French, Hawaian (CHF) 3.6-m telescope[4] with its large collecting area, excellent seeing conditions and the sensitivity of its Reticon receiver has made it possible to observe the lithium resonance line[5] in dwarf stars of the extreme population II, often called halo dwarfs (typical representative of the halo of the Galaxy). These stars are very old and their metal deficiency reflects the lack of metals at the time of their formation. They are faint and the lithium line is narrow and faint in such stars, so that its measurement requires high resolution spectra with a high signal-to-noise ratio. Good spectra were obtained for a few of these stars and lines as faint as 3 mÅ can be detected. A comparatively strong lithium line (23–50 mÅ) was observed[5,6] in all except the coolest star. This absence of lithium is easily understood when it is recalled that the convective zone is very deep in cool stars: the lithium is then driven down into very hot layers, where it is completely destroyed by proton fusion[7].

From the measured wavelength of the observed lithium line it seems that the absorbing species is essentially the ^{7}Li isotope.

A classical spectrum analysis using model atmospheres has been carried out to determine the abundance of lithium for each star. The high quality of the spectra means that the error on the equivalent widths is negligible. The random error in determination of the lithium abundance ($n_{\rm Li}$) comes essentially from the lack of precision about the effective temperature ($T_{\rm eff}$) of the stars. For this type of stars it is generally admitted that $\Delta\log T_{\rm eff}=0.01$. If $\log T_{\rm eff}$ is increased by 0.01, then $\log n_{\rm Li}$ will be increased by about 0.2 (Fig. 1).

Clearly, the present sample of Li abundances in population II dwarfs is very small; however, the abundance of lithium is

0028–0836/82/230483—03$01.00

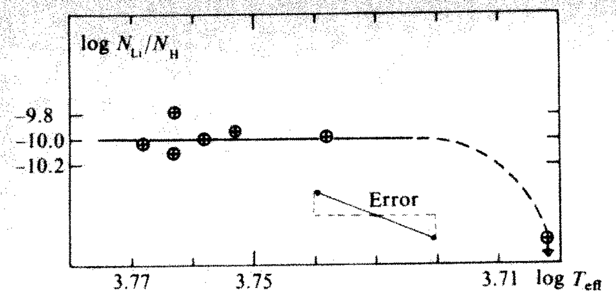

Fig. 1 Lithium abundance plotted against effective temperature (logarithmic scale) for very old metal-poor stars. The lithium abundance is remarkably constant except for the coolest star: here, deep convective movements carry the lithium into very hot layers where it is completely destroyed.

remarkably constant in all the observed halo dwarfs but the coolest one (Fig. 1). This constancy versus the effective temperature T_{eff} of the stars is also a measure of constancy versus the mass of these essentially unevolved stars. If confirmed by more observations, this suggests that lithium is not destroyed by convection in solar type stars of population II, at variance with what is assumed[8] in population I stars. Taking advantage of this constancy, it is easy to show that the lithium abundance (relative to hydrogen) in the atmospheres of old halo dwarfs is $N_{Li}/N_H = 10^{-10}$—about 10 times less than the population I abundance[1].

This lithium is not expected to come from the inside of the star: nucleosynthesis of lithium has been predicted only for stars in a much more advanced stage of evolution[9]. Nor is the ^{7}Li expected to come from outside: most of these are stars whose velocity, relative to population I interstellar clouds, is high, so that the accretion process is inefficient[10,11].

The lithium observed in the halo dwarfs has its origin in the lithium existing in the material which formed these stars. The abundance of lithium found in the atmosphere of the star should not be very different from the abundance in this material. Admittedly, several causes of depletion of lithium may exist: some lithium may be destroyed during the contraction of the protostellar cloud[7,12] (pre-main sequence phase); microscopic and/or turbulent diffusion (acting during the very long life in the main sequence of these very old stars) could deplete the lithium[13]; the stellar mass-loss acting over a long time could also cause depletion (H. Reeves, personal communication). All these effects are not yet well known for halo stars; moreover, at first sight it could be conjectured that they are mass (and/or temperature) dependent; this was confirmed by other observations, and the constancy of the lithium abundance suggests that these processes are not very efficient. Keeping in mind the causes of uncertainty, let us assume that $N_{Li} = 10^{-10}\ N_H$ is the abundance of the material which formed the halo dwarfs. This abundance cannot be significantly different from the abundance of the pre-galactic material: admittedly, the atmosphere of the halo dwarfs includes some material processed in supernovae; this material, when astrated, was on the one hand deprived of its lithium, and on the other hand strongly enriched in metals. As the halo dwarfs are metal poor, only a very small fraction of the astrated material can have been mixed in the pre-galactic material; the lithium abundance seems constant within rather wide limits of metal abundance (1/20–1/200 of the solar metal abundance). It seems therefore that we can take the lithium abundance of the atmospheres of the halo dwarfs as the abundance of the pre-galactic material.

Evaluated by mass, this pre-galactic lithium abundance is $X_7 = 5.2 \times 10^{-10}$ (assuming a helium abundance $Y = 0.25$ by mass). If attributed to the big bang, this abundance leads[14], according to the standard theory, to a rather low baryonic density of the Universe (Fig. 2) lower than the density previously derived by Boesgaard[1] and by Austin and King[3]. The density found remains, however, in agreement with that derived from the abundance of the deuterium[3], within the estimated errors. For an easier comparison with the work of Austin and King, the Hubble constant retained was $H_0 = 55$ km s^{-1} Mpc^{-1}.

The error of the primordial lithium abundance determination may be estimated as follows.

(1) The classical abundance analysis, using models of atmospheres, with a few simplifying assumptions (such as local thermodynamical equilibrium), may induce an error as high as a factor of 2 (about $10^{0.3}$ or 0.3 dex). However, the systematic part of this error is about the same for populations I and II, so that it cancels out, at least partly, when comparing relative abundance in populations I and II. When using several stars, the random part of the error decreases accordingly, even when adopting the parameters T_{eff} and g as they appear in the literature (without homogenization).

(2) There is some uncertainty about the possible depletion of lithium, owing to the possible proto-stellar destruction and/or depletion due to diffusion, and/or lithium depletion due to stellar wind. This uncertainty is difficult to estimate. We can adopt, as an upper limit, a factor of ~3 (0.5 dex), because Duncan[8] and Bodenheimer[12] predict only a factor of 2 for proto-stellar destruction for solar type stars.

Thus taking account of the cumulated errors, the final uncertainty about the difference between the lithium abundance in populations I and II is probably less than a factor of 6 (0.8 dex); so that we have to accept that the abundance of lithium is probably lower in population II than in population I.

It seems that the evolution of the Galaxy has not significantly decreased the abundance of the primordial lithium[2]; as lithium is destroyed inside stars and stellar envelopes, a lithium-producing process must be found. Spallation is only partially responsible for this production[15]; a promising possibility is production in novae[16].

Even considering the uncertainties involved in the interpretation of the lithium abundance in halo dwarfs, our work provides a clear demonstration that the Universe cannot be closed by

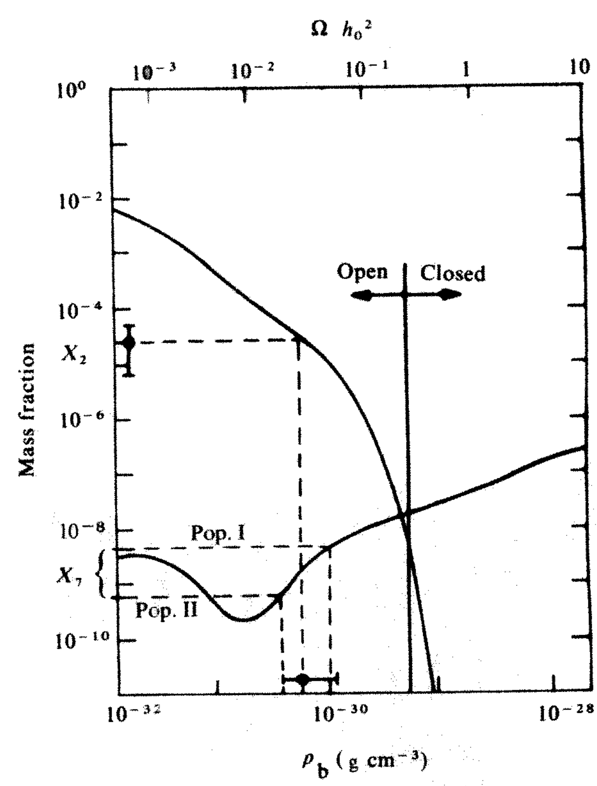

Fig. 2 The new lithium abundance X_7 found in this work leads to a rather low baryonic density, in agreement (within determination errors) with that derived from deuterium abundance. The values of the Hubble constant is the same as in ref. 3. If the cosmological constant Λ is assumed to be zero, this leads, more clearly than in previous work, to the conclusion that the baryonic density is not large enough to close the Universe.

nucleons, when assuming the validity of the standard model[14] of the big bang and assuming a zero value for the cosmological constant ($\Lambda = 0$). This result remains unchanged when compared with the model of Yang *et al.*[17], which has three pairs of neutrinos ($\Omega_N h_0^2 = 2 \times 10^{-2}$). More observations, a better theory of protostellar and stellar convection, a better theory of diffusion and a better theory of stellar wind are needed to obtain a more accurate value of the primordial lithium abundance. However, even within the present uncertainty, some agreement exists between the baryonic density predicted from lithium and deuterium abundances, and when confirmed, this agreement will support the validity of the standard model of the big bang.

We thank the CFHT staff and especially Drs B. Campbell, G. Lelièvre, J-P. Maillard and Mr B. Grundseth for help with the observations. The data were processed through the VAX computer of the Service Informatique of the Paris–Meudon Observatory: we thank especially Mr Tran Van Tue for help with tape decoding.

Five-minute oscillations as a subsurface probe of sunspot structure

John H. Thomas*, Lawrence E. Cram† & Alan H. Nye‡

* University of Rochester, Rochester, New York 14627, USA
† Sacramento Peak Observatory, Sunspot, New Mexico 88349, USA
‡ Rochester Institute of Technology, Rochester, New York 14623, USA

Observations are reported here which show that the 5-min oscillations in a sunspot umbra actually split into several individual modes of different period. We interpret these modes of oscillation as the response of the sunspot to forcing by the 5-min p-modes in the surrounding quiet atmosphere. Also, we show how detailed observations of the multiple 5-min modes in a sunspot may be used as a probe of the structure of a sunspot beneath the solar surface.

Oscillatory velocity fields in sunspots may be divided into two categories. The first category consists of the umbral oscillations (period 145–190 s) and the running penumbral waves (period 180–250 s). Observations suggest that these waves are resonant modes (see refs 1, 2), and theoretical work[3–7] has identified these waves with resonant magneto-atmospheric wave modes of the sunspot atmosphere itself. These waves, which are presumably excited by subsurface oscillatory convection, offer indirect evidence of the existence of overstable convective modes in the subphotosphere.

The other category of oscillations in sunspots consists of oscillations with periods around 5 min, the dominant period of oscillations in the quiet photosphere. Recent observations[8–10] have overcome the problems of stray light from the surrounding photosphere and the lack of an absolute wavelength reference and have confirmed the existence of 5-min oscillations in sunspot umbras, at power levels well below that in the quiet photosphere. As there are no resonant modes of sunspot oscillations in the 5-min range, we have suggested[11] that these 5-min oscillations represent the passive response of the sunspot to forcing by the 5-min p-mode oscillations in the surrounding gas. It is now well established that the 5-min oscillations in the quiet photosphere actually consist of several modes of oscillation, in the form of acoustic waves trapped in the upper convection zone (p-modes)[12]. These p-modes include a wide range of horizontal wavelengths with a moderate variation of frequency. It is expected that the geometry of the sunspot and the nature of the coupling between the acoustic waves and the sunspot flux tube will act as a filter, with only certain p-modes forcing the sunspot with observable amplitude.

The present observations were made as part of a large programme to study dynamical phenomena in sunspots, using the vacuum tower telescope and Echelle spectrograph at Sacramento Peak Observatory. Here we show only the results of two high-quality time series of velocity oscillations in the umbral photosphere measured in the spectral line Fe I λ6,302.5. The velocity was measured from photographic spectra using the Doppler shift of the magnetic V profile of the line, thus assuring that the origin of the signal is from within the sunspot and not due to scattered light. Also, a nearby telluric line of

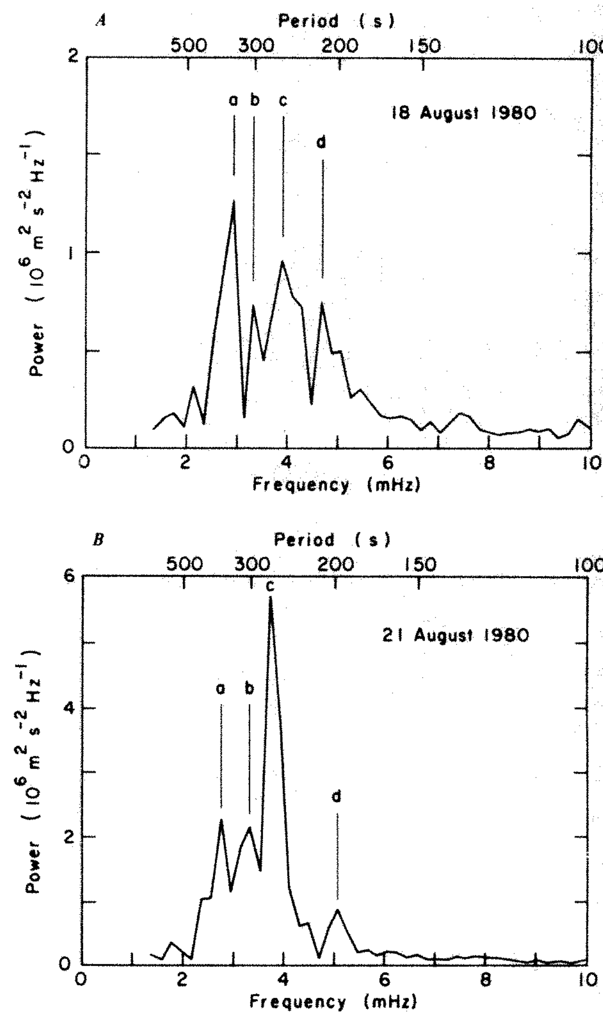

Fig. 1 The mean power spectrum of line-of-sight motions in the umbral photosphere for two runs: 18 August 1980 (*A*) and 21 August 1980 (*B*). The peaks have the following periods. *A*: a, 353 ± 6 s; b, 301 ± 4 s; c, 263 ± 3 s; d, 213 ± 5 s; *B*: a, 366 ± 6 s; b, 301 ± 4 s; c, 269 ± 4 s; d, 197 ± 4 s. Peaks a, b and c are interpreted as representing the response of the sunspot to individual p-mode oscillations in the surrounding atmosphere.

0028–0836/82/230485—03$01.00

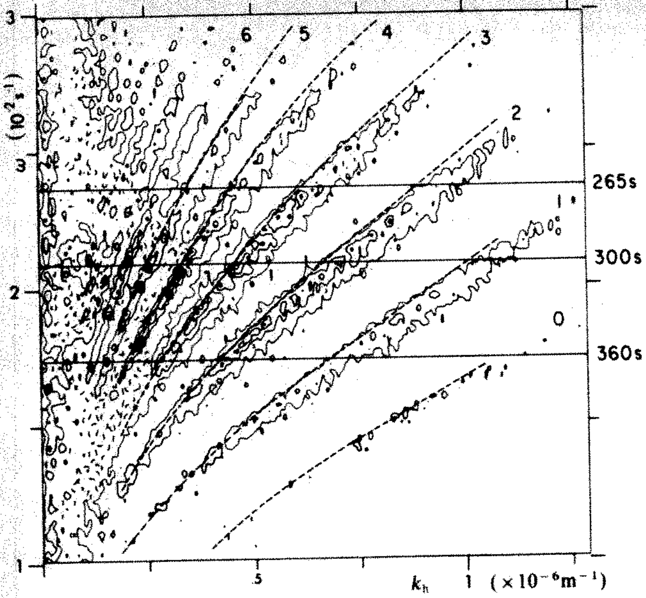

Fig. 2 Highly refined diagnostic diagram for the solar p-modes, due to Deubner *et al.*[14], showing contours of power on the frequency–horizontal wavenumber plane. Lines corresponding to the nominal periods of umbral oscillation near 5 min (360 s, 300 s and 265 s) are drawn to determine their points of intersection with p-modes of different radial mode number n (also shown).

O_2 was used as a wavelength reference, thus avoiding the dangers inherent in using a photospheric line as a velocity reference.

Figure 1 shows the mean power spectrum of the velocity field for the portion of the umbra covered by the entrance slit, for each of two runs (18 and 21 August 1980). Each power spectrum has three conspicuous peaks clustered around a 5-min period. Given the frequency resolution of our observations, the periods of these three peaks for both runs are consistent with nominal values of 265 s, 300 s and 360 s. Another conspicuous peak near 200 s in both runs is more likely to be associated with a resonant mode of the sunspot itself. The greater power in the peaks on 21 August, when the sunspot crossed the central meridian of the Sun, indicates that the velocity is predominantly vertical in the photosphere. The total power at periods near 5 min implies an r.m.s. vertical velocity of $\sim 50\ m\ s^{-1}$ in the umbra, at least a factor of five smaller than for the 5-min oscillation in the quiet photosphere.

Because of the limited temporal and spatial extent of the data (70-min time series with a 20-s sampling interval, over about 13×10^6 m in the umbra) there is statistical noise in the power spectrum. The noise level may be estimated in three ways: from the high-frequency limit of the power spectrum, from the statistics of the distribution of individual power spectra that are used to form the mean power spectrum for the entire umbra, and from the estimated number of degrees of freedom (~20) using Edmond's tables[13]. All three of these methods indicate that the 50% confidence level for each peak corresponds to roughly 25% of the peak amplitude. Any peak that is four times the noise level is marginally significant (50% confidence level), with greater confidence for higher peaks. Thus, in Fig. 1, the peaks near 360 s, 300 s, 265 s, and 200 s are all significant at well above the 50% confidence level. Note that the noise level is about the same on the two days while the signal increases in power on 21 August as the line-of-sight velocity becomes more nearly vertical.

We interpret the three periods of oscillation around 5 min (265 s, 300 s, and 360 s) as the response of the sunspot to three distinct modes of 5-min oscillation in the surrounding photosphere. We pursue this by plotting these three periods, in Fig. 2, on a highly refined k–ω (wavenumber–frequency) diagram for the photospheric oscillations (due to Deubner *et al.*[14]). Note that the three umbral periods cross all of the p-mode ridges in the k–ω diagram. We may identify the three umbral periods as the response of the sunspot to three consecutive p-modes, but there is ambiguity in choosing the correct set of p-modes. Each set of three mode crossings corresponds to a set of three horizontal wavenumbers and three corresponding horizontal wavelengths of p-mode oscillation. One might expect some relation between the diameter of the sunspot umbra and the wavelength of peak response to the surrounding p-mode excitation. The observed sunspot umbra is irregular in shape and has an area of $\sim 170 \times 10^{12}\ m^2$, giving an effective diameter (diameter of a circle of the same area) of 14.7×10^6 m. (This estimate is subject to the uncertainty in locating the umbral–penumbral boundary by photographic methods). This surface umbral diameter falls within the range of possible wavelengths. However, because the diameter of the sunspot should decrease with depth (due to increasing pressure in the surrounding convection zone), the surface diameter is probably not an appropriate value for comparison.

We suggest that observations of the multi-mode structure of 5-min oscillations in sunspots may be used as a probe of sunspot structure below the solar surface. The various p-modes have eigenfunctions with different depth dependence, with higher modes extending deeper into the convection zone, so that each mode 'probes' a different range of depths. This fact has already enabled the p-modes to be used as a probe of radial variations in the solar rotation rate in the convection zone[14–16]. Here we suggest a similar technique to probe the structure of a sunspot below the surface by measuring the response of the sunspot to the various p-modes. This method calls for accurate observations of the period and spatial structure of the various 5-min modes in the sunspot as well as theoretical work on the interaction between the p-modes and the sunspot flux tube.

An illustration of such a depth probe can be given on the basis of the present observations and a simple theoretical argument. Space–time plots of the umbral velocity field show a characteristic 'herringbone' structure with phase varying across

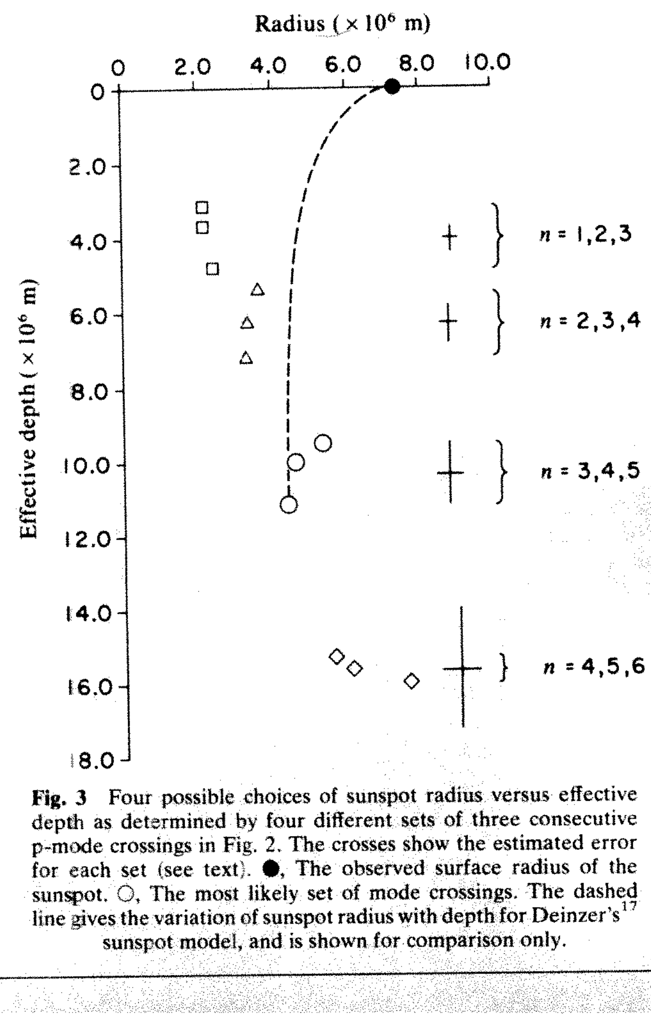

Fig. 3 Four possible choices of sunspot radius versus effective depth as determined by four different sets of three consecutive p-mode crossings in Fig. 2. The crosses show the estimated error for each set (see text). ●, The observed surface radius of the sunspot. ○, The most likely set of mode crossings. The dashed line gives the variation of sunspot radius with depth for Deinzer's[17] sunspot model, and is shown for comparison only.

the umbra. At any instant, diametrically opposite points at the edge of the umbra tend to be 180° out of phase and the centre of the umbra appears to be a node in the velocity field. This suggests that the peak response is occuring at a wavelength equal to roughly twice the umbral diameter. We will assume that the peak response is at a wavelength equal to exactly twice the local diameter and proceed. As discussed above, the various sets of three consecutive mode crossings in Fig. 2 predict alternative sets of three horizontal wavelengths and hence sets of three values of sunspot diameter. Each diameter corresponds to a different p-mode (different value of n) which probes a different effective depth. Values of the effective depth for the p-mode eigenfunctions have been calculated by Ulrich *et al.*[16]. The effective depth varies with horizontal wavenumber as well as radial mode number. For any set of mode crossings in Fig. 2 we can assign an effective depth to each of the three values of sunspot diameter and thus obtain a plot of sunspot radius versus depth, assuming a circularly symmetric sunspot flux tube.

The results of these calculations are combined in Fig. 3, where sunspot radius is plotted as a function of depth for each of the possible sets of mode crossings. The limited resolution in frequency (due to finite time series) and the spread of power in the ridges on the k–ω diagram give the uncertainty in calculated sunspot radius, and the uncertainty in k and ω gives the uncertainty in effective depth. For any given set of points in Fig. 3 the uncertainties mask the depth variation of sunspot radius, making each set of three points equivalent to a single piece of information about the subsurface sunspot geometry. The individual sets of three points in Fig. 3, corresponding to sets of three consecutive mode crossings, are distinct from each other, allowing a selection of the most likely set based on theoretical arguments about the expected depth variation of sunspot radius. For example, the theoretical model of Deinzer[17] is plotted in Fig. 3 for comparison and passes through the set of points corresponding to p-modes $n = 3$, 4 and 5. We use this only as an illustration of the method and not as a specific prediction for this sunspot. However, for the range of wavenumbers under consideration, modes $n = 3$, 4 and 5 have the most power in their ridges; they might be chosen on this basis as well.

Direct gravimetric detection of magma movements at Mount Etna

T. J. O. Sanderson

Geophysics Section, Imperial College of Science and Technology, London SW7 2BP, UK

Mount Etna is Europe's most active volcano, erupting some 2×10^{10} kg of new material each year[1]. Its eruptions generally have two distinct forms: continuous explosive activity near the summit with low rates of lava effusion, or massive, and often quieter, lava effusion from its flanks along regional tectonic fissures. The question of where magma is stored before eruption is not yet resolved. Here I present results from high-precision gravity surveys covering two recent eruptions. Gravity changes after the major flank eruption of March 1981 indicate draining of magma from a dyke 14 km long, at an elevation of 0–1 km and striking in a direction close to that of the eruptive fissure. Changes from the explosive sub-terminal eruptions of September 1980 do not indicate draining from any near-surface reservoir. It is proposed that short-term magma storage can occur close to the surface before a flank eruption, but that summit eruptive activity is consistent with a source at greater depth.

Recent research on Mount Etna has shown that it does not conform to the classic inflation–deflation model[2] which can be applied successfully to many other volcanoes, notably Kilauea[3,4]. Precise levelling and dry tilt studies show no gross systematic deformation, but only local anomalies[5], and horizontal deformation observed in the summit region is inconsistent with a simple sub-surface reservoir[6]. Furthermore, petrological studies on historical lava flows indicate little of the chemical differentiation which would be expected if substantial high-level magma storage were involved[7,8], and seismic investigations indicate a large volume of partial melt at a depth of 16–24 km beneath the volcano[9]. It has been concluded that magma rises directly from great depth to the surface without long-term storage in a magma chamber[10–12]. It is accepted, however, that high-level storage must take place in the short term, because all lavas show extensive crystallization of plagioclase, indicating residence at moderate to low pressures[12], and some flank effusions are only mildly explosive, indicating degassing before eruption. The lavas of 1910, 1928, 1950–51 and 1971 also show a limited degree of magmatic evolution due to differentiation[13–14]. This implies high-level storage on a time scale sufficient to give rise to crystallization and degassing, but insufficient to result in strong differentiation. To address the problem of where magma resides before eruption, a high precision gravity network was established on Mount Etna in September–October 1979 (ref. 15) with the aim of detecting small secular changes in the force of gravity as a result of intrusion or draining of matter.

Ninety-seven gravity stations have been set up, of which 48 are used in the surveys under discussion (Fig. 1*a*). They are sited on stable massive lava outcrops or permanent architecture. Station relocation is good to ±1 cm, and vertical reference to ±1 mm. Instrument orientation is constant at each station. Measurements are carried out with LaCoste and Romberg gravity meter G90, fitted with electrical readout. Tidal corrections are made using a harmonic tidal programme based on Cartwright and Tayler[16,17] and using gravimetric factors and anomalous phases determined for Mount Etna by Mohamed[18]. Tares and drift are removed using a least-squares optimization programme. Gravity values are referred daily to a base station at the Astrophysical Observatory at Serra la Nave and the network as a whole is referred to a datum based on this and calibration stations numbers 59, 61 and 64 of the Italian Geodetic Commission. The typical standard deviation of a single gravity tie with meter G90 is found to be 9 μGal, and the errors are normally distributed. Each station tie is performed if possible eight times on independent occasions, and it is estimated that calibration variations, datum inaccuracies and water-table effects contribute a further nominal error of 5 μGal. The resulting error for a gravity change is typically 8–15 μGal, depending on the number and quality of the ties made. In the interval September 1979–August 1980 gravity changes in the range −36 to +48 μGal were observed. A χ^2 test gives a probability of <1% that they are due to chance.

0028-0836/82/230487—04$01.00

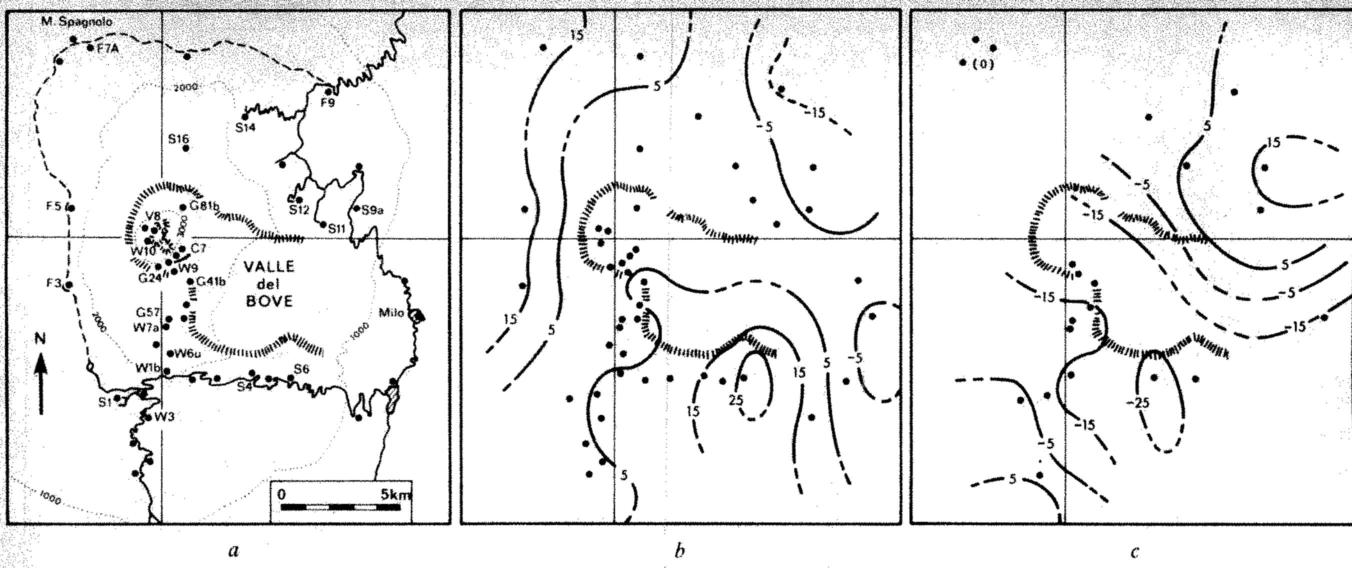

Fig. 1 *a*, Map of Mount Etna: ●, gravity stations; hatching, caldera rims. Topographic contours are in intervals of 1,000 m. *b*, Smoothed contours to show broad features of gravity changes between August and September 1980. Contours are plotted by computer, using a routine in which the gravity change value at any point is calculated as a weighted average of all measurements within a circular window around it. Measurements are weighted inversely to variance and the square of distance from any station, and are smoothed using a filter of cutoff wavelength 0.750 km. A window of radius 5 km is used. Contours are at intervals of 10 μGal, and are dashed where information is poor. Details of the contours should not be taken seriously. *c*, Smoothed contours to show broad features of gravity changes September 1980–March 1981.

A change in the measured force of gravity can be due to two effects. First, an uplift of terrain leads to a reduction in gravity according to the inverse square law. This reduction is ~ 0.22 mGal m^{-1} and can be used for the detection of vertical elevation changes[19]. Second, it can be due to sub-surface density changes or movements of matter. To distinguish between these effects 12 of the gravity stations are common to precise levelling stations of Murray and Guest[5]. They were measured simultaneously with the levelling traverse in September 1979 and July 1980. During this period gravity changes of between −36 and 13 μGal were observed at stations for which the elevation changes were respectively −0.6 cm and 0.4 cm (J. B. Murray, personal communication). If the gravity changes were due to elevation changes the corresponding elevation changes would be +16.4 cm and −5.9 cm. The observed changes are not only too small by an order of magnitude, but they are of opposite sense. This result, and the fact that some 35 dry tilt stations covering the volcano show no pattern of inflation or deflation[5], is a justification for interpreting the gravity changes as due to sub-surface accumulation of magma without corresponding ground deformation.

Such accumulation, whether the magma reservoir is in the form of a dyke system or a cylindrical conduit, can occur in several ways. If the reservoir is connected to an open surface, degassing to the atmosphere occurs, leaving the magma more dense. If the system is closed, it can accommodate the introduction of matter through bubble compression[20] or through bulk compression[21]. Whether the system is open or closed, magma may be introduced at the expense of trapped gases, which are either compressed, absorbed or simply expelled. Mount Etna can be considered, on the basis of tectonic considerations and observation of surface fissure trends, as a system of vertical radial dykes extending along major regional faults[22]. It is proposed here that magma is rising passively into vertical fissures in which the gas pressure and magma level are variable. The magma is not intruding actively through consolidated rock and causing great elastic strain; it is effectively filling a void. Eruption can then occur as a result of tectonically controlled block movements and swelling of magma as pressure is released[22]. If limited surface deformation does occur, as was observed for 2 yr before the 1978 eruption[5,12], this is due to stresses associated with the changing level of magma in the fissure, but the strain involved is not a reflection of swelling equal in volume to the magma newly introduced. A similar, though less extreme, discrepancy has been observed between surface deformation and apparent subsurface volume change on Kilauea[23].

The observed gravity changes on Mount Etna in the period 1979–80 are readily interpretable in terms either of known summit morphology changes or of density changes in historical fissure zones[24]. Dykes involved in the modelling are typically some 500 m below the surface, of vertical extent $\sim$1,000 m and of width 1–5 m. However, the parameters are poorly constrained, as the amount of matter gained or lost is not known independently.

In the case of an observed eruption accurate estimates can be made of the amount of material lost from the volcano. Known gravity changes then enable tight constraints to be placed on regions from which it could have come. Consider the

Table 1 Measured gravity changes (μGal) for intervals August–September 1980 and September 1980–March 1981, with associated errors

Only those stations measured with accuracy 12 μGal or better are included. The two results in parentheses are corrected for elevation (see text).
* Elevation control exists.

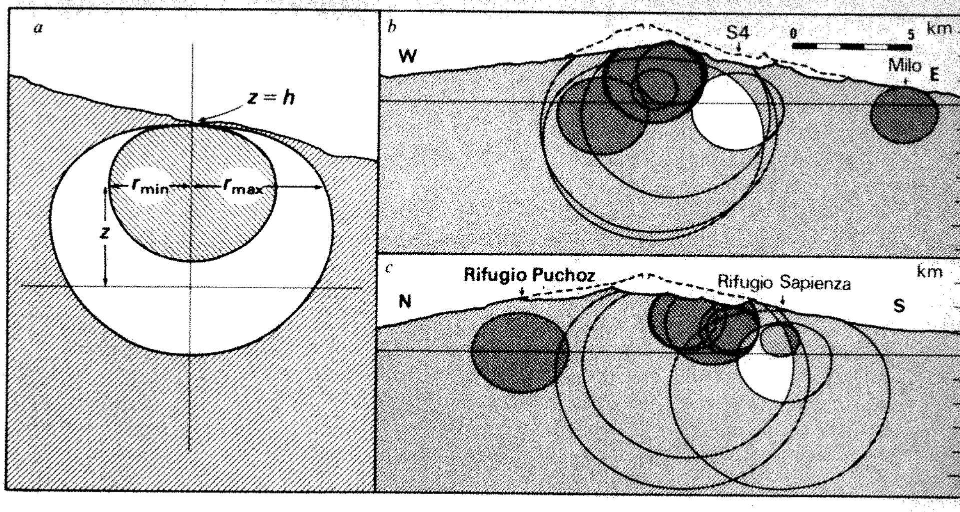

Fig. 2 *a*, Forbidden regions for point mass magma source. Hatching from top left to bottom right indicates a region too close to a station; hatching from bottom left to top right indicates a region too far from one. Sections are shown: *b*, W–E, 4 km south of the summit and *c*, N–S, 2 km east of the summit. The summit profile is shown as a dashed line. The blank region is permissible.

eruption of March 1981. The eruption was only mildly explosive, and followed a series of smaller but highly explosive eruptions during the winter from the North-East Crater[25]. On 17 March 1981, a fissure opened in the north-west flank of the volcano at elevation 2,250 m and gave rise to strong lava fountaining and massive lava effusion. During the next 6 days the fissure system lengthened to 7.5 km in a north-northwest direction and gave rise to an areal coverage of 4.72 km^2 of lava, which reached the River Alcantara at 800 m elevation and threatened the town of Randazzo (Fig. 3*d*). The total volume of lava is estimated at 18.6×10^6 m^3, a mass of about 4.7×10^{10} kg (estimate by J. B. Murray, from mapping by J. E. Guest, C. R. J. Kilburn, R. M. C. Lopes, J. B. Murray, H. Pinkerton and S. Scott).

A gravity survey was made immediately after the eruption and compared with readings taken in September 1980. The results are corrected for the attraction of new lavas lying on the surface. All those results with error bars better than 12 μGal are tabulated in Table 1 with associated errors, and are plotted as smoothed contours in Fig. 1*b*. They show a substantial decrease at all stations high on the southern flank. Towards the region of Rifugio Citelli observed changes were positive or insignificant and at a station 0.5 km from the rift itself there was no significant change. Snow cover prevented measurement of stations in the northern upper reaches and in the Valle del Bove. Snow cover also prevented elevation change control. However, precise levelling surveys have been carried out in August 1981. Two gravity stations showed unusually high elevation changes: station C7, close to the central craters, showed −4 cm (J. B. Murray, personal communication), and station F7a, 0.5 km from the rift, showed +3 cm (M. Grimaldi, personal communication). None of the other stations discussed here showed changes of more than 1.5 cm. As these measurements were made over the interval July/August 1980–August 1981 they are not strictly comparable with gravity changes measured between September 1980 and March 1981, and have not therefore been used to apply an elevation correction to the gravity results. The effect of applying such a correction to results at stations C7 and F7a is included in Table 1, and does not materially alter the picture.

Let us assume that the changes are due to the eruption, and begin with the hypothesis that the erupted magma came from one localized region within the volcano. The magma is equivalent to a sphere of radius 160 m and can be treated as a point mass for depths of the order of 1 km. Now, at station G41b, for example, the measured gravity change was −22 μGal ± 8. At the 95% confidence level the gravity change therefore lies between −38 and −6 μGal. This range of possible values defines 'forbidden' regions from which the magma could not have come. If a station elevation is h above sea level and the total mass erupted is M, then magma loss is permitted only from a region of radius r from a vertical axis beneath the station (Fig. 2*d*), where r is a function of elevation z, and satisfies the inequality:

$$\left(GM\frac{(h-z)}{(\Delta g-2e)}\right)^{2/3}-(h-z)^2<r^2<\left(GM\frac{(h-z)}{(\Delta g+2e)}\right)^{2/3}-(h-z)^2$$

Here G is the universal gravitational constant, Δg is the measured gravity change and e is the error associated with it. M and Δg are negative. The inequality defines spheroidal lobes of radius r_{min} and r_{max} beneath the station. Magma loss is permissible from any point between the two lobes. A three-dimensional envelope of lobes for all stations indicates which regions are permissible for magma loss (Fig. 2*b*, *c*). A relatively small region remains unforbidden. This is the region in which

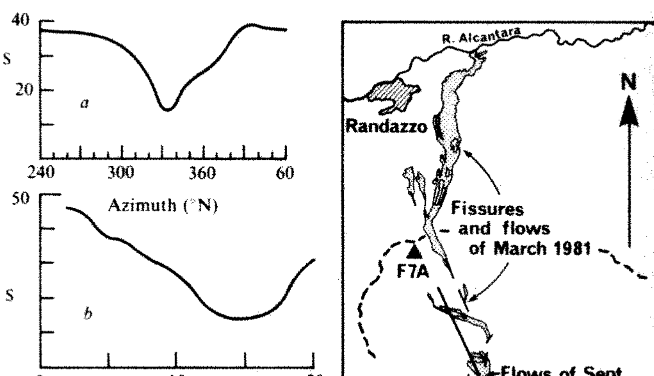

Fig. 3 Minimization of the statistic *S* against variation of azimuth (*a*), length (*b*) and depth (*c*) to upper surface of a dyke modelling the March 1981 eruption. The optimum dyke is shown in plan (*d*) and in section (*e*) relative to the eruptive fissures. (Map of fissures and flows from mapping by C. R. J. Kilburn (September 1980) and Guest *et al.* (March 1981).)

magma could have been stored before eruption, assuming that the observed changes were due to magma loss and that the loss was localized. The optimum point for magma loss can be found by minimizing residuals, and occurs at a point 2 km east and 4 km south of the summit. This model corresponds to the 60% probability level on a χ^2 test with 16 d.f., and therefore cannot be rejected. The fact that a point mass solution is possible, and that it lies so far south of the summit may be due partly to the strong southern bias of the stations available for survey.

Let us consider a more realistic model. We relax the point mass requirement and suppose instead a thin vertical dyke of variable size and position. Because no data are available for the northern summit region we assume the dyke to be symmetrical about the summit convergence of known historical fissure systems, which lies about 1.5 km east-southeast of the central crater (G. Kieffer, unpublished). The total mass of the dyke is set to 4.7×10^{10} kg and its vertical extent, which is not a sensitive parameter, is set to 1,000 m.

Modelling is performed using a computer program which models a dyke of any azimuth, length and depth as a lattice of point masses. For each model the sum of squared residuals, S, is calculated, and we search for an absolute minimum. A pronounced minimum exists, and its local behaviour is shown in Fig. 3*a–c*, where S is plotted against variation of each parameter. The optimum dyke is of azimuth $335°\pm5°$, length $14\,\text{km}\pm3$ and has its top surface at elevation $1{,}000\,\text{m}\pm500$. For this dyke, $S=14.1$, and it cannot be rejected at the 50% confidence level. Its position in plan and section is shown in Fig. 3*d*, *e*. It corresponds well with the surface activity of the March 1981 eruption.

A similar set of measurements was made immediately after the sub-terminal eruptions of September 1980. These occurred from the North-East Crater and were short-lived and highly explosive. The total mass of eruptive products is estimated at 2.8×10^{10} kg (C. R. J. Kilburn, personal communication).

No broad-scale gravity reduction was observed, and there were no reductions significant at the 95% level. Only one station, F9 to the north-east, showed a gravity reduction significant at the 68% level. Results are displayed, as before, in Table 1 and Fig. 1*c*. Stations on the south and south-east flanks showed a continuation of an upward trend which had been observed since 1979 and stations along the western flanks showed a pronounced increase. The increases were in the range 20–40 μGal. At the summit there was no significant change. In the absence of negative changes we cannot provide a simple model for the magma source; no model gives a fit which cannot be discounted at the 95% level. If the source is constrained to lie beneath the summit the statistic S improves as the source is lowered but never becomes acceptable. On this evidence the summit effusion of lava in September 1980 was not associated with a reservoir at detectable depth. It is proposed that the observed positive gravity changes were due to filling of radial dykes, associated with a sudden uprush of magma to the summit from a source well below sea level.

I conclude that these results support the view that Mount Etna underwent two distinct types of eruption during this period: a highly explosive summit eruption from a source well below sea level; and a massive flank eruption associated with draining from a radial dyke near sea level, which had become charged with magma during the preceding 6–12 months.

This work was funded by NERC. I thank D. R. Cowan, J. E. Guest, C. R. J. Kilburn, R. G. Mason and J. B. Murray for useful discussions and comments.

Active *in situ* disaggregation of oceanic crust and mantle on Gorringe Bank: analogy with ophiolitic massives

Yves LaGabrielle

GIS Océanologie et Géodynamique, U. B. O., avenue Le Gorgeu, 29200 Brest, France

Jean-Marie Auzende

Centre Océanologique de Bretagne, BP 337, 29273 Brest cedex, France

The *Cyagor II* cruise (May 1981) using submersible *Cyana SP 3000* on Gorringe Bank off south-west Portugal confirmed the scheme proposed at the end of *Cyagor I* cruise[1,2] that during the middle Cretaceous (110 Myr BP), Gorringe Bank, an old transform fault of Triassic–Liassic age, appears to have tilted to the north-east leading to the exposure of a section of oceanic mantle and crust. Due to its location at the boundary between European and African plates, Gorringe Bank suffered tectonic reactivation and uplifting during compressive and shearing-type events that occurred at the Cretaceous–Tertiary boundary and during the Tertiary (Eocene–Miocene). During the 12 dives of the *Cyagor II* cruise (Fig. 1), phenomena linked to the disintegration of serpentinites and gabbros in the deep-sea domain have been studied *in situ* with more detail than before[3]. Such processes have been suggested from studies on samples dredged or cored in oceans, or from observations in ophiolitic belts but direct observation had not enabled the magnitude of such phenomena to be measured. The observations on Gorringe Bank suggest that the processes described here are active in many oceanic sites. They help us to understand better the significance of many ophiolitic detritic beds more or less closely associated with pelagic sediments. We now compare the observations made at sea, especially on Gorringe Bank with similar observations in ophiolitic zones in mountain belts, which suggests that the ophiolite complexes have formed in a similar way to the breccias seen on the ocean floor.

Nine dives in areas where gabbros (Ormonde) and serpentinites (Gettysburg) outcrop revealed a very jagged deep-sea landscape made of small terraced cliffs. Each cliff, strongly fractured feeds a wide scree-covered slope. Fractures become more numerous at the top of the cliffs so that they are crowned by an unstable jumble of blocks. The size of the clasts released by the serpentine and gabbro disaggregation ranges from 1 mm to a few metres (Fig. 2).

Some large blocks of gabbro and serpentinite (between 1 and a few metres across) can be found a long way from any outcrop (100–1,000 m) where no other gabbroic or serpentinitic detritus occurs in the sediment. Under gabbro cliffs, two domains can be distinguished (Fig. 3): the first comprises 15°–40° slopes

which are scree-covered and composed of heaps without any apparent order—small blocks, cobbles, pebbles mixed with coarse sands are all present. The absence of pelagic sediments on this scree reveals the incessant activity to which they are subjected. The second domain comprising 5°–15° slopes is an area of transition between the scree-covered slopes and the shelves covered with pelagic sediments—sand-banks scarcely covered with small blocks lay there. Sometimes sands form rhomboidal ripples moving downwards. These sand-ripples were often observed lying on pelagic sediments. These sands were found to be composed of pyroxene, monomineralic fragments of plagioclase and, less frequently, of dolerite rock fragments.

The serpentinite cliff feeds extremely varied scree with both decimetric blocks and gravels. At the foot of the scree, pelagic mud is strewn with small blocks and unjointed broken stones.

The *in situ* observations made on Gorringe Bank include those of active alteration processes in the deep-sea environment, as well as of erosion and transport of ophiolitic materials. The processes that were seen can be linked to different causes. The first is the presence of rocky outcrops. The observations underline the multiplicity of escarpments, cliffs and fracture zones where gabbros and serpentinites are exposed. An intensive alteration is favoured by the internal fabric of the rocks themselves, particularly in the case of the gabbros. The alteration of granular type is linked with the crystallization of clays which are formed instead of plagioclases and then, release the grains of pyroxene. On the other hand, mechanical disaggregation takes place preferentially in the tectonized zone. In the case of Gorringe Massif, the known tectonic events[1,2] date from Triassic–Liassic when the transform motion deduced from plate geometry was recorded by the development of shear zones in the gabbros and serpentinites.

This shearing of the compressive tectonics which are still affecting the Massif, as shown by the level of natural seismicity in the area and by first-motions studies[16], has undoubtedly facilitated the creation of these highly tectonized zones. In the case of serpentinites, the tectonization plays a fundamental part in producing lenticular fracturing of the rock to give easily detached angular fragments of different sizes.

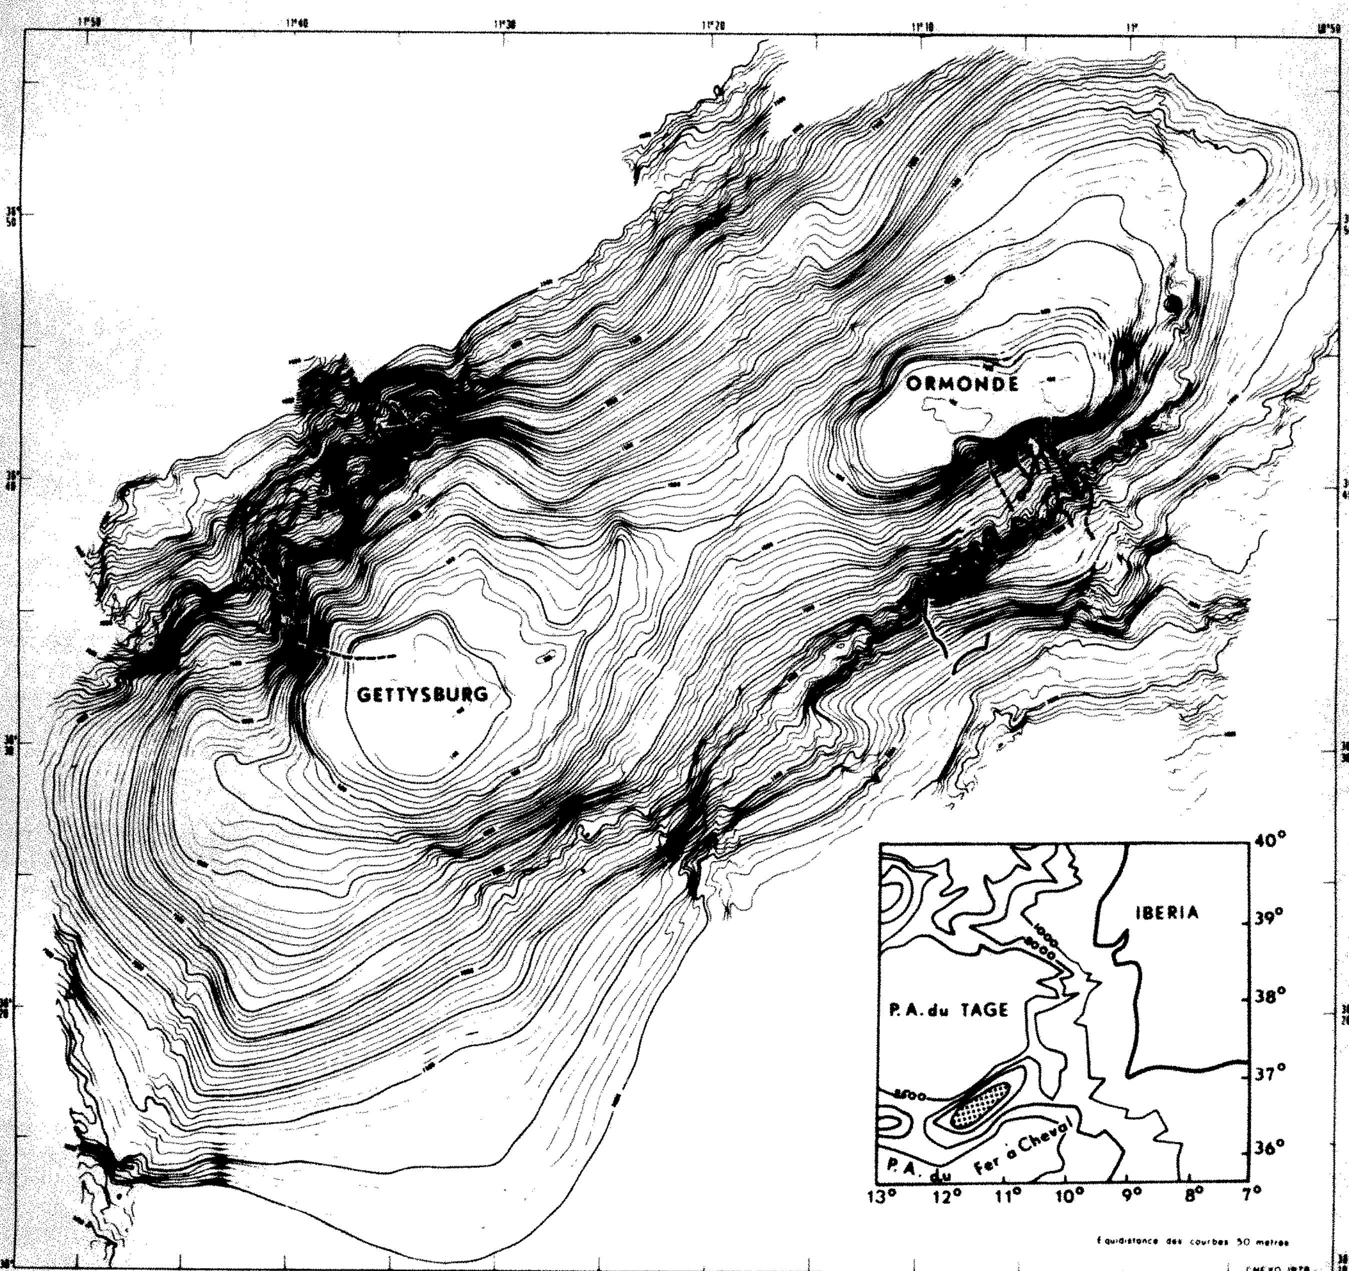

Fig. 1 Bathymetric map of Gorringe Bank with locations of *Cyana SP 3000* dives. Solid lines, *Cyagor II* cruise 1981; dashed line, *Cyagor I* cruise 1977.

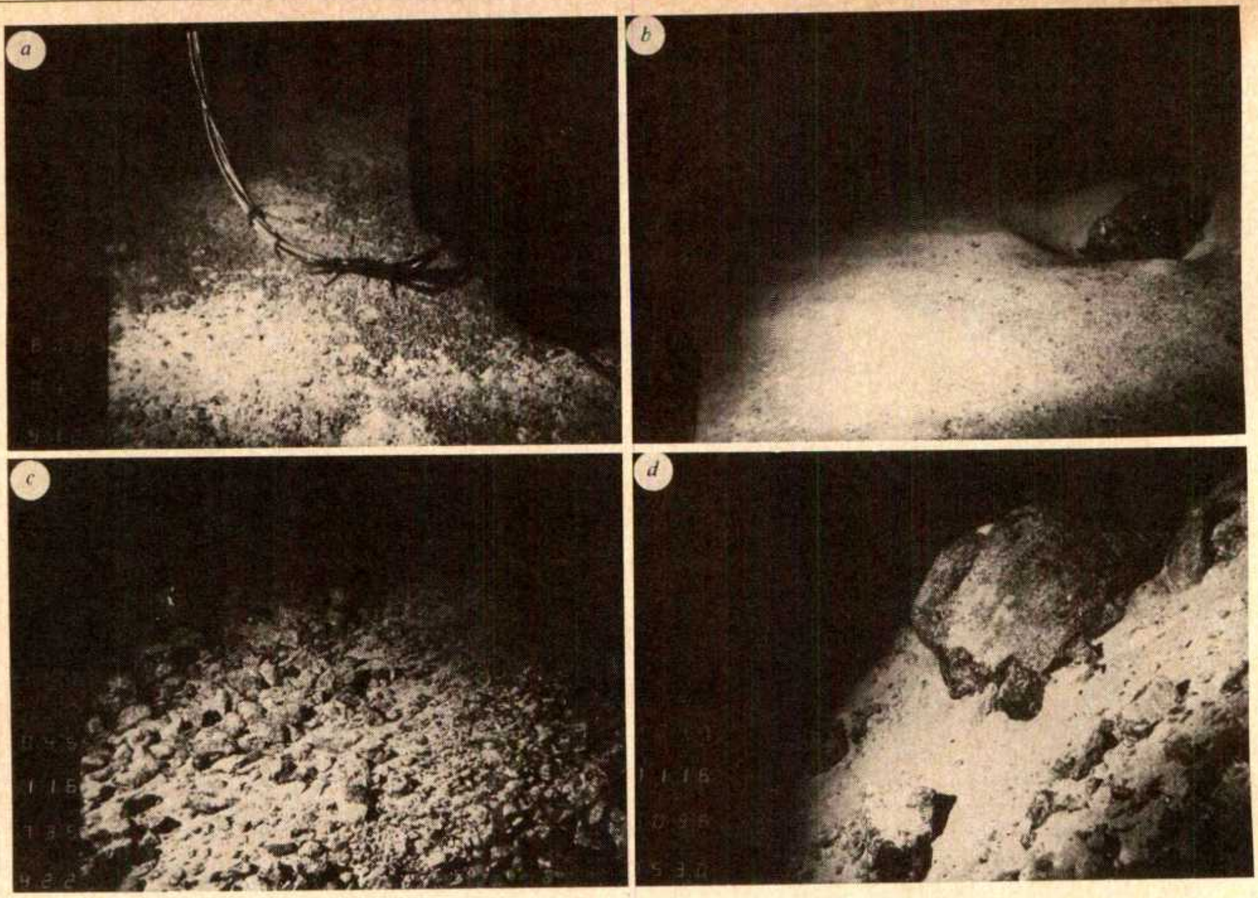

Fig. 2 Photographic plate: *a*, sands and gravels of gabbro; *b*, isolated block of gabbro; *c*, cobbles, pebbles and coarse sands of serpentinite; *d*, blocks of serpentinite in pelagic sediments.

The debris broken up by the double effect of granular alteration and tectonic disaggregation occupies a large area near the foot of the escarpment. Associated gravitional mass flows, distalites and coarse turbidites are bound to have participated in the filling of the adjacent abyssal plains.

Material, probably resulting from processes similar to those we have observed, has been located in many parts of the oceans, particularly in the proximity of complex structures involving a great variety of rocks of the mantle and of the oceanic crust such as mid-ocean ridges[4,11,12,17–20], fracture zones[7,8,21–33], and marginal basins[34–42]. These materials are likely to be more important than previously estimated in the sedimentary series of oceanic basins.

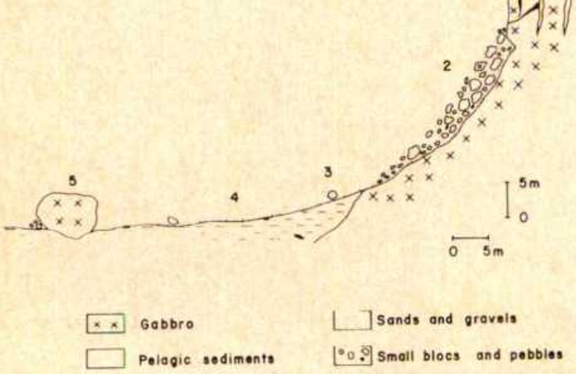

Fig. 3 *In situ* observations on Gorringe Bank (Mont Ormonde). 1, Highly fractured bedrock; 2, unbedded blocks, pebbles and sand at the foot of an escarpment; 3, small blocks isolated in sand and gravels; 4, sand and gravel ripples; 5, block of metric size.

Thus the genetic model obtained when studying oceanic data leads us to consider that any outcrop of the oceanic crust, whether tectonized or not, supplies detrital material. Most of this material remains *in situ* at the foot of the cliffs. The remainder is scattered in the surrounding autochthonous sedimentation mainly in two forms: metre-sized blocks which may slide down the slopes, and fine grained or coarse sand transported by turbidity currents. This latter fraction is consequently included in diversified and genetically different formations.

In mountain belts two types of deposits may be found for ophiolitic detrital products; *in situ*, that is to say closely associated with large igneous ophiolitic bodies, and scattered in the metasedimentary series[13–15,43–51]. These series may form independent tectonic units, so that the ophiolitic detrital material they contained will seem totally disconnected from its sources.

One can note a striking analogy between old and present day oceanic crust detritism found in the ocean and ophiolitic debris found in the mountain belts. However, we conclude that these types of detritic formations probably occupy a significant place in the total volume of ancient and present day oceanic sediments.

The results obtained in the ocean and particularly the *in situ* observations in the Gorringe Massif enable us to specify the morpho-structural framework of these present day and ancient deposits (cliffs, rugged escarpments, small basins). In all known cases in the oceans these structures belong or have belonged to areas topographically high in comparison with the oceanic floor (fracture zones, ridges, aseismic ridges). Thus, when these detritic levels are found in the chains, one must wonder if there is a relation between their genesis and the presence in the old ocean (Tethys Ocean, for example) of structures of abnormal topography. Those structures could result from an early intra

oceanic tectonic event (as on Gorringe, for example) and, despite variable causes, could be constant.

We thank J. F. Stephan, R. Blanchet and H. D. Needham for reviewing this article, the officers and crew of N. O. *Suroit*, the submersible *SP 3000 Cyana* team, and M. L. Augris for helping with the translation of the manuscript. Contribution no. 762 of the Centre Océanologique de Bretagne.

Spherulitic crystallization in lamprophyric magmas and the origin of ocelli

Harald Carstens

Department of Geology, Aarhus University, DK-8000 Århus C, Denmark

Ocelli are rounded structures containing polycrystalline feldspar aggregates and minor amounts of mafic minerals; they occur in lamprophyre dykes all over the world. Ocelli are usually interpreted in terms of liquid immiscibility[1–3]. In alkaline lamprophyre dykes along the south coast of Norway[4], ocelli are closely associated with globular structures (varioles) which I have assumed[5] were formed as a result of a splitting of the magma into two fractions. The re-examination of these Norwegian dykes reported here, however, has shown that varioles, ocelli and leucocratic feldspar-rich segregations formed by spherulitic and closely related growth mechanisms from undercooled volatile-rich magmas without an intervening stage of liquid phase separation.

The morphology of the crystalline aggregates varies widely and is related to the distance from the dyke margins. The dykes nearly lie flat and never exceed 2 m in thickness. Depending on the mode of crystallization three different zones can be distinguished (Fig. 1). (1) A marginal zone, including a chill zone, characterized by globular growth units. Mutual impingement of the globules has here resulted in the formation of a polyhedral cell structure (Fig. 2). Dykes <30 cm thick are globular throughout. The thickness of the marginal zone in the larger dykes is 10–15 cm. The globules exhibit features characteristic of spherulitic growth. (2) An intermediate zone containing feldspatic segregations. This zone is only present in the upper part of dykes >50 cm thick. (3) A central homogeneous zone.

A very fine-grained chilled zone, 2–3 mm thick, is usually present in the marginal zone. The chilled zone contains many globules, the size of which is remarkably uniform and ~0.1 mm in diameter. In polarized light, each globule shows a black cross demonstrating that crystal fibres radiate in all directions from a central nucleation point. Microphenocrysts of kaersutite, titaniferous magnetite and augite are commonly enclosed in the globules. Kaersutite and augite are arranged with their long dimensions parallel to the dyke walls. The globules are usually arranged in long sub-parallel chains or layers parallel to the dyke margins presumably reflecting nucleation and growth along flow lines in the magma.

The size of the globules and the polyhedral cells, hereafter termed spherulites, increases away from the chilled zone and may become 10–12 mm in diameter 10–15 cm from the contact. The spherulites are essentially composed of alkali-feldspar, kaersutite, ±augite and Ti-magnetite. The feldspar forms elongate, curved and branching crystals radiating from a central point. However, with increasing grain size inwards from the dyke margins it often becomes impossible to recognize radiate crystal arrays because any section which does not intersect the centre of the spherulite appears to consist of a granular crystalline aggregate.

The polyhedral cells are separated by a layer of a greenish material, which sometimes contains pyrite. The thickness of this layer is <10 μm in the chill zone and increases to ~100 μm in the dyke marginal zone.

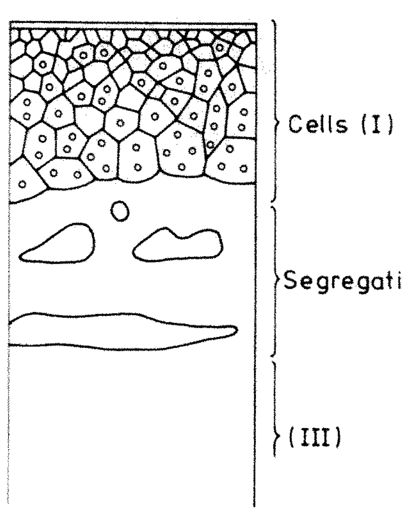

Fig. 1 Development of cells and leucocratic segregations in the marginal (I) and intermediate (II) zones respectively. Ocelli are indicated by circles. Not drawn to scale.

0028–0836/82/230493—02$01.00

Except for the finest compact spherulites of the chill zone, the spherulites always contain some rounded patches consisting almost exclusively of alkali feldspar. In each patch the crystals radiate from a common centre (Fig. 3*a*), and inwards in the dykes there is a change from a fibrous to a more lath-shaped morphology. These cone-shaped growth units (fan spherulites) apparently nucleated along the growth front of the larger spherulites in which they occur. It is frequently observed that they have grown from side-branches of radiating feldspar crystals (Fig. 3*b*). The fan spherulites actually represent the ocelli of the earlier description[4], which imposes constraints on the formation of the features. The observations preclude the possibility that the ocelli separated as liquid droplets.

With increasing distance from the dyke walls the polyhedral cell structure gradually disappears. This is due to a transition in morphology of the spherulites from compact to open, in the terminology of Keith and Padden[6]. When two open spherulites meet during growth the lamellae from both extend across the 'boundary' producing an interleaving structure.

The leucocratic segregations[4] in the intermediate zone are closely related to the ocelli of the marginal zone. The most abundant phase, alkali feldspar, shows a marked tendency to occur in thin bands or lenses roughly parallel to the dyke walls. Some bands consist of open, coarse spherulites, others consist of curved, branching feldspar crystals with preferred elongation inwards forming a comb-layer[7,8]. Kaersutite, which comes next in abundance, does not appear to grow directionally. The lamprophyre itself is very rich in kaersutite and Ti-magnetite along the upper and lower boundary of the segregations. The segregations contain scattered rounded ocellar structures, consisting of superimposed feldspar lamellae which are attached to one another like pages in an open book.

Chilled zones arise when the magma, coming in contact with the cold walls of the host rock, becomes greatly undercooled by the high rates of heat extraction. The higher the cooling rates, the lower the temperature at which nucleation occurs. Spherulitic growth is generally associated with rapid cooling rates[9], and chill zones would thus be an ideal environment for the growth of spherulites. The withdrawal of heat formed thermal gradients normal to the dyke walls, and crystallization proceeded from the margin inwards. The increasing size of the polyhedral cells away from the contact shows that the rate of nucleation decreased in the same direction. The growth of the spherulites approached a steady state and solidification terminated by the impingement of adjacent spherulites. The mafic sulphide-rich boundary layer which separates the cells has resulted simply from the impingement of enveloping boundary layers of rejected elements advancing ahead of the outer boundary of the spherulites. The thickness of the layer should be of the order of twice the characteristic distance of the boundary layer or $2\,D/G$ where D is the diffusion coefficient and G the growth rate[6]. Assuming, for example, a diffusion coefficient of $10^{-7}\ \mathrm{cm^2\ s^{-1}}$, the growth rate of the spherulites in the chill zone would be of the order of $0.1\ \mathrm{mm\ min^{-1}}$.

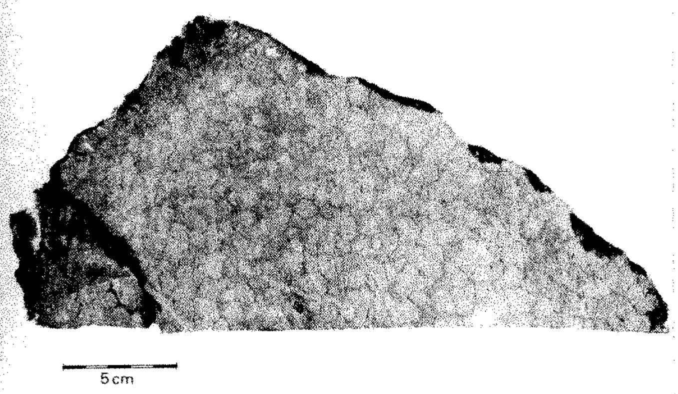

Fig. 2 Weathered specimen showing polyhedral cells. The structure is never observed on fresh surfaces, but may be developed by etching. The ocelli are 0.5–1 mm in diameter.

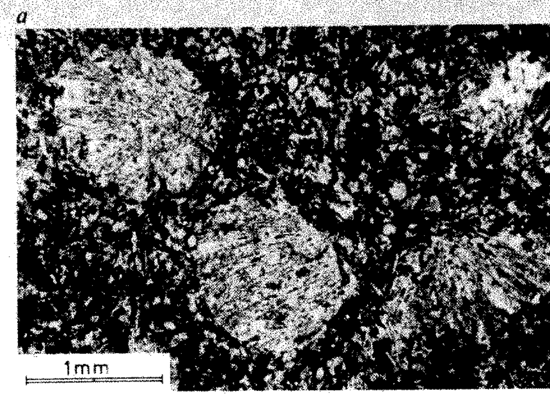

Fig. 3 *a*, Fan spherulites (ocelli), all belonging to the same cell. *b*, Branching feldspar terminating in fan spherulites (ocelli).

The textural developments seem to be related to feldspar nucleation difficulties in a lamprophyric magma, and the crystallization sequence is considered to have been determined by the relative ease of nucleation of the minerals involved rather than by equilibrium phase relationships. Delayed nucleation of feldspar is common in systems varying in composition from granitic to basaltic[9] presumably because of a slow rate of formation of embryonic clusters of equilibrium size. Thus, feldspar phenocrysts are always absent in lamprophyres and the fundamental shape of the feldspar is frequently spherulitic/dendritic indicating crystallization from an undercooled liquid. In the marginal zone, the high rate of cooling produced undercoolings of sufficient magnitude to permit the nucleation of feldspar simultaneously with the mafic minerals with the result that spherulites of melt composition grew and formed a cell structure. In the intermediate zone, slower cooling rates induced early nucleation of the mafic minerals relative to feldspar. The growth of kaersutite and magnetite established composition gradients in the melt perpendicular to the dyke walls. The melt was exposed to an increasing degree of undercooling by loss of water and iron to crystallizing kaersutite and ore minerals, and when feldspar finally did nucleate, conditions were favourable for the growth of feldspar-rich spherulites or alternatively inward growth of fan-shaped bundles of feldspar. The leucocratic segregations thus formed by periodic build-up of appropriate conditions of undercooling.

Regardless of the detailed mechanisms involved, the present study has shown that the globules (varioles), the polyhedral cells, the leucocratic segregations, and the ocelli which occur in them, are polycrystalline aggregates formed by crystal growth, the structural variations being a kinetic effect related to cooling rates. The observations presented here have produced no evidence in favour of liquid–liquid phase separation, although this still remains a possible explanation for the formation of other ocellar structures.

I thank Gary C. Lofgren for valuable discussions and criticism and C. H. Donaldson for helpful comments.

Isolation of a natural hatching stimulus, glycinoeclepin A, for the soybean cyst nematode

Tadashi Masamune, Masaki Anetai, Mitsuo Takasugi & Nobukatsu Katsui

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

The cyst nematodes (genera *Heterodera*, *Globodera* and others)[1] generally have a limited host range. This specificity arises from the fact that the hatching of larvae from cysts occurs in response to specific stimuli secreted by the host plants[2–4]. Because of the scientific interest and importance in agriculture of these stimuli, since their first recognition[5] in 1922 much time and effort[2–4] has been expended in attempts to purify and characterize them. However, success has been limited by the extremely small amounts of active substance available. We report here the isolation of a natural hatching stimulus for the soybean cyst nematode from the roots of kidney bean. The substance, designated as glycinoeclepin A, stimulates the hatching of larvae from the eggs *in vitro* at a concentration of 10^{-11} to $\sim 10^{-12}$ g ml^{-1} in water at 25 °C.

The soybean cyst nematode (*Heterodera glycines* Ichinohe) parasitizes a small group of host plants, including soybean (*Glycine max*), kidney bean (*Phaseolus vulgaris*) and adzuki bean (*Phaseolus angularis*), and causes 'soybean sickness'[6]. Tsutsumi and Sakurai[7] demonstrated that the hatching of larvae from cysts of the nematode was stimulated by root diffusates from the host plants. Since then various factors affecting hatching have been examined in detail[8–11]. The present investigation is based on these findings.

The bioassay for hatching was performed with free eggs. The cysts were isolated from infected soil collected in October at Memuro, Hokkaido, and stored in a refrigerator at 5 °C. Before the test, the cysts were soaked in water at 25 °C for 10 days, then dissected in water and sieved through a 325-mesh sieve. The dissected cyst wall fragments remained on the sieve. The eggs and larvae were transferred to a beaker of water so that 1 ml of the aqueous suspension contained 150–200 eggs. Then 1 ml of the suspension was transferred to a Syracuse watch glass, to which 8 ml of distilled water and 1 ml of the test solution were added. The whole suspension was kept at 25 °C and the number of the larvae hatched was counted after 10 days. The per cent hatching rate was expressed as $P = P_t - P_w$, where P_t and P_w denote the per cent hatching observed in the test solution and in distilled water, respectively. The test solution was said to be active when the hatching rate, P, exceeded 50%. Hatching rate is an adequate measure of hatching and emergence[7].

Hatch-stimulating concentrates were prepared from aqueous extracts of the roots of two subspecies ('Hon-kintoki' and 'Beni-kintoki') of kidney bean rather than from their root diffusates. Dried and powdered roots (113 kg) of Hon-kintoki, collected in late July at Memuro (1 hectare), were extracted with water at a temperature of <10 °C, and the aqueous suspension, after concentration at <30 °C, was acidified to *p*H 2–3 and extracted again, with chloroform. The chloroform solution gave 'chloroform extracts A' (102 g), which were fractionated according to the procedure summarized in Table 1, guided by the bioassay. Repeated chromatography yielded a highly active fraction, fraction L (~50 μg). Dried roots of Beni-kintoki were also treated and fractionated in almost the same manner to give the corresponding fraction with the same activity. These fractions were homogeneous and identical by analytical HPLC over various columns (μ-Bondapak NH_2, MicroPak NH_2-10, μ-Bondapak C_{18} and μ-Bondapak/Phenyl) and by the respective field desorption (FD) mass spectra (Fig. 1). The identification of glycinoeclepin A as the active substance was also checked by the division of fraction L into five fractions by chromatography on two separate columns (μ-Bondapak NH_2 and μ-Bondapak C_{18}) followed by the bioassay of each fraction after hydrolysis.

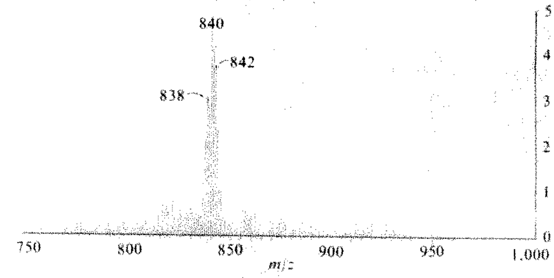

Fig. 1 FD mass spectrum of *p*-BPE of glycinoeclepin A.

The FD mass spectrum (Fig. 1) established that the bis(*p*-bromophenacyl) ester of glycinoeclepin A (GEA *p*-BPE) has a molecular weight of 838 and hence that glycinoeclepin A is a dibasic acid with the molecular weight of 446. The high-resolution FD mass spectrum ($m/z = 838.1334$) indicated that GEA *p*-BPE is best represented by $C_{41}H_{44}O_9Br_2$ (calculated $m/z = 838.1352$) and hence the acid by $C_{25}H_{34}O_7$. This was supported by the ^{1}H-NMR spectrum (Fig. 2) of GEA *p*-BPE, which revealed about 34 hydrogen and 7 oxygen atoms (two —COOH, one —OH, one —O— and one $-\overset{|}{C}{=}O$) in the acid.

Long-term potentiation of the perforant path *in vivo* is associated with increased glutamate release

A. C. Dolphin, M. L. Errington & T. V. P. Bliss

Division of Neurophysiology & Neuropharmacology, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

Long-term potentiation (LTP) of synaptic transmission following brief trains of high-frequency stimulation in hippocampal pathways has attracted attention as a possible physiological correlate of memory. The mechanism of LTP is little understood, and what evidence there is suggests that both pre- and postsynaptic mechanisms are involved[1–7]. Previous findings that Ca^{2+} is required for LTP[8,9], and that LTP is accompanied by a prolonged increased in Ca^{2+} uptake[10], suggest that an increase in impulse-dependent release of transmitter, a process critically dependent on presynaptic Ca^{2+} levels[11,12], may be an important component of this form of synaptic plasticity. A recent report[13] that release of previously accumulated ^{3}H-D-aspartate is increased following tetanic stimulation of afferent fibres to CA1 pyramidal cells in hippocampal slices is also consistent with a presynaptic mechanism. However, there has been no direct evidence relating LTP to an increased stimulus-dependent release of transmitter. We have now investigated whether LTP in the perforant path (PP) of the rat is associated with a change in the release of neurotransmitter. A modification of the push–pull cannula technique has enabled us to infuse ^{3}H-glutamine and measure the subsequent release of newly synthesized ^{3}H-glutamate, and at the same time to monitor the field potentials evoked in the dentate gyrus by stimulation of the PP. We have found a prolonged increase in the release of glutamate, the probable transmitter of the PP[14,15], following the induction of LTP in this pathway.

In anaesthetized rats, a push–pull cannula was placed in the molecular layer of the dentate gyrus, where PP fibres terminate on the apical dendrites of granule cells. Two insulated stainless-steel wire recording electrodes were attached to the outer cannula so that the exposed tip of the upper electrode lay roughly midway between the ends of the inner and outer cannulae, and the lower electrode extended 0.2–0.4 mm beyond the inner cannula (Fig. 1*a*). Correct placement of the electrode/cannula assembly was achieved by lowering it to a depth at which the negative-going potential evoked by stimulation of the PP was maximal, as recorded through the upper (dendritic) electrode. The potential recorded through the lower (somatic) electrode, positioned in the granule cell body layer, was used to monitor synaptic transmission during the experiment; the amplitude of the initial positive-going component of this response, which we refer to as the synaptic wave (Fig. 1*a*), was used as a measure of the strength of synaptic activation[16]. Following the induction of LTP by a high-frequency stimulus train (see Fig. 1 legend) an increase in the amplitude of the synaptic wave normally occurs (Fig. 1*a*), persisting with little decrement after the first 15 min (Fig. 1*b*, high-frequency train delivered at the time indicated by the arrow, mean of 11 animals showing LTP).

To investigate the release of glutamate in the dentate gyrus, the area to be perfused was preloaded with the radiolabelled precursor, ^{3}H-glutamine. Because the enzyme glutaminase, which converts glutamine to glutamate, is concentrated in presynaptic terminals[17], most of the infused ^{3}H-glutamine is probably taken up by the glutamate-utilizing terminals of the PP, rather than in postsynaptic or non-neuronal elements[18–20]. ^{3}H-glutamine (20 μCi) was infused through the inner cannula over 30 min. One hour later, perfusion with oxygenated medium was begun. The ^{3}H-glutamate present in sequential fractions of the perfusate was separated and measured as described in Fig. 2 legend.

In control experiments, the release of ^{3}H-glutamate into the perfusate while the PP was stimulated continuously at 0.1 Hz showed a steady decline during the perfusion (Fig. 2*a*). The release of ^{3}H-glutamate was at least partially stimulus dependent, since in seven animals, when the rate of stimulation was increased 30-fold, from 0.1 to 3 Hz, and the stimulus voltage was doubled, 120 min after the start of perfusion, the release of ^{3}H-glutamate was markedly increased (Fig. 2*b*). Note, however, that although larger potentials were recorded with no decrement throughout this 75-min period of increased stimulation, the mean outflow of ^{3}H-glutamate returned to a level not significantly greater than control values within 45 min, possibly due to depletion of the pool of ^{3}H-glutamate.

In another set of animals, the pattern of ^{3}H-glutamate release following the induction of LTP was investigated. The PP was stimulated at 0.1 Hz throughout the experiment, and superimposed on this, a high-frequency train (250 Hz for 0.5 s, stimulus voltage doubled) was delivered to the PP 120 min after the start of perfusion (arrows in Figs 1*b*, 2*c* and *d*). LTP of the PP–granule cell synapse (as judged by an increase in the amplitude of the synaptic wave lasting for 30 min or more) was produced in 11 out of 17 animals. The mean time course of potentiation is shown in Fig. 1*b* for all the animals in which LTP occurred. All these animals showed a prolonged increase in the release of ^{3}H-glutamate after the induction of LTP; indeed, the average level of released ^{3}H-glutamate in the potentiated animals remained above the corresponding average control value until the end of the experiment, 75 min later (Fig. 2*d*). In contrast, the six animals which received a high-frequency train, but in which the criteria for LTP were not met, showed only a slight elevation of ^{3}H-glutamate release following the train compared with control animals (Fig. 2*c*). As a further control that the prolonged increase in ^{3}H-glutamate release shown in Fig. 2*d* was associated with the events following the high-frequency conditioning train rather than the train itself, the same number and strength of stimuli used to produce LTP were given at a lower frequency (2 Hz) to five animals, 120 min

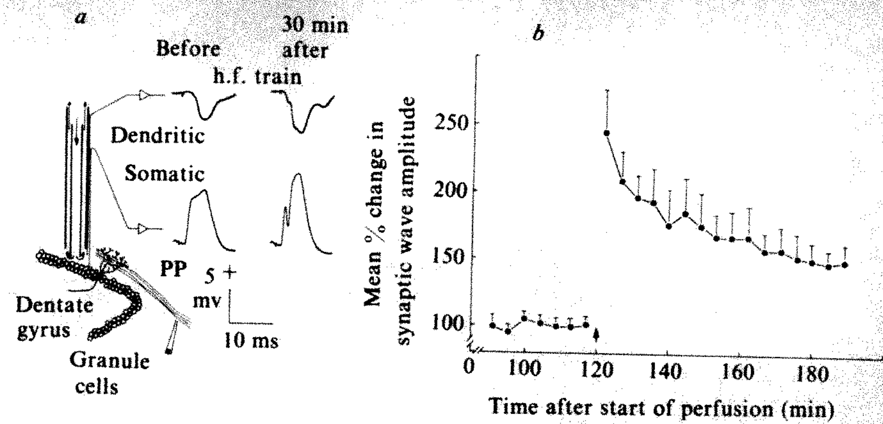

Fig. 1 Long-term potentiation in the perforant path during perfusion of the dentate gyrus through a push-pull cannula. Experiments were performed on male Sprague-Dawley rats (300–330 g), anaesthetized with urethane (1.5 g kg^{-1}, intraperitoneally). *a*, Two recording electrodes (insulated stainless-steel wire, 0.1 mm o.d.) were glued to the outer ('pull') tube of the concentric push-pull cannula (0.83 mm o.d., Plastic Products, Clark Electromedical). The upper electrode protruded 0.2 mm, and the lower electrode 0.5–0.7 mm below the outer cannula. The electrode/cannula assembly was lowered stereotaxically into the dentate gyrus of the hippocampus. The outer cannula was fixed to the skull with dental cement, and the inner ('push') cannula was then lowered so that its tip protruded 0.3 mm below the outer cannula. The PP was stimulated through a concentric bipolar stimulating electrode (Rhodes, Clark Electrochemical) with constant voltage pulses (0.05 ms, range 10–50 V) at a strength near threshold for a population spike (the negative-going spike superimposed on the synaptic wave and reflecting the discharge of granule cells). Throughout the experiment, evoked potentials were recorded every 90 s on a chart recorder, and on disc for subsequent computer analysis. Examples are shown of potentials recorded from the upper (dendritic) and lower (somatic) electrodes during perfusion in a single animal, immediately before and 30 min after a high-frequency (h.f.) stimulus train (250 Hz, 0.5 s, stimulus voltage doubled). *b*, Graph showing the mean percentage increase (±1 s.e.m.) in the amplitude of the synaptic wave for all animals ($n = 11$) which displayed LTP after receiving a high-frequency conditioning train 120 min after the onset of perfusion. In each animal the amplitude of the synaptic wave was measured at a fixed latency and expressed as a percentage of its mean amplitude during the 30 min preceding the conditioning train.

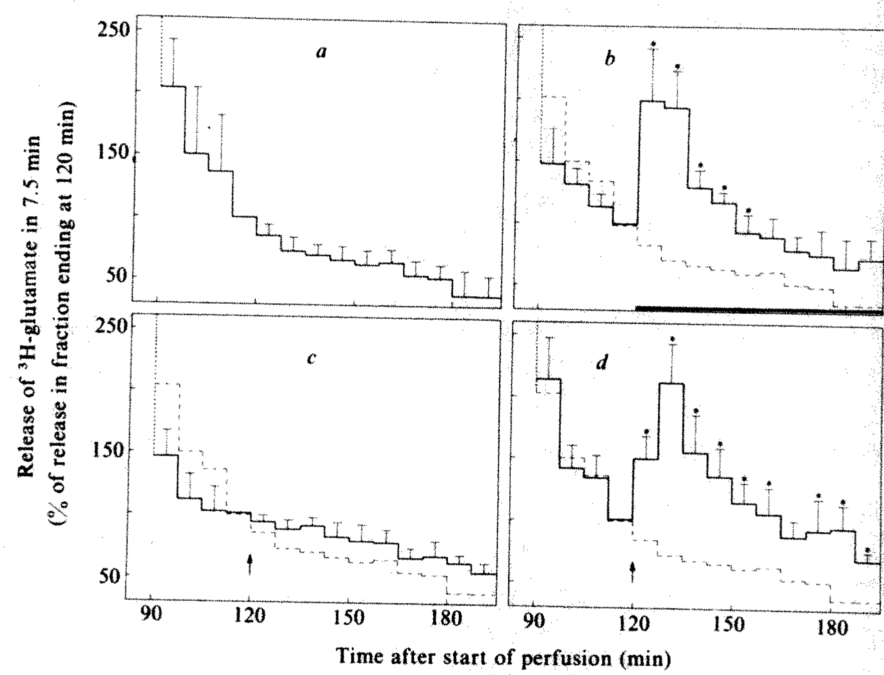

Fig. 2 *In vivo* release of ^{3}H-glutamate from the dentate gyrus perfused through a push–pull cannula. In all experiments ^{3}H-glutamine (20 µCi, 0.75 nmol) was infused in 3 µl oxygenated (95% O_2/5% CO_2) perfusion medium (composition in mM: Na^+, 152; K^+, 3.7; Mg^{2+}, 1.2; Ca^{2+}, 1.8; Cl^-, 140; $H_2PO_4^-$, 1.2; SO_4^{2-}, 1.2; HCO_3^-, 16; glucose, 10) containing a trace of phenol red, at a rate of 0.1 µl min^{-1}. Perfusion with continuously oxygenated medium at 10 µl min^{-1} was begun 1 h later, using a dual-channel peristaltic pump. Sequential 7.5-min fractions of perfusate were collected on dry ice. The phenol red served to mark the entry of the perfusate into the fraction collector, and thus the lag time of the apparatus (8 min). ^{3}H-glutamate was separated from ^{3}H-γ-aminobutyric acid and from their precursor ^{3}H-glutamine as previously described[21,22] using anion-exchange columns. The ^{3}H-glutamate released in a single experiment was expressed for each fraction as a percentage of the release in the fraction ending at 120 min. Values for each group of animals are given as mean ± 1 s.e.m. for all fractions between 90 and 195 min following the start of perfusion. *a*, Control perfusion, PP stimulated continuously at 0.1 Hz ($n = 7$). Values for control ^{3}H-glutamate release are repeated in *b*, *c* and *d* (dashed lines), where * indicates significant increase in ^{3}H-glutamate release compared with control ($P < 0.05$, Student's *t*-test). *b*, PP stimulated at 0.1 Hz until 120 min after start of perfusion when the rate was increased to 3 Hz and the stimulus strength was doubled for the remainder of the experiment as indicated by the solid bar ($n = 7$). *c*, *d*, PP stimulated continuously at 0.1 Hz, and at 120 min after the start of perfusion (arrow) a conditioning train was given (see Fig. 1 legend). *c*, ^{3}H-glutamate release in animals not showing LTP ($n = 6$). *d*, ^{3}H-glutamate release in animals showing LTP ($n = 11$).

after the start of perfusion. No potentiation occurred, and there was no difference in ^{3}H-glutamate release relative to controls, apart from a small increase in the fraction corresponding to the low-frequency train (results not shown).

Much evidence points to glutamate as having a transmitter role in the PP[14,15]. Our finding of a stimulus-dependent release of glutamate in this pathway (Fig. 2*b*) provides additional evidence for such a role. The main finding here, that LTP is associated with a prolonged increase in ^{3}H-glutamate release thus strongly suggests that a sustained increase in stimulus-dependent release of this transmitter is at least one of the mechanisms underlying LTP. This does not rule out the possibility that other changes involving, for instance, increased dendritic uptake of Ca^{2+} (ref. 10), altered dendritic morphology[4], or other mechanisms leading to an enhanced postsynaptic sensitivity[5] also contribute to LTP. The relative roles of pre- and postsynaptic events in the long-term enhancement of synaptic efficacy remain to be determined.

Reversal of current through calcium channels in dialysed single heart cells

K. S. Lee & R. W. Tsien

Department of Physiology, Yale University, School of Medicine, New Haven, Connecticut 06510, USA

Calcium channels contribute to important cellular functions such as impulse conduction, rhythmic activity, muscle contraction, and secretion[1] and are a major target for modulation by neurohormones and drugs[2,3]. Despite their importance, Ca channels are much less well understood than Na and K channels because of several problems reviewed by Hagiwara and Byerly[1]. First, few preparations allow good control of electrical potential and ionic composition on both sides of the membrane, yet display strong Ca currents. Second, current carried by Ca channels is often obscured by ion movements through other membrane pathways. Third, outward current flow through Ca channels, carried by Ca^{2+} or any other ion, has been difficult to demonstrate. This is unfortunate because measurements of the potential at which current reverses (E_{rev}) have been crucial in understanding ion permeation and selectivity in other ionic channels (see ref. 4). In molluscan neurones, attempts at recording outward current through the Ca channel have not succeeded, largely because of overlap by nonspecific outward current[5–7]. In multicellular cardiac muscle preparations, strong depolarizations produce a decaying outward current that Reuter and Scholz attributed to K efflux through the Ca channel[8]. Their interpretation is controversial, however, since the evidence leaves open other explanations for the outward current—for example, Na efflux via Na–Ca exchange[9], or K efflux through K-selective channels. To overcome these problems, we studied Ca channels in single isolated heart muscle cells[10–12] using a suction pipette method[13]. We were able to record robust Ca currents with minimal interference from other time-dependent currents while controlling potential and ion composition on both sides of the membrane. Here we present experimental evidence for a genuine reversal of ionic current through Ca channels due to outward movement of K^+ ions, in support of the hypothesis of Reuter and Scholz.

Single isolated cells were obtained from the ventricles of adult guinea pig hearts by enzymatic dissociation using collagenase and hyaluronidase. Relaxed cells with cylindrical geometry were chosen for study; in a separate series of microelectrode recordings, such cells displayed resting potentials near −80 mV, vigorous contractions, and action potentials with full plateaus. A suction pipette (tip diameter 5–10 μm) provided access to the inside of the cell for voltage clamp and internal dialysis[13]. The internal dialysis fluid contained (in mM): 75.5 K-aspartate, 29 K_2HPO_4, 17.5 KH_2PO_4, 5.5 glucose (*p*H 7.0, *p*Ca 6.4). In some experiments (Fig. 2*a*, *b*), potassium salts were replaced by caesium salts. Except where otherwise noted, the external solution contained (in mM): 137 NaCl, 11.9 $NaHCO_3$, 0.42 NaH_2PO_4, 5.4 KCl, 1.05 $MgCl_2$, 1.0 $CaCl_2$, 5.5 glucose and 10 μM tetrodotoxin (TTX, *p*H 7.4). In these solutions, the resistance of the suction pipette tip was usually 0.8–1.2 MΩ, and the magnitude of the peak inward Ca current was a few nanoamperes. The resulting ohmic drop of a few millivolts was offset by series resistance compensation. Transmembrane voltage and current signals were recorded and analysed using a Digital Equipment 11/03 minicomputer. All experiments were done at room temperature (21 °C).

In all experiments, the membrane potential was held at −40 mV to inactivate any Na channels not blocked by 10 μM TTX. Figure 1 shows membrane currents associated with a series of 150-ms clamp pulses, spaced 10 mV apart. The magnitude of the peak inward current increases gradually with depolarization up to 0 mV as more and more Ca channels become activated (*a*). With pulses above +10 mV (Fig. 1*b*), the time-dependent inward current diminishes and eventually disappears at +70 mV. Beyond this apparent reversal potential, E_{rev}, the time-dependent current becomes increasingly outward. This pattern of current inversion was found consistently in each of the 70 cells we examined; with 1 mM Ca^{2+} outside and 150 mM K^+ inside, E_{rev} was always found near +60 or +70 mV.

Figure 1*b* illustrates the inversion of time-dependent current over the time scale of Ca channel inactivation. If the reversal is a property of current flow through Ca channels themselves, it should also be evident during the first few milliseconds following a clamp step, as the Ca channels open. Figure 1*c*, *d* shows records taken at a fast sampling rate in another single cell. The traces show membrane current after subtraction of linear capacity and 'leak' currents. Activation of inward Ca current becomes increasingly rapid over the range between −30 and +10 mV (*c*). This is in qualitative agreement with previous work on multicellular preparations (for example, ref. 8), but at all potentials the time-to-peak Ca current is briefer in these single cells. The family of records in panel *d* shows the behaviour at more positive potentials. The time-dependent current is maximally inward at +20 mV, virtually absent at +75 mV, and increasingly outward beyond this E_{rev}. Thus, the records are consistent with a true reversal of Ca channel current.

The ionic nature of the outward current at strongly positive potentials was explored by varying the ionic composition of the external or internal solutions. The outward current cannot be attributed to Ca efflux because intracellular free Ca^{2+} was kept low by the internal anions, and in some experiments (Fig. 2*a*), by internal EGTA as well. (The effectiveness of the Ca^{2+} buffering was indicated by the absence of contractile activity even at strong depolarizations). Furthermore, the decaying outward current cannot be explained by Na^+ efflux carried by electrogenic Na–Ca exchange as proposed by Mullins[9], since it was seen in the absence of internal or external Na^+ (Fig. 2*a*), or in the absence of external Ca^{2+} (Fig. 2*d*). The experiment illustrated by Fig. 2*a*, *b* went on to test the idea that the outward current is carried by K^+ ions. We found that the decaying outward current was abolished when Cs replaced K in the internal dialysate (*b*), as expected if K^+ ions carry current much more effectively than Cs^+ ions.

If potassium ions carry the outward current, does K^+ move through the Ca channel itself, or through another pathway such as a K-specific channel? One possibility is that K-efflux occurs through a Ca-activated K current, $I_{K(Ca)}$. This is a reasonable hypothesis since such currents have already been found in heart (for example, ref. 14), but it would require near-perfect cancellation of I_{Ca} and $I_{K(Ca)}$ at the apparent reversal potential (Fig. 1*d*), a result not found in systems where these currents are known to overlap (for example, ref. 15). Figure 2*c*–*e* provides direct evidence against an explanation involving $I_{K(Ca)}$. Panel *c* shows inward Ca current at 0 mV, and decaying outward current at +90 mV. Removal of extracellular Ca (*d*) abolishes the inward Ca current, and increases the background leak conductance, but leaves the decaying outward current at +90 mV virtually unchanged. This argues against $I_{K(Ca)}$ as the mechanism of the outward current, since removal of Ca_o should quench any intracellular Ca transient that occurs beneath the surface membrane despite the presence of internal Ca buffers. The ineffectiveness of external Ca removal contrasts with the immediate abolition of the time-dependent outward current by exposure to the inorganic calcium channel blocker Cd^{2+} (Fig. 2*e*; see also Fig. 4*d*–*f*).

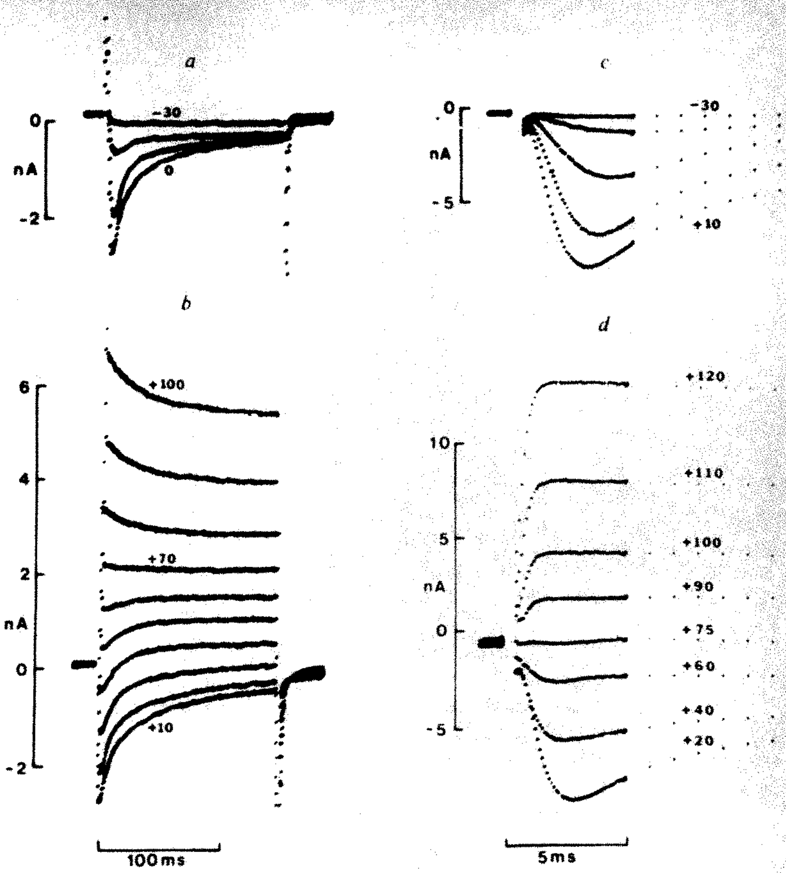

Fig. 1 Voltage and time-dependence of Ca channel current. *a*, *b*, Total membrane current records during a series of depolarizing pulses from a holding potential of −40 mV to levels spaced 10 mV apart. Pulses separated by at least 5 s. Capacity and leak current not subtracted. Current signal was filtered at 1 kHz and sampled at 1 kHz. Cell 64B. *c*, *d*, Membrane current records on a faster time scale from another cell, after digital subtraction of capacity transient and leak current. Current signals were filtered at 3 kHz. Sample rate was 10 kHz initially, then 1 kHz starting 5 ms after onset of voltage pulse. Linear 'leak' conductance and capacity current were estimated as the current during a hyperpolarizing pulse from −40 to −50 mV at the end of the run. 'Leak' conductance was 0.035 μS. The capacitative transient settled with a final time constant of 235 μs and its area corresponded to a total cell capacitance of ~184 pF. Data points are not shown for the first 300 μs after the onset of the voltage pulse while the membrane potential settled and the total current signal came into the range of the analog-to-digital converter. Cell 79G.

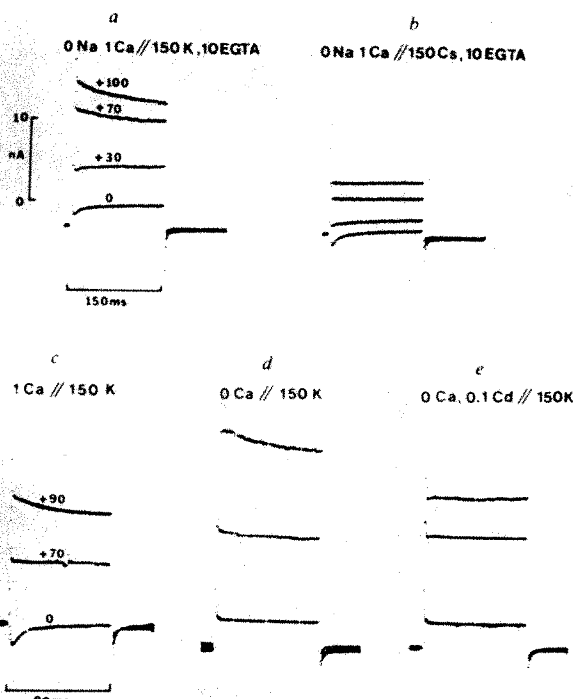

Fig. 2 Effects of removing internal K^+ or external Ca^{2+}. *a*, *b*: Effect of Cs^+ substitution for K^+ on decaying outward current. Total membrane currents recorded in 0-Na 0-K solution containing (in mM): 1 $CaCl_2$, 2.8 $MgCl_2$, 84 Cs-aspartate, 146 sucrose and 5.5 glucose, buffered to *p*H 7.4 with Tris. All internal solutions contain 10 mM K-EGTA. Addition of EGTA reduced the free Ca^{2+} concentration in the dialysate (kindly measured by Dr C. O. Lee using Ca^{2+}-sensitive microelectrodes) from ~0.4 μM to an undetectably low level. Voltage steps from a holding potential of −40 mV to levels indicated. *b*, Records taken with 150 Cs^+ in place of K^+ in internal solution; *a*, records taken 2 min after changing internal solution to the usual 150 K^+ dialysate. Cell 66B. *c–e*, Effects of changes in external divalent cation concentration from another experiment using solutions decribed in text: *c*, with 1 mM Ca outside; *d*, 0–Ca outside; *e*, 0–Ca + 100 μM Cd outside. Results in *d* taken after 90 s in 0–Ca solution. Cell 47B.

Can the decaying outward current be explained by the behaviour of a conventional voltage-dependent K channel? We found no reduction of the decaying outward current with 20 mM internal tetraethylammonium (TEA) or 1 mM external 4-aminopyridine (4-AP), levels that are usually effective at inhibiting K channels in heart and other excitable cells[16,17]. Unfortunately, higher doses of these agents were precluded by apparently nonspecific side-effects; 5 mM 4-AP produced a large outward holding current and increased leak conductance; even at 20 mM, intracellular TEA quickly diminished the inward Ca current and hastened the disappearance of all time-dependent current changes.

The most critical tests of whether the decaying outward current is carried by Ca channels came from experiments where Ca channels were blocked pharmacologically or inactivated by membrane depolarization. The idea behind the experiments was simple: if there is a genuine reversal potential where Ca channel current is zero because Ca influx and K efflux cancel, interventions that selectively inhibit Ca channels should have no effect at that potential. Figure 3 shows the effect of D600, a potent methoxy derivative of verapamil that is widely used as an inhibitor of Ca channels. A run before exposure to the drug shows a typical inversion of time-dependent current (*a*). After exposure to 0.3 μM D600 (*b*), both decaying inward and decaying outward currents were inhibited; the residual current in D600 is nearly linear and time-independent over the voltage range illustrated. Figure 3*c* superimposes current traces taken at three key test levels before and after D600. At the putative reversal potential, where time-dependent current vanishes, control and D600 traces coincide, just as expected if the driving force for net Ca channel current were zero and if D600 had no effect on leakage current.

The voltage-dependence of peak current and late current as obtained by this D600 dissection are plotted in Fig. 3*d*. Some features of the current–voltage relationships are surprising. First, late D600-sensitive current is appreciable, even though the predominant time-dependent current change seems largely complete at the end of the 150-ms clamp pulse (*c*). Second, persistent D600-sensitive current is significant even over the range between −50 and −30 mV, where there is very little

time-dependent inward current. Third, peak and late D600-sensitive currents grow quite large at strongly positive potentials; both I–V relationships show upward curvature between +30 and +100 mV.

The results illustrated in Fig. 3 are representative of a total of five experiments with 0.1–5 μM D600. The simplest interpretation is that Ca channel current truly reverses and that D600 blocks current flow in either direction. It could be argued that the null effect at E_{rev} is fortuitous, and that D600 not only blocks the Ca channel but also a voltage-dependent K channel. However, this explanation is very unlikely in view of the more extensive evidence illustrated in Fig. 4. Using the approach introduced in Fig. 3, we looked at varying degrees of Ca channel inhibition, not only by D600 (Fig. 4*a–c*), but also by the inorganic blocker Cd^{2+} (Fig. 4*d–f*), and by inactivation with depolarizing prepulses (Fig. 4*g–i*). In all three types of experiments, partial reduction of inward current below E_{rev} was associated with a partial decrease of outward current above E_{rev}, while the nearly time-independent current near E_{rev} remained essentially unchanged. These results provide strong evidence for a genuine reversal of Ca channel current at strong depolarizations. At the nearly physiological concentrations of Ca^{2+} and K^+ used in these experiments, the outward current is due to K^+ efflux through the channel, as originally hypothesized[8]. K^+ ions are not the only monovalent cations which can permeate the Ca channel. An outward movement of Cs^+ ions can also be detected in external media lacking permeant divalent cations or containing barium instead of calcium. Like the outward K^+ movement, the outward Cs^+ current can be inhibited by D600, Cd, or depolarizing prepulses; these interventions have no effect at the reversal potential seen with Ba^{2+} outside and Cs^+ inside, but reduce inward and outward currents recorded on either side of E_{rev}[18].

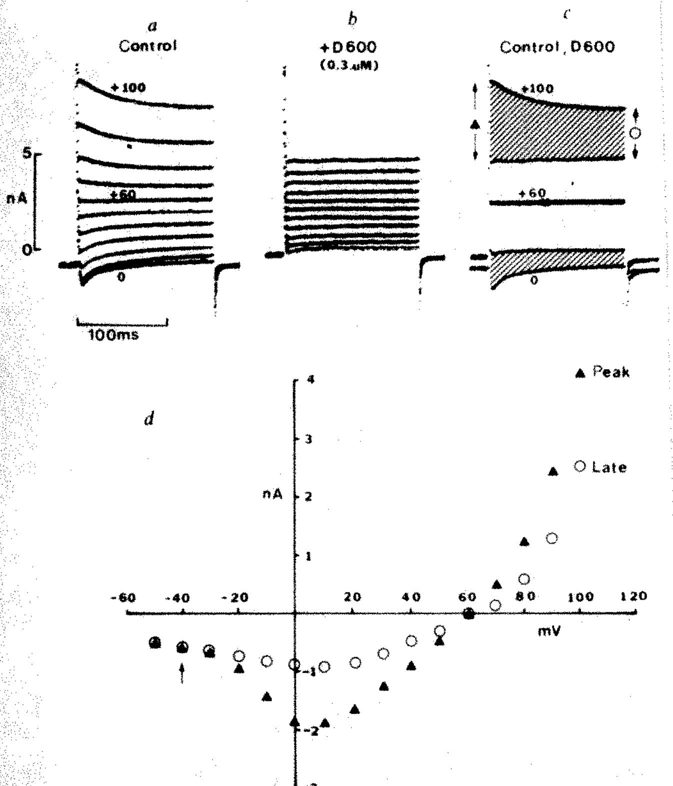

Fig. 3 Pharmacological dissection of calcium channel current using D600. *a*, Total membrane currents recorded during depolarizing pulses from −40 mV to levels spaced 10 mV apart, in conditions similar to Fig. 1*b*. *b*, Current records associated with the same set of voltage pulses after 5 min exposure to 0.3 μM D600. *c*, Repeat of current traces in *a* and *b*, for pulses to 0, +60 and +100 mV. The shaded areas indicate D600-sensitive current. Peak (▲) and late (○) D600-sensitive current at 100 mV were measured as indicated. *d*, Voltage-dependence of peak and late D600-sensitive current measured from signals shown in *a* and *b* and from records during pulses to levels below 0 mV. Arrow marks holding potential. Symbols at −40 and −50 mV denote changes in steady current. Cell 64A.

There is no conflict between these results in heart cells and earlier studies in dialysed molluscan nerve cells that did not show outward current through Ca channels[5–7]. The neurone experiments were done with Cs^+ or $Tris^+$ as the intracellular cations, with Ca^{2+} outside. In similar ionic conditions, our heart

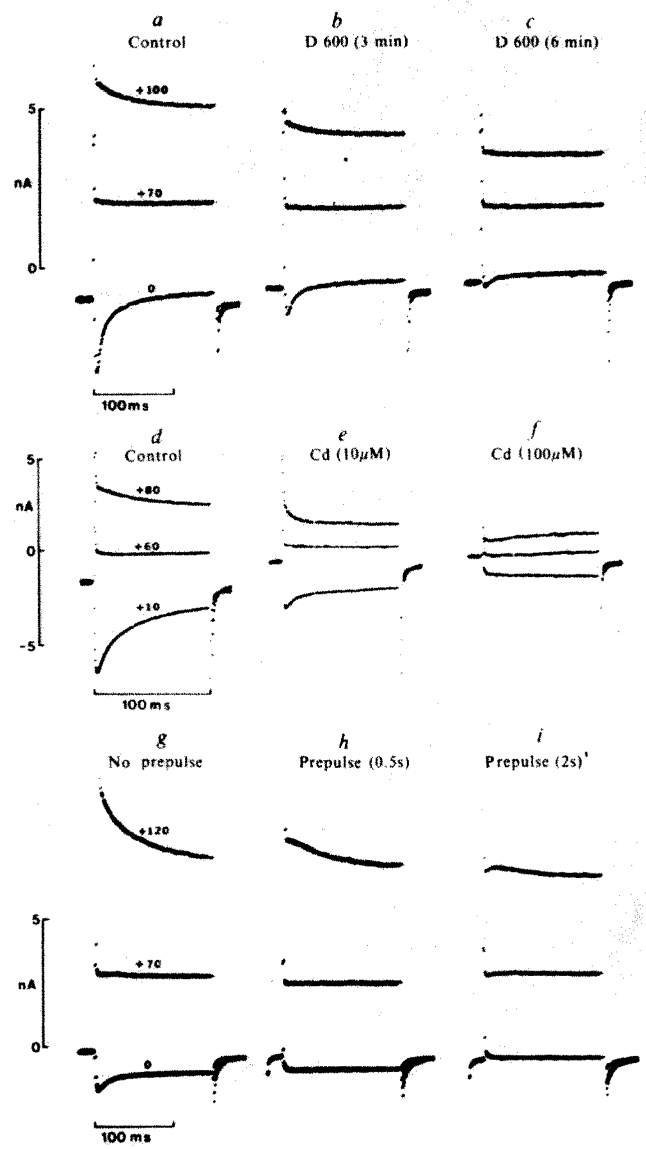

Fig. 4 Graded effects of interventions that reduce Ca channel conductance. *a–c*, Progressive development of D600 inhibition: *a*, 1 min after beginning D600 exposure, before any significant Ca channel block; *b*, after 3 min, when inward Ca current was roughly halved; *c*, after 6 min, when D600 effect had reached steady state. Cell 65C. Panels *d–f*, graded effect of external Cd^{2+}. The records in *d* and *e* were taken within a few minutes after increasing the external Cd^{2+} concentration, after block had reached steady state. In a total of six experiments using 10–500 μM Cd^{2+}, four cells showed no significant change in the level of current at the apparent reversal, one cell showed an upward shift, and one cell gave a downward shift. The Cd^{2+}-sensitive current resembled the D600-sensitive current illustrated in Fig. 3*d*. The speeding of inactivation evident in panel *e* was a consistent finding at low levels of Cd^{2+}. Cell 46A. Panels *g–i*, graded inactivation by conditioning prepulses to −10 mV. The current records were evoked by test pulses from a holding potential of −40 mV to the levels indicated. *g*, No prepulse preceding test pulses; *h*, 0.5 s conditioning prepulse, separated from test pulses by 20 ms repolarization to −40 mV; *i*, 2 s conditioning prepulse. Time-dependent current were reduced to a greater extent in *i* than in *h*; the Ca current recorded during prepulses to −10 mV showed a corresponding slow decline between 0.5 and 2 s. Cell 73A.

cells also lack decaying outward currents over the voltage range between 0 and +120 mV (Fig. 2*b*; ref. 18). It is interesting that outward Cs current can only be detected in the absence of external Ca. Presumably, Ca^{2+} ions bind to the channel much more strongly than Ba^{2+} ions[1], preventing significant outward movement of Cs^+, but not the efflux of the more permeant cation K^+.

These experiments show for the first time the feasibility of studying cardiac Ca channels while changing intracellular ions at will. As in the case of various patch clamp techniques[19,20], the suction pipette method offers its own unique combination of advantages. The relatively large pipettes used here give direct recordings of ensemble properties of ionic channels, like whole cell recordings using fine-tipped pipettes[19,21], but they also allow manipulation of the medium on the cytoplasmic side of the membrane, like cell-free patches[19,20]. Lability of Ca channel function does not seem to be a serious problem: inward and outward Ca channel currents often remain relatively stable for up to 30–40 min with external Ca and for even longer with external Ba. Systematic variations in intracellular constituents might give further improvements. But our experience already augurs well for future studies on modulation of Ca channels by adrenaline, acetylcholine or digitalis, and the role of putative intracellular mediators such as cyclic nucleotides or Ca^{2+} ions[2,3,22]. Intracellular Ca is also thought to promote Ca channel inactivation in a variety of excitable cells[23] including certain heart cells (for example, ref. 24). However, this cannot be the only mechanism since, as Fig. 2*d* shows, outward current through these Ca channels undergoes inactivation even in the absence of permeant divalent cations.

We thank Esther W. Lee for technical assistance and B. P. Bean and R. W. Aldrich for helpful discussion. This research was supported by the American Heart Association and the USPHS.

The permeability of cell membranes to Ca^{2+} ions is of great importance for a variety of cellular functions such as secretion of neurotransmitters and hormones, or contractile activation of heart cells. In several cell types including cardiac muscle, Ca^{2+} channels are gated by membrane potential and regulated by neurotransmitters[1–3]. We have used the patch clamp technique[4] in order to obtain information about the properties of single Ca channels in cultured heart cells. With Ba^{2+} carrying the inward current the single channel slope conductance is about 25 pS, and the probability of channel opening increases markedly with voltage. The channels become inactivated over a membrane potential range of about 60 mV. The mean channel open time is about 1 ms at 25 °C. However, a second much slower clustering behaviour primarily determines the slow activation time course of averaged currents. Isoprenaline does not affect single channel conductance, but seems to lengthen the mean open time and to decrease intervals between bursts.

Tissue cultured myocytes were obtained from neonatal rat hearts[5,6]. After seeding, the cells were incubated for 2–4 days in a culture medium containing 0.1 mM 8-bromo cyclic AMP to increase the likelihood of detecting single Ca channels[7]. Most cells used for our experiments had spindle-like shapes and showed striations. Single-channel currents were recorded from cell-attached membrane patches with seals between 10 and 100 GΩ (ref. 4). The recording pipette contained 96 mM $BaCl_2$ solution with 20 μM tetrodotoxin (buffered at *p*H 7.4 with 10 mM HEPES); thus, the current carrier was Ba^{2+} rather than Ca^{2+}. The composition of the bathing solution was (mM): NaCl 137, KCl 5.4, $MgCl_2$ 1, $CaCl_2$ 0.02, glucose 10, HEPES buffer 10 (*p*H 7.4); temperature 24–26 °C. Consistent results have been obtained from experiments on 24 patches with Ca channel activity, most of which had only a single Ca channel present. Our analysis of single Ca channel properties presented here is based primarily on results obtained from five patches, each of which provided rather complete information; three of these had only a single Ca channel present.

Calcium channels switch randomly between open and closed states, and appear not to dwell at intermediate conductance levels; some depolarizations produce one or more channel openings of various durations, whereas for others, the channel fails to open at all (Fig. 1).

The steady-state probability that a channel will be open depends on membrane potential, as does the current that flows while the channel is open (Fig. 2). We have estimated the single channel current (i) by eye (Fig. 2*a*) and calculated open probability (p) from

$$I = Npi \qquad (1)$$

where the mean current I was found by time-averaging the current flowing through calcium channels over 50 or 100 ms, and N is the number of channels functioning in the patch ($N = 1$ for Fig. 2). The probability of a channel being open increases with depolarization, at a maximum rate of about e-fold per 10 mV, from nearly zero at a membrane potential of −30 mV to 0.7 at around +30 mV. Over this same voltage range, the open channel current–voltage relationship is approximately ohmic with a slope conductance of about 25 pS (isotonic $BaCl_2$ extracellularly).

During long depolarizing steps Ca channels show inactivation that is 20 or 30 times slower than activation (Fig. 3*a*). We studied steady-state inactivation by measuring Ca channel currents at a fixed potential after holding the membrane potential at various conditioning levels (Fig. 3*b*). This inactivation occurs through a decrease in the probability that a channel is available to open, and not through a decrease in single channel current, *i*. Steady-state inactivation increases with conditioning depolarization and can be fitted by a Boltzmann distribution. Channels are half-inactivated at a membrane potential of about

−35 mV, while channels just begin to be activated with depolarizations slightly greater than this (about −30 mV).

We have estimated the average duration of a channel opening, $\bar{t}$, by the equation

$$\bar{t} = \frac{p}{r} \qquad (2)$$

where p is the fraction of the time a channel spends open (from equation (1)) and r is the average opening rate obtained by counting the number of opening transitions n during the period T over which the time-averaged current was calculated ($r = n/T$). When necessary the average opening rate was corrected for openings too brief to be detected; this correction assumed an exponential distribution of open times, and was at most 1%. The mean open time was always close to 1 ms. For example, for the experiment that yielded the records shown in Fig. 2,

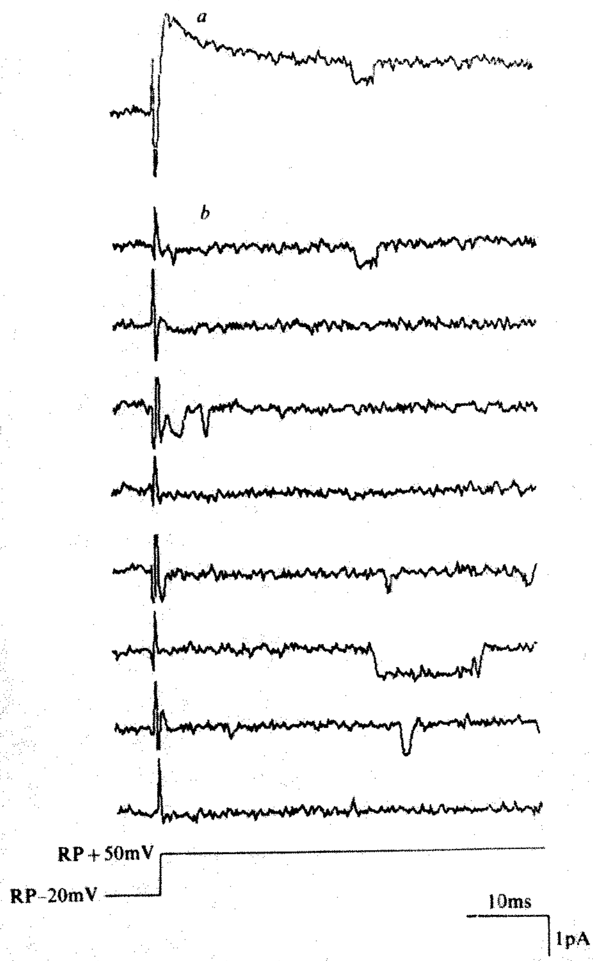

Fig. 1 Single Ca channel currents from cultured rat heart cells. In record *a*, the capacitive transient was reduced by analog compensation[4]. The eight sequential records in *b* have had the remaining capacitive transient and the leakage current subtracted (the first record in *b* is derived from *a*). Records were inspected visually, and portions containing channel activity or obvious artefacts were excluded from the leakage current average. Membrane potential of the patch was held at 20 mV negative to the resting potential (RP) and stepped to RP+50 mV. Resting potential of this cell was estimated to be −50 mV; this was done by comparing unit currents through Ca-activated inward current channels[5] in these cell-attached patches with the unit current carried by Ba^{2+} ions through such channels in detached patches, for which the true membrane potential is known (D. Colquhoun, E. Neher, H.R. and C.F.S., unpublished results). These channels were frequently observed in these experiments, but in the voltage range where we have studied Ca channel current they carry only a small unit current; thus, they can easily be distinguished from the Ca channel currents and make no appreciable contribution to the observed current.

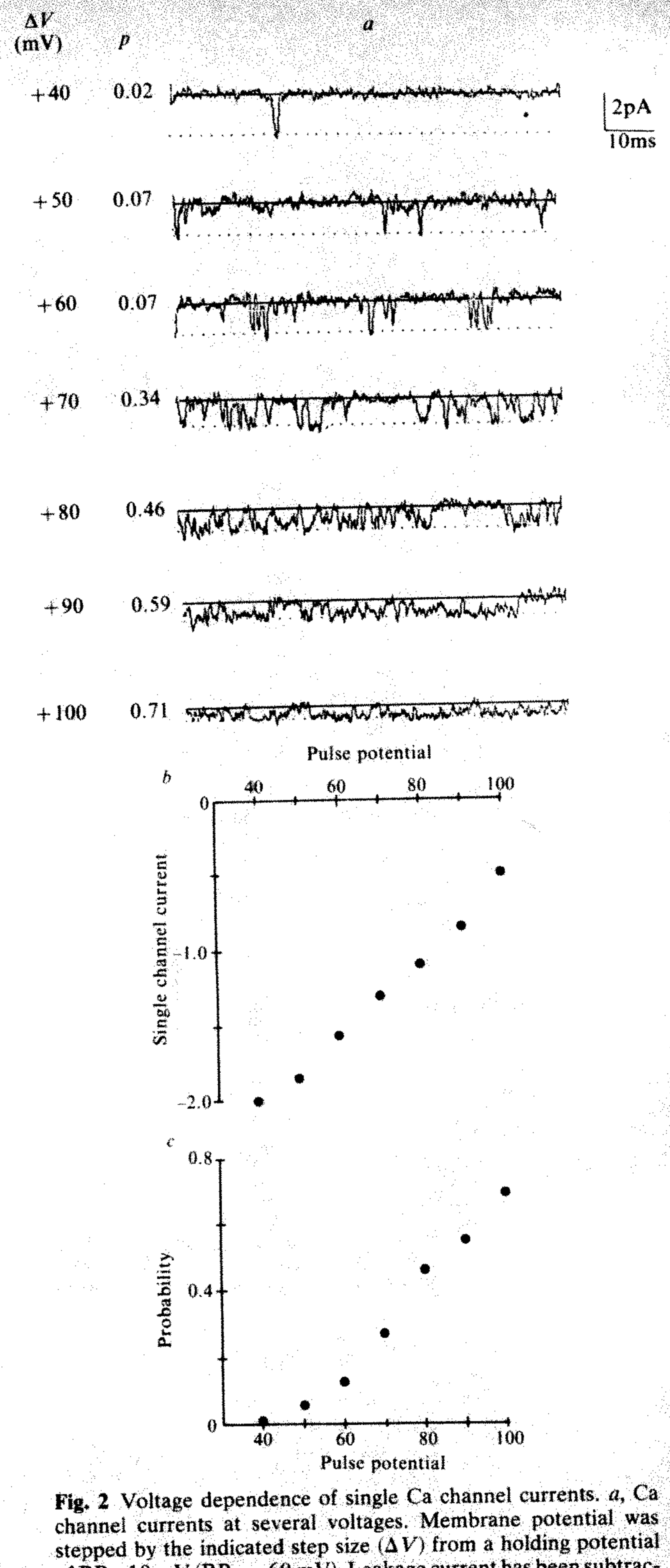

Fig. 2 Voltage dependence of single Ca channel currents. *a*, Ca channel currents at several voltages. Membrane potential was stepped by the indicated step size (ΔV) from a holding potential of RP − 10 mV (RP ≈ −60 mV). Leakage current has been subtracted from these records. The solid lines indicate the baseline after leak subtraction. The dotted lines indicate the measured open-channel current. Beside each record is the average probability (p) that the channel was open, as determined from the individual record shown (see text, equation (1)). This patch had only a single active Ca channel. Data were filtered at 1 kHz. *b*, Voltage-dependence of open channel current. Open channel current was fitted visually for the experiment in *a* for each membrane potential. A pulse potential of 40 mV corresponds approximately to a membrane potential of −30 mV, as above. *c*, Voltage dependence of Ca channel gating. The time-averaged probability that the single active Ca channel in this patch was open was determined (for each voltage) by dividing the average current by the open channel current (equation (1)). Average current was measured over a 90 ms interval beginning 5 ms after the start of each pulse.

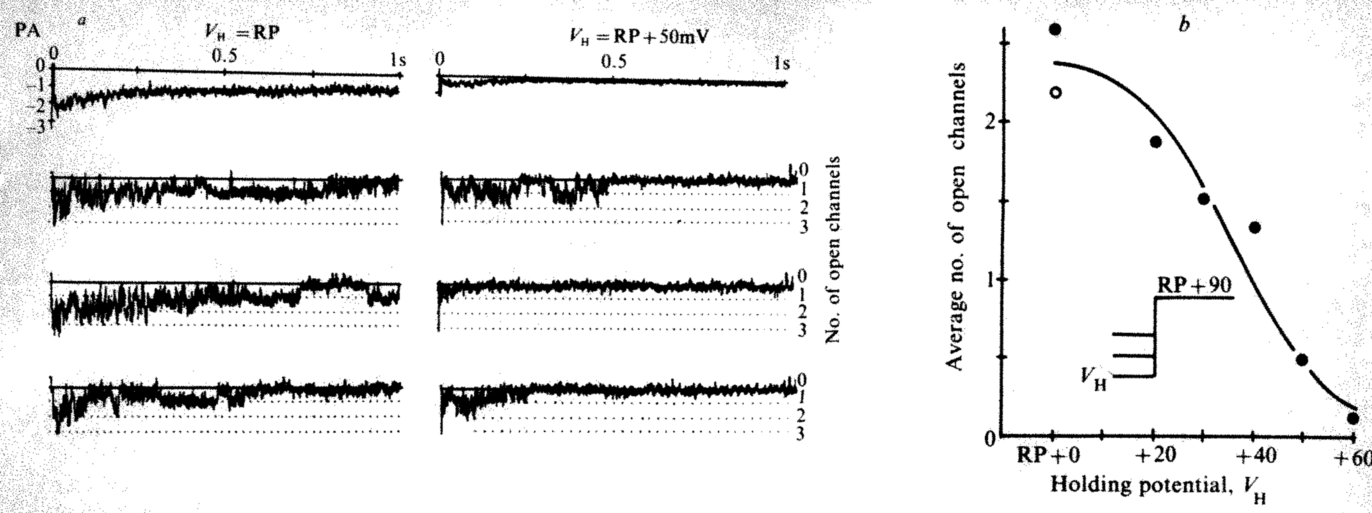

Fig. 3 Inactivation of Ca channel currents. *a*, Ca channel currents at a fixed potential, stepping from two different holding potentials. Left, V_H (holding potential) = RP; right, V_H = RP + 50 mV (RP ≈ −70 mV). Command potential is RP + 90 mV in both cases. At top is the average current, calculated from about 20 individual records, for each holding potential (leakage current subtracted). There is no significant change in time-to-peak when the averaged records are scaled to the same amplitude. Below are examples of three individual records from each holding potential (same scale as averages). Dotted lines on the individual records are spaced 0.86 pA apart, which is the size of a single channel current at RP + 90 mV. Notice the additional clustering which occurs on a very slow (hundreds of milliseconds) time scale. This patch showed a maximum of four open channels for large depolarizations. Data were filtered at 1 kHz. *b*, Voltage dependence of Ca channel inactivation. The time-averaged number of open channels in the first 50 ms of a test pulse to PR + 90 mV is plotted as a function of holding potential. The average number of open channels is found by dividing the average current during the first 50 ms of the test pulse by the unit open channel current which did not vary with holding potential. The solid line is a Boltzmann distribution:

$$N = N_0[1 + \exp((V_m - V_{0.5})/k)]^{-1}$$

with parameters chosen for the best visual fit: N_0 = 2.4 open channels; $V_{0.5}$ = RP + 35 mV; k = 10 mV. The open circle is a repeat of the V_H = RP point, done at the end of the inactivation series. Observations of Ca channel activation before and after the inactivation experiment illustrated here agree closely with the activation curve in Fig. 2*b*.

the mean open time increased from 0.65 ms at a pulse potential of 60 mV to 1.4 ms for an 80 mV pulse. Although the standard errors of these measurements are less than 10% of the mean, we estimate that systematic errors of closer to 15% are present due to uncertainties in counting opening transitions (the interested reader should count openings in the records of Fig. 2). Our values for mean open time are therefore close to the estimates reported for Ca channels in snail neurones[8] and bovine chromaffin cells[9].

The Ca channels studied here exhibit distinctive gating behaviour. Their openings are not dispersed at random throughout the period of depolarization, but rather tend to occur in groups of two or more closely spaced openings separated by longer silent times (see Fig. 2*a*, +60 and +70 mV). It is as if the channel enters an 'activated' condition in which it rapidly flickers open and closed. The average current is activated (see Fig. 3*a*, upper row) with a time constant on the order of 10 ms, and this longer time seems to reflect the burst length rather than the characteristic time (~1 ms) of the individual openings.

The β-adrenergic agonist isoprenaline, mimicking the action of the hormone adrenaline, causes an increase in cardiac calcium currents[1,2,10]. We have investigated the effects of this drug at the single channel level in several preliminary experiments. Isoprenaline caused no increase in the single channel current, but in one experiment (10 μM) it produced a 60% increase in the mean open time which was manifest as a corresponding increase in the probability from 0.06 to 0.09 ($V_m \approx +10$ mV). A similar but smaller effect was observed in a second experiment (1 μM). If this effect is confirmed by a more complete analysis, isoprenaline can be viewed as causing an increased conductance[10], at least partly, by altering the fraction of time an 'activated' channel spends in its open state (see ref. 2).

The kinetic properties of single Ca channel currents qualitatively agree with previously reported kinetic data on global Ca currents in a variety of cardiac tissues[1]. We find a steep increase in the probability of channels opening over the same potential range where activation of Ca conductance occurs[1,11]. Our single channel records exhibit steady-state inactivation kinetics similar to those reported for global Ca currents[1,11]. However, in contrast to previous results there is a smaller range of overlap between potentials where channels open and become inactivated. This may partly be due to the fact that we have used isotonic $BaCl_2$ solution in our pipette which is known to alter surface charges[12] and thereby shift activation and inactivation ranges along the voltage axis. We have used Ba^{2+} instead of Ca^{2+} ions because of their higher permeability through Ca channels[3,8].

Our measurements of single channel conductance yield values that are more than an order of magnitude larger than those estimated from fluctuation analysis in molluscan neurones in comparable conditions[13]. However, they are consistent with two reports on single Ca channels in snail neurones[8], and bovine chromaffin cells[9]. In the latter note, bursts of channel openings, presumably similar to those observed in our study, have also been mentioned.

In comparison with Na channels[14,15], Ca channels show a much more complex kinetic behaviour. There is a fast gating process (mean channel open time ~1 ms at 25 °C) and a slower one that results in bursts. It is interesting to speculate that one of the gating processes is regulated by some intermediate metabolic step, such as phosphorylation of the Ca channel. In this respect it will be important to pursue our preliminary isoprenaline results, since β-adrenergic catecholamines are thought to regulate the Ca conductance through such a mechanism[1,2].

This work was performed in the Department of Pharmacology, University of Berne and was supported by the Roche Research Foundation and the Swiss NSF. We thank C. Becker for providing tissue culture cells, Dr A. Cachelin for help with some of the experiments, and Roche Animal Farm, Füllinsdorf for the gift of pregnant rats.

Calcium-binding protein parvalbumin is associated with fast contracting muscle fibres

M. R. Celio & C. W. Heizmann

Anatomisches Institut der Universität Zürich, Gloriastrasse 19, CH-8006 Zürich, and Institut für Pharmakologie und Biochemie der Universität Zürich, Winterthurerstrasse 260, CH-8057 Zürich, Switzerland

The basic mechanism underlying the contraction–relaxation cycle of vertebrate muscles is a Ca^{2+} exchange between the sarcoplasmic reticulum and the myofibrils. Relaxation is achieved by retrieval of Ca^{2+} from the myofibrils and transfer to the sarcoplasmic reticulum. However, it is uncertain whether the rate of Ca^{2+} uptake by the sarcoplasmic reticulum can account for the known speed of relaxation[1,2]. In fast contracting muscles the Ca^{2+}-binding protein parvalbumin is postulated to facilitate relaxation[3–8]. Using immunohistochemical techniques, we show here that parvalbumin is located exclusively in type II (fast-twitch) mammalian skeletal muscle fibres which can be further subdivided into five subgroups displaying distinct staining intensities. As the active state decays more rapidly in fast than in slow muscles[9,10], our results support the contention that parvalbumin may be concerned with rapid muscle relaxation[3–8] and in addition suggest a range of relaxation properties in muscle fibres belonging to the same histochemical fibre type.

Newborn and adult Wistar rats of both sexes were killed and various skeletal muscles quickly dissected out, stretched and frozen in isopentane cooled by liquid nitrogen. The muscles were then divided and the respective halves separately processed for histochemical and immunohistochemical localization. Additionally, heart muscle tissue taken from the atria and ventricles, smooth muscle tissue of the gut, great vessels and non-pregnant uteri, as well as specialized, small cross-striated muscles with a high intrinsic speed of contraction (external eye muscles and intrinsic laryngeal muscles[9]) were dissected out, fixed in Bouin fluid and embedded in paraffin. The high solubility of parvalbumin prevented the use of unfixed or postfixed cryostat sections for the immunohistochemistry. Monospecific antisera to rat muscle parvalbumin were used in dilutions up to 1:30,000 in phosphate-buffered saline (PBS). The specificity of the antisera has been described elsewhere[11]; there is no cross-reaction[12] with troponin-C, calmodulin or S-100 protein. Sections were further processed according to the unlabelled antibody technique of Sternberger[13]. Briefly, goat-anti-rabbit IgG (Nordic) was applied for 30 min, followed by peroxidase–antiperoxidase complex (Sternberger–Meyer Inc.). The peroxidase-dependent reaction was detected by means of diaminobenzidine HCl/H_2O_2. Control slides were processed identically and simultaneously with preimmune sera of the same animal and with preadsorbed antisera.

Parvalbumin immunoreactivity in the extensor digitorum longus muscle of newborn rats appears on postnatal days 3 or 4. In adult rats, anti-parvalbumin antisera stain extensor digitorum longus extrafusal muscle fibres in at least five different degrees of intensity (Fig. 1*a*). In the soleus muscle the parvalbumin immunostaining is much less conspicuous (Fig. 1*b*). The parvalbumin immunostaining pattern (Fig. 2*a*) was correlated with histochemical fibre typing by staining serial sections for myofibrillar ATPase[14,15] after preincubation at *p*H 4.3 (Fig. 2*b*) and with formalin followed by *p*H 10.6 (Fig. 2*c*). Several laboratories have shown near-equivalence of formalin-based and acid-based subdivisions of fast fibres[16–18]. Accordingly, formaldehyde-resistant fast fibres will here be designated type IIA, and formaldehyde-sensitive ones type IIB. The muscle fibres could thus be histochemically classified into the main groups: type I (Fig. 2*b*) (slow-twitch, oxidative), type IIA (fast-twitch, oxidative-glycolytic) and type IIB (fast-twitch, glycolytic)[14,15,19] (Fig. 2*c*). The type IIB fibres showed the strongest immunoreactivity towards parvalbumin antisera (Fig. 2*a*) and could be differentiated into two subgroups showing graded

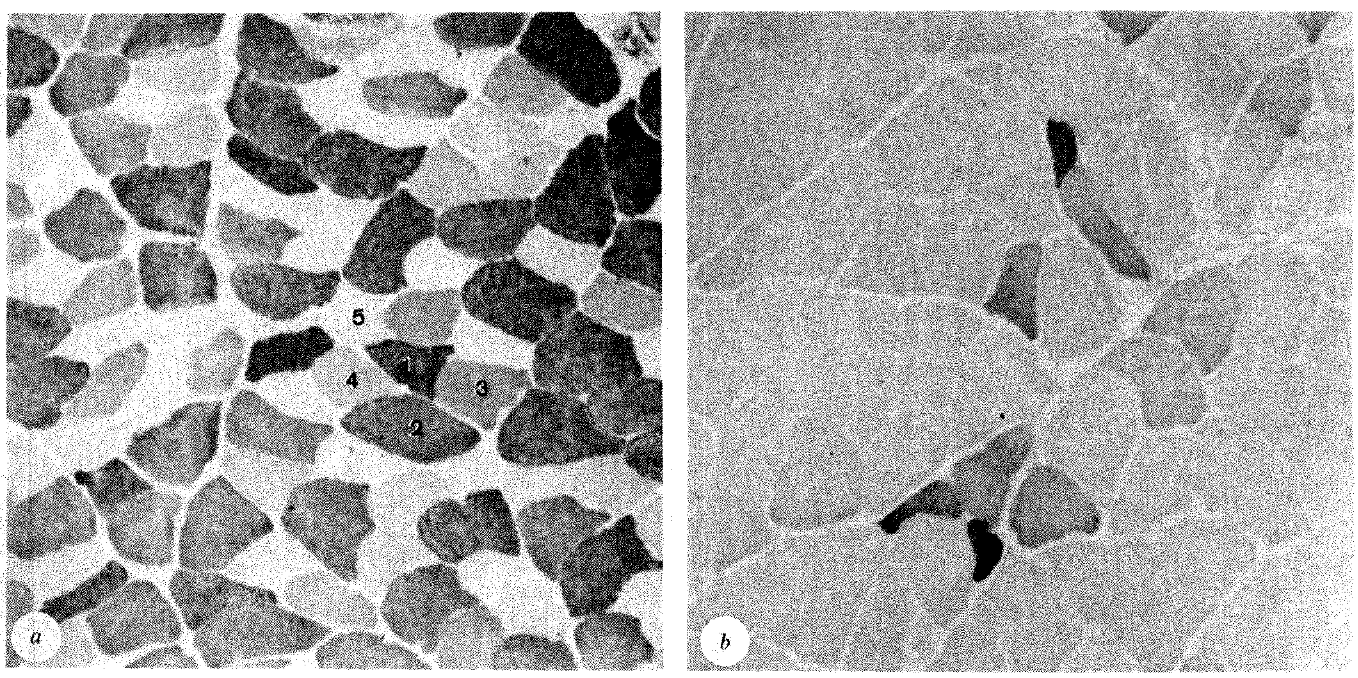

Fig. 1 *a*, Survey of a transverse section through the belly of the musculus extensor digitorum longus (EDL; fast contracting/fast relaxing[9]) of an adult rat incubated with parvalbumin antiserum and processed by the peroxidase–antiperoxidase technique[13]. The parvalbumin immunostaining shows a chequered appearance with at least five different shadowings in staining intensity, even at the extreme antiserum dilution of 1:20,000. *b* Shows a cross-section of the ipsilateral soleus (slow contracting/slow relaxing[9]) of the same animal processed identically. In the soleus very few muscle fibres are labelled by the parvalbumin antiserum. ×150.

0028–0836/82/230504—03$01.00

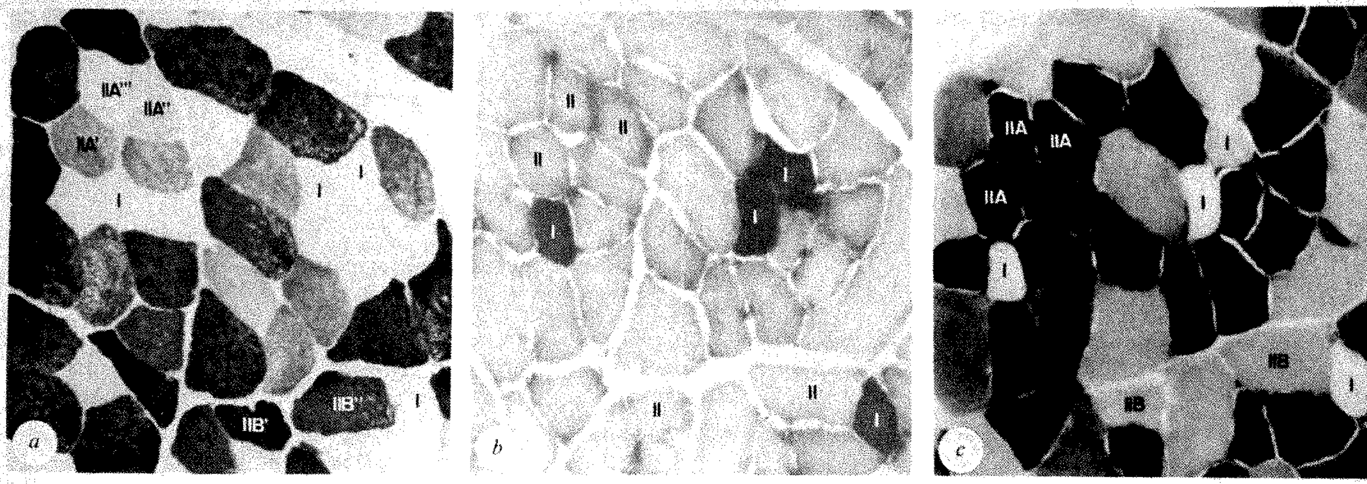

Fig. 2 Consecutive transverse sections of the EDL of an adult rat, analysed for parvalbumin immunoreactivity (*a*) and enzyme-histochemical fibre types (*b*, *c*). Adult Wistar rats (Ivanovas) were killed by a blow to the head and the muscles quickly dissected out, frozen in isopentane cooled by liquid nitrogen and halved with a precooled razor blade. One part was freeze-substituted with acetone for 1 week at −70 °C and fixed at the same temperature with a mixture of acetone (90 ml), formalin (40% per 5 ml), acetic acid (1 ml) and water (4 ml) for another week. The specimens were thawed, embedded in Paraplast and the sections incubated with antisera against rat muscle parvalbumin in dilutions varying between 1:5,000 and 1:30,000 for 48 h in a moist chamber at 4 °C. The immune complex was visualized by the unlabelled antibody technique of Sternberger[13]. Identical distribution and localization of parvalbumin immunoreactivity were achieved after perfusion fixation of the rat's body with Bouin fluid and embedding of the muscles in paraffin (see Fig. 4 legend). The second half of the muscle was cut in a cryostat and the sections processed for acid-stable (*p*H 4.3) ATPase activity (*b*) and formalin/alkali-stable (*p*H 10.6) ATPase activity (*c*), following established procedures[14–18]. Corresponding areas were photographed and muscle fibres identified. Type IIB fibres (*b*, *c*) display two distinct degrees of staining intensity with parvalbumin antisera (IIB', IIB'' in *a*) while type IIA fibres (*b*, *c*) may even show three (IIA', IIA'', IIA''' in *a*). IIA''' fibres are actually devoid of parvalbumin immunoreactivity and in this respect resemble type I fibres. Note that the strongest immunolabelling is detectable in the small-calibre IIB' fibres (*a*). ×148.

differences in staining intensity. The type IIA muscle fibres were moderately stained in three distinct degrees of intensity (Fig. 2*a*). Type I muscle fibres always remained nonreactive (Fig. 2*a*). In muscles spindles, one nuclear chain fibre was immunolabelled, whereas bag fibres were not (Fig. 3). High parvalbumin immunoreactivity was detectable in fibres belonging to the global portion of the musculus rectus lateralis oculi (Fig. 4*b*) and in the musculus thyreoarytenoideus lateralis (Fig. 4*a*). The slow tonic fibres in the orbital layer of external eye muscles (Fig. 4*b*) as well as the musculus thyreoarytenoideus medialis (vocalis) were nonreactive (Fig. 4*a*). Cardiac muscle fibres and smooth muscle cells were never labelled by parvalbumin antisera (not shown).

The immunostaining was reproducible for a wide range of antiserum dilutions. Identical correlations with histochemical fibre typing were obtained using other fixatives and embedding procedures (see figure legends). The staining pattern was homogeneous and evenly distributed over the whole muscle fibre in longitudinal section (not shown) and in cross-section.

A discussion of the role of parvalbumin in muscle hinges on the hypothesis that parvalbumin facilitates the relaxation by shuttling Ca^{2+} from troponin-C to the sarcoplasmic reticulum[3–8]. The sarcoplasmic reticulum is actually well developed in type II muscle fibres[20], which are rich in parvalbumin, and type II muscle fibres form the bulk of fast muscles, which as a whole are indeed fast relaxing. Our observation of a high parvalbumin content in such fibres supports the notion that parvalbumin is implicated in muscle relaxation, as the decay of the active state is shorter in fast than slow motor units. This assumption is strengthened by the observation that parvalbumin immunoreactivity appears on days 3 and 4 after birth in the extensor digitorum longus, coincident with changes in contraction properties, in particular the decrease in the relaxation time after a twitch or tetanus[21,22]. Similarly, it is probable that the parvalbumin-positive intrafusal nuclear chain fibre relaxes faster than do nuclear bag fibres[23].

The teleological meaning of rapid relaxation is that muscle fibres are sooner ready for a new contraction. It is therefore not surprising that parvalbumin immunoreactivity is particularly high in fibres of muscles characterized by very high contraction frequencies. In the rat[9,10] these muscles are the external eye muscles and the inner laryngeal muscles, both displaying the highest intrinsic speed of shortening and the shortest twitch half-relaxation times.

Type I muscle fibres show a relatively poorly-developed sarcoplasmic reticulum and lack parvalbumin immunoreactivity. Like cardiac muscle, they are well provided with mitochondria which may be involved in Ca^{2+} homeostasis[24]. As no isoforms of parvalbumin have been found in rat skeletal muscles[25], the relative staining intensities presumably correspond to differences in the concentration of parvalbumin within these muscle fibres and may reflect a continuum in relaxation properties. This is consistent with the finding of metabolic subpopulations of type II fibres and the proposition of a dynamic continuum of muscle fibres[26–31] correlated with the wide spectrum of contraction times[32,33].

An incidental effect attributed to parvalbumin is that it might, by releasing heat as it takes up Ca^{2+}, contribute substantially to the 'unexplained' heat output displayed by many muscles early in tetanus[34]. This hypothesis may now be tested by comparing muscles with high and low parvalbumin concentrations.

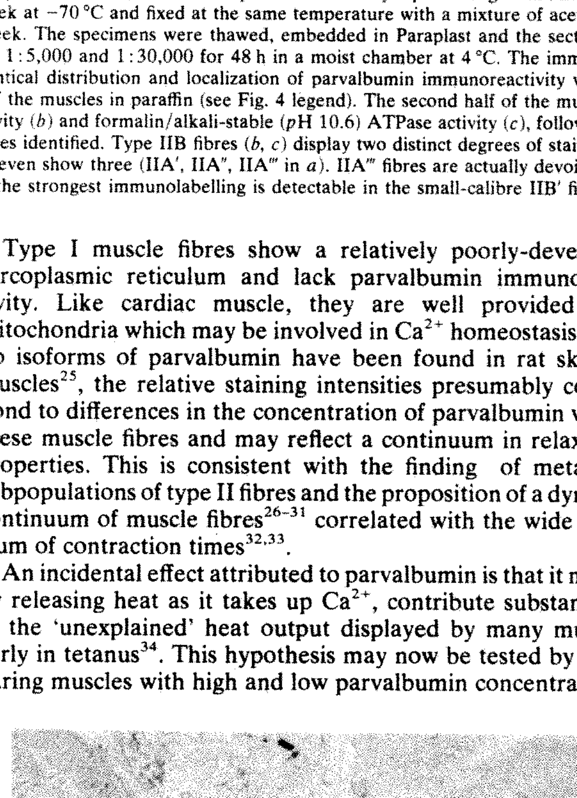

Fig. 3 Cross-section through the intracapsular polar region of a muscle spindle of the soleus muscle. Four miniature muscle fibres are suspended in the spindle capsule. One chain fibre (c) is strongly parvalbumin-reactive whereas the second chain fibre (c) as well as the bag fibres (b) are only weakly labelled. The parvalbumin immunostaining of soleus muscle spindles was always unequivocal, in contrast to that of identically treated EDL muscle spindles. I and II: types I and II extrafusal muscle fibres (as determined in following sections treated for the histochemical detection of ATPase). ×250.

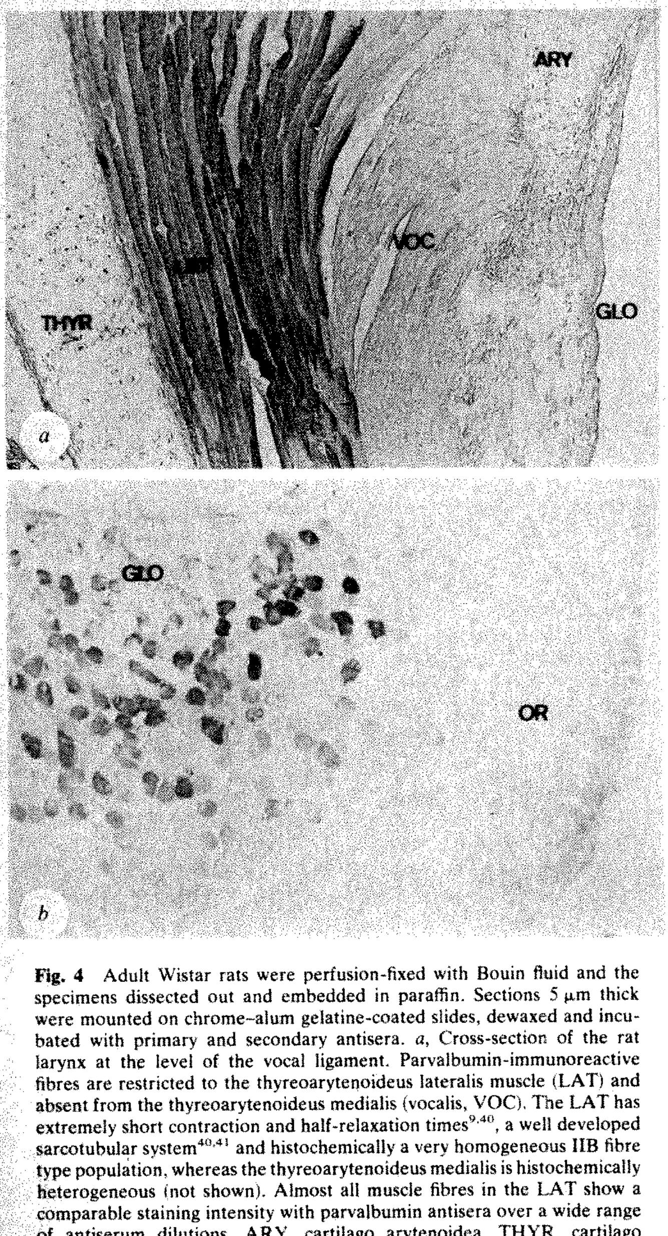

Fig. 4 Adult Wistar rats were perfusion-fixed with Bouin fluid and the specimens dissected out and embedded in paraffin. Sections 5 μm thick were mounted on chrome-alum gelatine-coated slides, dewaxed and incubated with primary and secondary antisera. *a*, Cross-section of the rat larynx at the level of the vocal ligament. Parvalbumin-immunoreactive fibres are restricted to the thyreoarytenoideus lateralis muscle (LAT) and absent from the thyreoarytenoideus medialis (vocalis, VOC). The LAT has extremely short contraction and half-relaxation times[9,40], a well developed sarcotubular system[40,41] and histochemically a very homogeneous IIB fibre type population, whereas the thyreoarytenoideus medialis is histochemically heterogeneous (not shown). Almost all muscle fibres in the LAT show a comparable staining intensity with parvalbumin antisera over a wide range of antiserum dilutions. ARY, cartilago arytenoidea, THYR, cartilago thyreoidea, GLO, glottis. ×125. *b*, Cross-section of an external eye muscle. Only fibres restricted to the global portion (GLO) of the rectus lateralis muscle are recognized by parvalbumin antisera, whereas the small-calibre fibres of the orbital layer (OR), with a known slower contraction time[42], remain unlabelled. The intensity of immunostaining with parvalbumin antisera varies among muscle fibres, reflecting the presence of a wide range of different histochemical fibre types[43]. ×100.

Our results demonstrate an association of the Ca^{2+}-binding protein parvalbumin with the fast-contracting muscle fibres of rat muscles, in agreement with earlier findings on fish muscles[35–39]. Parvalbumin could therefore represent a reliable system for Ca^{2+} homeostasis, allowing rapid cyclic relaxation in phasically active muscle fibres. Furthermore, parvalbumin immunohistology seems to be a very sensitive auxiliary technique to enzyme histochemistry and myosin immunohistology for classifying muscle fibres into various subtypes.

We thank Drs E. Jenny and W. Zenker for supporting this work, Drs A. Rowlerson and M. Müntener for valuable discussion and Mrs H. Tedaldi, Mrs H. Weber and Miss Chr. Hemmerle for technical assistance.

Natural resistance of mice to infections with *Salmonella typhimurium* and *Leishmania donovani* is regulated by chromosome 1 gene(s) designated *Ity* and *Lsh*, respectively[1,2]. Given the fact that these two microorganisms are taxonomically and antigenically distinct, and yet the host response to them is regulated by the same locus or complex[3,4], one might expect that the resistance to other intracellular pathogens would be controlled similarly. Innate resistance of inbred mice to infection with *Mycobacterium bovis* (BCG) is regulated by a single, dominant, autosomal gene designated *Bcg* which is known to exist in two allelic forms: resistant Bcg^r and susceptible Bcg^s (ref. 5). The distribution of Bcg^r and Bcg^s alleles, among a total of 14 inbred and 38 recombinant inbred (BXD and BXH) strains, matches exactly that established for resistant and susceptible alleles of *Lsh* (gene controlling resistance to *Leishmania donovani*) and *Ity* (gene controlling resistance to *Salmonella typhimurium*), suggesting that resistance to all these pathogens is controlled by the same chromosome 1 locus. The existence of such a chromosomal locus is further supported by the *Bcg–Lsh* and *Bcg–Ity* linkage as established by formal backcross analysis.

0028–0836/82/230506—04$01.00

Mice of selected inbred and recombinant inbred strains were infected intravenously with a dispersed inoculum of BCG[6] at a dose of $2-3 \times 10^4$ colony-forming units (CFU) of BCG. The number of viable BCG organisms in the spleen was determined 3 weeks after infection. All the inbred mouse strains which were tested segregated into two distinct groups with respect to the host response to BCG infection: resistant strains (*Bcg*^{r}), in which practically no proliferation of BCG inoculum occurred, and susceptible strains (*Bcg*^{s}), which allowed up to 100-fold BCG multiplication in their spleens (Table 1). Segregation into resistant and susceptible strains matches exactly that which was established for *Ity*- and *Lsh*-regulated resistance to *S. typhimurium* and *L. donovani*[7,8].

Recombinant inbred strains BXD and BXH (originating from the BCG-susceptible C57BL/6J progenitor, and the BCG-resistant DBA/2J and C3H/HeJ progenitors, respectively), when infected with BCG, also segregated into two distinct groups (Figs 1, 2). The strain distribution pattern (SDP) of *Bcg*^{r} and *Bcg*^{s} alleles among BXD and BXH strains was found to be completely concordant with that established for *Ity*^{r}, *Ity*^{s} and *Lsh*^{r}, *Lsh*^{s} alleles[3,4]. One strain deserves a comment: BXH-2 typed as susceptible to BCG while reported to be *Lsh*^{r} and *Ity*^{r}. However, the (C57BL/6J × BXH-2)F_1 hybrid mice were found to be resistant to BCG ($\log_{10}$ BCG $= 4.69 \pm 0.14$), thus clearly indicating that the phenotypic susceptibility to BCG of BXH-2 strain is caused by a factor unrelated to the *Bcg* gene that overrides the resistance conferred by the *Bcg*^{r} allele. It is of interest that the BXH-2 strain was also found to express high levels of murine leukaemia virus, and has a high incidence of lymphoma. The basis for these characteristics is not fully understood, but was acquired after the strain was already inbred[9].

We have also examined the linkage between *Lsh* and *Bcg* in a backcross population. F_1 hybrids between B10.A (*Bcg*^{s} *Lsh*^{s}) and A/J (*Bcg*^{r} *Lsh*^{r}) were mated to the susceptible B10.A parent to produce backcross progeny. These were infected with BCG, and splenectomized 3 weeks later for *Bcg* typing. The animals were then infected with *L. donovani* after a further 3 weeks and the *Lsh* type was established in their livers[8]. Preliminary experiments confirmed that neither splenectomy nor previous infection with BCG influenced the *Lsh* typing. These manipulations did not change the susceptibility to *L. donovani* of B10.A control mice, nor did they change the resistance to *L. donovani* to (B.10.A × A)F_1 control mice. Of 26 [(B10.A × A)F_1) × B10.A] backcross animals, 12 were typed as resistant to BCG and 14 were typed as susceptible to BCG, consistent ($\chi^2 = 0.15$, $P > 0.7$) with the hypothesis that the trait of resistance to BCG is under monogenic, dominant control[5]. Furthermore, all 12 of the BCG-resistant backcross mice proved to be resistant to *L. donovani*, and all of the BCG-susceptible backcross mice proved to be susceptible to *L. donovani*. A similar experiment to establish the linkage of *Ity* with *Bcg* could not be done since splenectomy influenced the *Ity* typing: splenectomized mice of *Ity*^{r} strains became

r = Resistant; s = susceptible. *Bcg* typing performed on spleens 3 weeks after intravenous infection with 3×10^4 CFU BCG[5]. *Lsh* typing performed on livers 2 weeks after intravenous infection according to Bradley[8] and expressed as Leishman–Donovan units (LDU) per liver according to Actor[15]. An animal typed as *Bcg*^{r} (resistant) if the $\log_{10}$ BCG count in the spleen was <4.5 (2 s.d. above the mean BCG count of resistant (B10.A × A)F_1 controls, 95% confidence limit). An animal typed as *Lsh*^{r} (resistant) if the LDU in the liver was <46 (2 s.d. above the mean LDU count of resistant (B10.A × A)F_1 controls, 95% confidence limit). The LDU counts were generally somewhat lower and their range was greater in F_1 × B10.A backcross susceptible mice than in B10.A parents. Although the *Lsh* gene undoubtedly dominates the regulation of resistance to *L. donovani* these results suggest that other genes also have some effect in controlling the acute growth rate of this parasite. Same conclusion was already reached by Bradley[8].

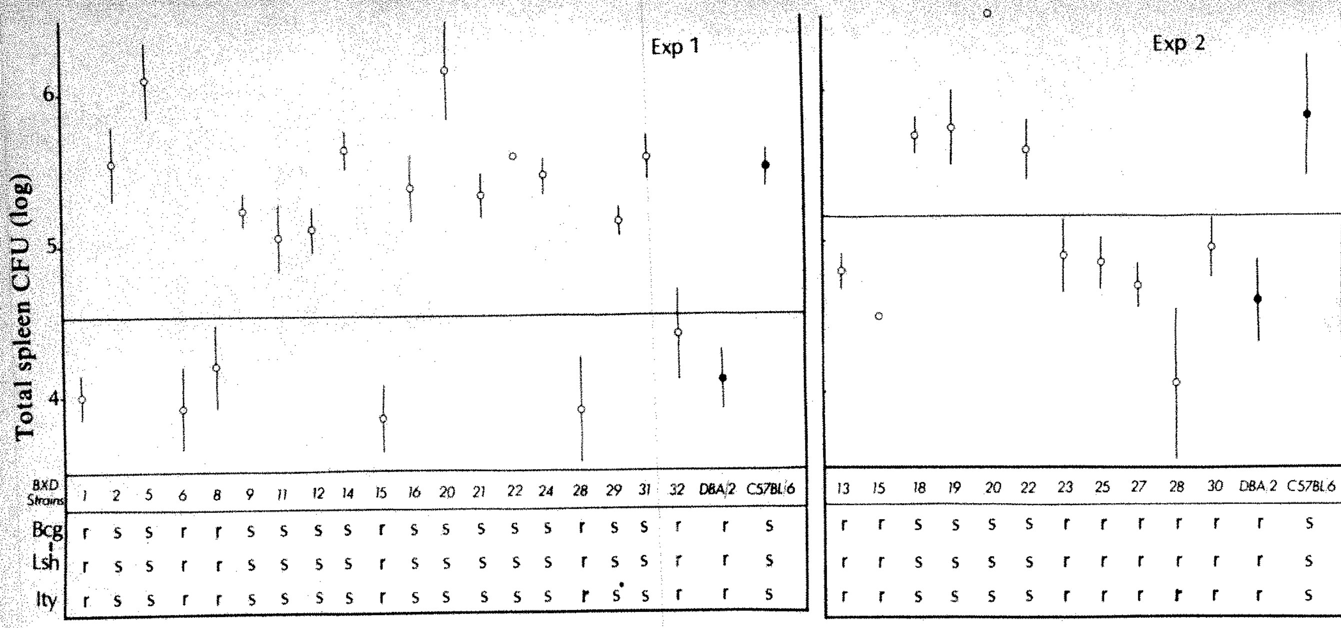

Fig. 1 Typing of BXD RI strains for resistance to BCG. Two to eight animals of each recombinant inbred strain and six animals of control DBA/2 and C57BL/6 strains were infected with 2–3 × 10^4 CFU BCG in two separate experiments. Geometric means ± s.d. of viable BCG in the spleens of infected animals were calculated 3 weeks after the infection. The horizontal line represents 95% confidence limit (two standard deviations above the mean of BCG numbers in the spleens of resistant DBA/2 progenitors) for typing of strains as *Bcg*^{r} (below the line) or *Bcg*^{s} (above the line). *Lsh* type of BXD strains was taken from Bradley *et al.*[2] except for BXD-28 and BXD-20. *Lsh*^{s} allele of these strains, identified by Plant *et al.*[4], was confirmed by us according to the criteria described in Table 2 (mean LDU 4,445 ± 57 got BXD-18 and 7,059 ± 1,066 for BXD-20, with values of LDU 116 ± 25 for *Lsh*^{r} control and 11,355 ± 2,455 for *Lsh*^{s} control in that particular experiment). *Ity* types of BXD strains were taken from O'Brien *et al.*[3] except for BXD-28 and BXD-29. Designation of *Ity* alleles of these two strains is taken from Plant *et al.*[4]. The *Ity*^{r} type of BXD-28 strains was confirmed according to the criteria described in Table 3, by typing (BXD-28 × B10.A)F_1 mice (7/7 animals survived the typing dose of 10^4 *Salmonella* i.v.). r, Resistant; s, susceptible.

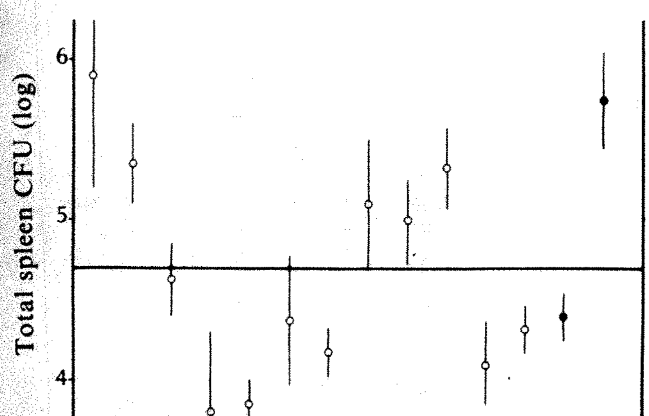

Fig. 2 Typing of BXH RI strains for resistance to BCG. Details as for Fig. 1, except for the resistant progenitor which in this case is C3H/HeJ. r, Resistant; s, susceptible; ?, some of the BXH strains were not *Ity* typed because of the interfering influence of the *Lps*^{d} mutation in the genome of C3H/HeJ progenitor; *, *Ity* type established by A. D. O'Brien (personal communication). Note that BXH-2 is designated as *Bcg*^{r} although phenotypically susceptible for BCG (see explanation in the text). BXH-10 is designated as *Lsh*^{s} according to the criteria described in Table 2 (mean LDU 990 ± 290), in variance with Bradley *et al.*[2]. *Ity*^{s} allele of BXH-10 strain was established by typing (BXH-10 × B10.A)F_1 mice, according to the criteria described in Table 3 (0/8 animals survived the typing dose of 10^4 *Salmonella* i.v.).

phenotypically susceptible to *S. typhimurium* infections. The reverse experiment (*Ity* typing first, with subsequent *Bcg* typing) also proved to be technically impossible. *Ity–Bcg* linkage was, therefore, established by progeny testing which eliminated the necessity of splenectomy and of double infection of an individual animal. Twenty-five randomly chosen males of the [(B10.A × A)F_1 × B10.A)] backcross generation were mated to *Bcg*^{s}–*Ity*^{s} females of B10.A strain. The resulting progeny were *Ity*-typed and the corresponding males of the parental generation were subsequently *Bcg*-typed. We reasoned that, if the *Bcg* and *Ity* genes were identical or closely linked, the offspring of BCG-susceptible (*Bcg*^{s}/*Bcg*^{s}, homozygous) backcross males mated with *Bcg*^{s}*Ity*^{s} females should breed true and all should type as *Salmonella*-susceptible (*Ity*^{s}/*Ity*^{s}, homozygotes). The offspring of BCG-resistant (*Bcg*^{r}/*Bcg*^{s}, heterozygous) backcross males and B10.A females should segregate between *Salmonella*-susceptible (*Ity*^{s}/*Ity*^{s}, homozygotes) and *Salmonella*-resistant (*Ity*^{r}/*Ity*^{s}, heterozygotes) progeny.

Due to a laboratory accident, eight of the backcross males (BC 18–BC 25) were lost before they could be *Bcg*-typed. Fortunately, two litters of their mating with B10.A females were available and the *Bcg* type of the males could, therefore, be deduced from *Bcg* typing of the litter. When the results of *Bcg* and *Ity* typing were matched, a *Bcg*^{r}–*Ity*^{r} or *Bcg*^{s}–*Ity*^{s} concordance was found among 24 out of 25 first backcross males. The only discordance, BC 22, (*Bcg*^{s}(?)–*Ity*^{r}) is inconclusive because the *Bcg* typing was based on only six progeny, and could have resulted from chance segregation ($P = 0.016$), even if the BC 22 male had been *Bcg*^{r}/*Bcg*^{s}.

Collectively, the data presented here clearly establish that *Bcg*, the gene controlling resistance to *Mycobacterium bovis* BCG, maps on chromosome 1 and that it is either identical to, or linked with, the gene(s) controlling resistance to *S. typhimurium* and *L. donovani*. Since no conclusive recombination between the *Bcg*, *Ity* and *Lsh* alleles was found by back-

cross analysis, and because of the full concordance of SDP of resistant and susceptible alleles of *Bcg*, *Ity* and *Lsh* among the total of 38 RI strains examined, these data suggest that the genetic control of resistance to *M. bovis* BCG, *S. typhimurium* and *L. donovani* is exerted by a single gene with pleiotropic effect. An alternative interpretation, that of a complex of closely-linked genes[3], seems less likely although it obviously cannot be ruled out completely. The fact that the susceptible allele is recessive, and that it is limited to a relatively few inbred strains, is more compatible with the possibility that the susceptibility gene might represent a mutation and be of a recent origin, rather than being a variant of a polymorphic gene that occurs in natural populations. That being the case, a single mutation from resistance to susceptibility would be more likely than the accumulation of three independent mutations to susceptibility genes (Bcg^s–Lsh^s–Ity^s) in coupling on the same chromosome.

The phenotypic expression of the gene in question is, so far, recognized *in vivo* only: in each case the resistant allele expresses itself as slow (or null) net growth rate of the particular microorganism in the liver or spleen[5,10,11] early in the course of infection, most probably before the specific immune response is established. It seems likely that the cellular expression of the resistant allele(s) is a bacteriostatic effect of the intracellular milieu of the parasitized macrophage[12], although no clear *in vitro* data are available as yet. The normal (resistant) allele might have other functions (either in macrophages or other cell types) but it would not be surprising if its chief function were the defence against intracellular parasites. Accordingly, the discovery of the mechanism by which this gene exerts its effect could reasonably be expected to shed considerable light on how macrophages help to control infections by organisms of medical significance. A consideration of common features (for example, biochemical or nutritional requirements for multiplication) of these three taxonomically distinct pathogens (*L. donovani*, *S. typhimurium* and *M. bovis*) could provide a starting point in this endeavour. We propose that natural resistance to other infections, such as tuberculosis and leprosy, to name but two, is also regulated by this gene. The biological implications of these findings for identification of genetically susceptible individuals and for the development of appropriate strategies for their protection and treatment are obvious.

This research was supported, in part by NIH contract N01-CB-84269, MRC grants 5389, 5448 and 6431 and grant GM18684 from the National Institute of General Medical Sciences. The Jackson Laboratory is fully accredited by the American Association for Accreditation of Laboratory Animal Care.

***Ity*, a gene controlling natural resistance to *Salmonella typhimurium* infection[1,2], and *Lsh*, which controls innate resistance to *Leishmania donovani* infection[3], are both located on chromosome 1 of the mouse[4,5] and it has been suggested[6] that they might be identical. O'Brien *et al.*[7] examined salmonella resistance in recombinant inbred (RI) strains of mice, and observed discordant responses in three strains (BXD-18, BXD-20, BXD-29) from one progenitor strain combination (C57BL/6J × DBA/2J) when compared with the published *Lsh* typing[5]. On the basis of this and additional information on salmonella resistance in (C57BL/6J × BXD-18)F$_1$ and [(C57BL/6J × DBA/2J) × BXD-29] backcross mice, it was concluded that *Ity* and *Lsh* are closely linked but distinct genetic loci. We have now re-examined both leishmania and salmonella resistance in larger numbers of these putative recombinant strains and in various hybrid and backcross generations, and our results indicate that BXD-18 and BXD-20 retype as *Lsh*^{s} and BXD-29 as *Ity*^{s}. Hence there is no longer any discordance between *Lsh* and *Ity* typings for the RI strains. The results do, however, suggest additional modifying genetic control of salmonella resistance in BXD strains involving at least two other genetic loci. There is therefore no clear evidence to demonstrate that *Ity* and *Lsh* are not the same genetic locus.**

Initially we examined leishmania and salmonella resistance in the three BXD strains thought to differ at *Lsh* and *Ity* and in an additional strain (BXD-28) found earlier[7] to be intermediate in its susceptibility to *S. typhimurium* TML strain. (The BXD mice used in our experiments were derived from stock sent by Dr Benjamin Taylor of the Jackson Laboratory.) Salmonella resistance was further examined in the progeny of BXD-29 mice mated with stock DBA/2, C57BL and (C57BL/10ScSn × DBA/2)F$_1$ mice kept at the Wright Fleming Institute at St Mary's Hospital Medical School, London. C57BL/10ScSn and CBA/Ca mice used as susceptible and resistant controls respectively for *Lsh* typing were obtained from Olac 1976 Ltd. Mice were typed individually for susceptibility to either *S. typhimurium* C5 or *L. donovani* infection as previously described[2,3]. In addition, (C57BL/6J × BXD-29)F$_1$ mice bred at the Jackson Laboratory were tested for resistance to *S. typhimurium* C5 (ref. 2) and TML (ref. 7) in the two laboratories.

Two BXD-18 and eight BXD-20 mice all typed as *Lsh*^{s} (Fig. 1). In each case, the original typing of *Lsh*^{r} by Bradley *et al.*[5] was based on examination of two mice whose parasite counts fell well within the *Lsh*^{r} range (Fig. 1, actual counts previously unpublished). This suggests that BXD-18 and BXD-20 had not proceeded to fixation for either allele at *Lsh* at that time. Our more recent *Lsh*^{s} typings are now consistent with the earlier[7] unequivocal *Ity*^{s} typings for BXD-18 and BXD-20 and thus eliminate two of the putative recombinants.

Lsh typing of eight BXD-28 and seven BXD-29 mice (Fig. 1) confirm the original typings (*Lsh*^{r} and *Lsh*^{s} respectively) of Bradley *et al.*[5]. In the case of BXD-28, the geometric mean spleen count of $4.61 + 0.98$ obtained after re-examining 20 mice with *S. typhimurium* C5 agrees closely with the mean of 4.46 obtained in the earlier[7] work with the TML strain of *S. typhimurium*. For BXD-29 mice, however, the geometric mean spleen count of $5.50 + 0.95$ based on examination of 34 mice with the C5 strain is significantly higher than the mean of 3.9 obtained after examination of only 5 mice with the TML strain, which led to the earlier[7] typing of BXD-29 as *Ity*^{r}. On the basis of our original criteria[4] for typing individual mice using 10^3 *S. typhimurium* C5 and day 10 organ counts, 22 of 34 BXD-29 mice with spleen and liver counts $>10^5$ type as *Ity*^{s}. The remainder were high in the *Ity*^{r} range with the geometric mean 2 logs higher than that for DBA/2 *Ity*^{r} controls. Our combined C5 and TML results (Fig. 2), which show 16 of 17 (C57BL/6J × BXD-29)F$_1$ and 26 of 28 (BXD-29 × C57BL)F$_1$ mice with spleen and liver counts clearly in the susceptible ($>10^5$) range, support the hypothesis that BXD-29 is, in fact, *Ity*^{s}. This would explain the previous finding[7] that 58% of BXD-29 mice tested died by day 30 when given only 25 organisms of the TML strain.

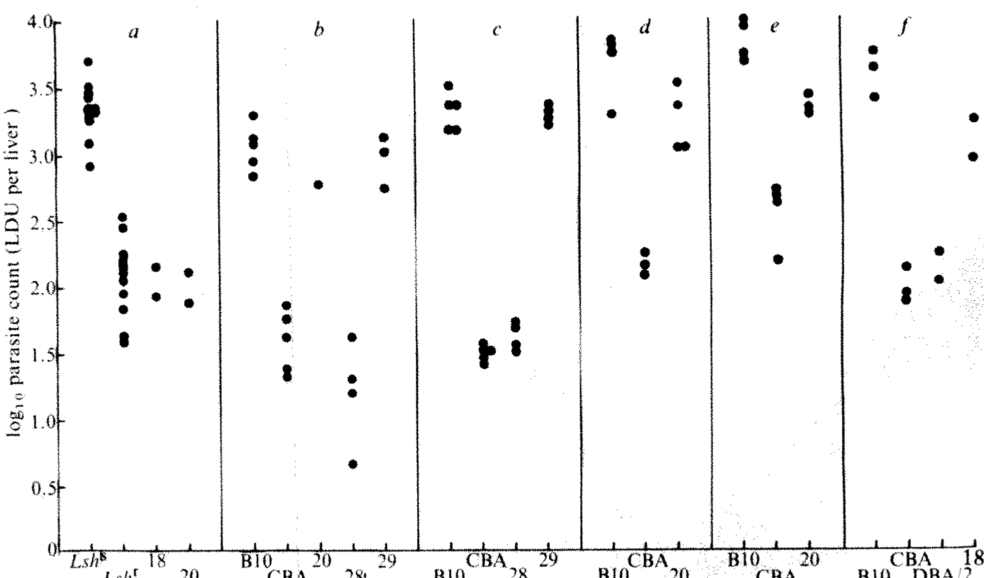

Fig. 1 *Lsh* typing experiments for RI (BXD-18, 20, 28, 29) and control *Lsh*^{s} (C57BL/10ScSn or B10) and *Lsh*^{r} (CBA/Ca and DBA/2) strains of mice. Mice were injected with $1-5 \times 10^7$ amastigotes of the L82 strain of *L. donovani* and examined 15 days later. The number of parasites per 500 liver cell nuclei was counted from Giemsa-stained impression smears and the results expressed as 'Leishman-Donovan units' (LDU) as described previously[12]. Counts for individual mice are shown for six separate typing experiments. *a* Shows actual counts for mice used in the original *Lsh* typing experiments of Bradley *et al.*[5]. Counts for BXD-18 and BXD-20 mice are compared with the range of *Lsh*^{s} and *Lsh*^{r} counts obtained for all BXD strains examined in that experiment. Both clearly fell well within the *Lsh*^{r} range of counts. *b–f* Show the results of our more recent typing experiments. Counts for BXD-28 and BXD-29 Mice (*b*, *c*) fell clearly within control *Lsh*^{r} and *Lsh*^{s} ranges respectively. Counts for BXD-18 and BXD-20 mice (*b*, *d–f*) always fell towards the lower end of the *Lsh*^{s} range of counts, irrespective of parasite dose. Although this difference was not always significant in individual experiments, it does suggest some additional modifying genetic control of *Lsh*^{s} counts. B10, BXD-18 and BXD-20 counts all differed significantly from control *Lsh*^{r} counts ($P < 0.001$) and, in each experiment, there was at least a 0.5 log$_{10}$ LDU separation between the lowest susceptible and highest resistant counts. The retyping of BXD-18 and BXD-20 as *Lsh*^{s} has recently been confirmed in another laboratory[10] where parasite counts again fell at the lower end of the susceptible range of counts.

0028-0836/82/230510-02$01.00

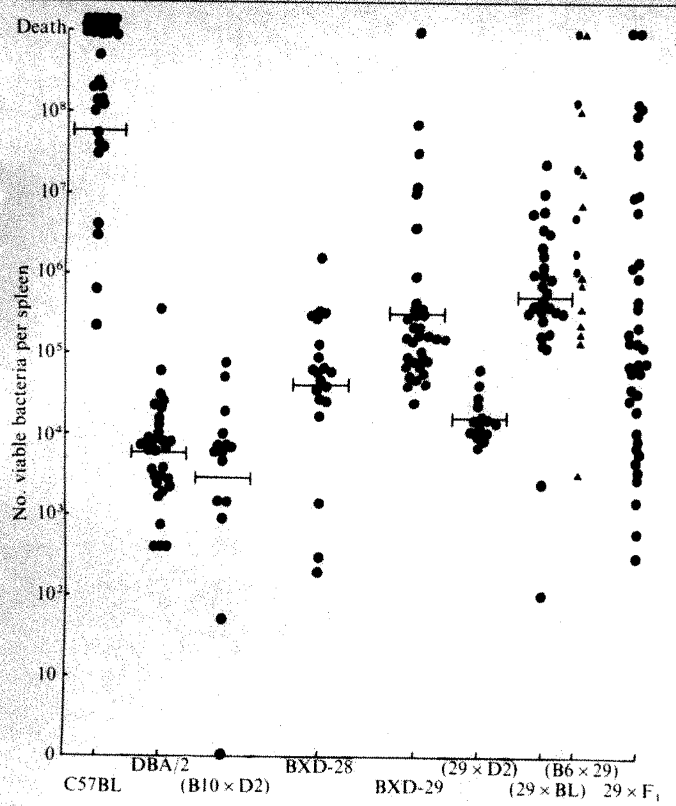

Fig. 2 *Ity* typing experiments for RI (BXD-28, 29) strains and the F_1 hybrid combinations: (C57BL/10ScSn × DBA/2) or (B10 × D2); (BXD-29 × DBA/2) or (29 × D2); (BXD-29 × C57BL) or (29 × BL); (C57BL/6J × BXD-29) or (B6 × 29); and [BXD-29 × (C57BL/10ScSn × DBA/2)F_1] or (29 × F_1). Mice were injected subcutaneously with 10^3 *S. typhimurium* strain C5 (●) or TML (▲) and examined 10 or 9 days later respectively. Viable bacteria in spleens and livers were estimated as previously described[2,4,7]. Bacterial loads in the livers agreed closely with the viable bacterial counts per spleen shown for individual mice. Dead mice were estimated at 10^8 bacteria per spleen in calculating the $\log_{10}$ geometric mean spleen counts indicated for each group. The RI strains and hybrids are compared with control Ity^s (C57BL) and Ity^r (DBA/2) strains.

A range of sensitivity from highly susceptible (10^7–10^8 counts or death by day 10) through intermediate (10^5–10^6) to highly resistant (10^2–10^4) was observed in [BXD-29 × (C57BL/10ScSn × DBA/2)F_1] backcross mice (Fig. 2). This implies multigenic control additional to *Ity*. The possibility of additional genetic influence on the sensitivity to *S. typhimurium* infection in the intermediate BXD strains has already been considered[7] and is consistent with the previous observations[1,8,9] of increased susceptibility in the Ity^r DBA/2 progenitor strain compared with other Ity^r strains. A single additional gene bearing susceptible alleles in the DBA/2 progenitor and resistant alleles in the C57BL/6 progenitor is insufficient, however, to explain the present results. We propose, therefore, that at least two other genes are involved in modifying the phenotypic expression of *Ity* in the BXD intermediate strains.

We therefore conclude that it is not proved that *Ity* and *Lsh* are distinct genetic loci. The fact that no recombinants were detected among 22 RI strains from 4 other progenitor strain combinations[7] supports our hypothesis that the progenitors of BXD are introducing additional genetic influence on the outcome of salmonella infections. The recent finding[10] that *Bcg*, a gene controlling innate resistance to *Mycobacterium bovis* infection in mice,[11] types in concordance with the present *Lsh* and *Ity* typings for the BXD strains also supports our conclusions. We therefore favour the hypothesis that a single gene on chromosome 1 controls innate resistance and susceptibility to these three, and possibly other, intracellular infections via one mechanism, rather than a complex of tightly linked genes.

We thank Jane Ferguson and Orysia Ulczak for assistance in the laboratory, Ben Taylor for supplying the RI strains and the Wellcome Trust for financing trans-Atlantic discussion. The work was supported by grants from the MRC, the Wellcome Foundation and the Uniformed Services University of the Health Sciences.

Recognition of conformational determinants on H–2 by cytolytic T lymphocytes

Linda A. Sherman

Department of Immunopathology, Scripps Clinic & Research Foundation, La Jolla, California 92037, USA

The specificity of cytolytic T lymphocytes (CTL) differs from that of B lymphocytes insofar as they exhibit a marked preference for recognition of major histocompatibility complex (MHC) encoded cell surface antigens. In murine systems, this is reflected both in the high frequency of CTL which recognize H–2 alloantigens[1–5] and also in the requirement for recognition of syngeneic H–2 antigens in conjunction with cellularly presented foreign antigens, so called MHC restricted recognition[6–10]. Various models for T-cell recognition have been proposed in an attempt to explain both this predisposition for MHC recognition and the basis for restricted recognition (reviewed in refs 10, 11). Most models have fallen into one of two general categories; those which attribute recognition to two independent combining sites on the T cell receptor(s), one specific for foreign antigens and one specific for MHC antigens; and those which accommodate recognition of both molecules using a single combining site which recognizes a neoantigenic determinant composed of a complex of both molecules. In order to understand the basis for determinant recognition, the specificity of individual clones of C57BL/6 CTL induced in response to a point mutation in the H–2K^b molecule has been analysed. Using a series of H–2K^b mutants as targets it was found that a single clone can recognize two or more mutants which, although different from each other with respect to the position of their amino acid substitutions, appear to have independently gained the same new determinant. This strongly suggests that CTL can respond to conformational nuances in self H–2 molecules as shared by these different K^b mutants. On this basis, it is proposed that MHC restricted recognition may represent the recognition of conformational alterations of self resulting from the interaction of MHC molecules and foreign antigens.

In order to approach questions concerning T-cell recognition, this laboratory has carried out a detailed analysis of the recognition of H–2 antigens by individual CTL clones[12–15]. Most revealing in terms of probing the basis for determinant recognition have been the results of fine specificity analysis of monoclonal CTL stimulated as a result of a single amino acid substitution in the H–2K^b molecule, the B6.C–H–2^{bm11} anti-C57BL/6 response (bm11 anti-B6)[13]. A large proportion (25%) of such clones did not recognize any of the five different H–2K^b mutants which were used as targets. Considering that each of these mutants differed from the stimulating K^b molecule by only one

or two amino acid substitutions, and that in most cases each mutation occurred at different positions on the molecule[16], it is unlikely that all of these different mutations could have resulted in an amino acid substitution in the particular determinant recognized by a single clone. A more likely explanation for such lack of recognition would be that, in some if not all mutants, these particular wild-type determinants have been lost due to conformational changes resulting from the mutation[17,18]. In the case of antibody recognition of globular proteins, such a mechanism has previously been used to explain how the antigenic integrity of a particular determinant can be disrupted by a distal amino acid substitution[19].

This suggests the possibility that a conformational alteration might also create new determinants which were, by analogy, in positions on the molecule different from the site of the amino acid substitution responsible for their creation. In support of this possibility, Melief and co-workers previously demonstrated that, although B6-anti-mutant CTL populations would most strongly react against the K^b mutant used as stimulator these CTL demonstrated detectable cross-reactivity on a variety of disparate K^b mutants[18]. This suggested different K^b mutants may have gained some similar determinants. A possible mechanism would be that each mutation creates its own set of conformational differences in the K^b molecule and that amino acid substitutions in different parts of the molecule could independently effect a conformational change which, fortuitously, resulted in a similar determinant.

The experiments described in this report constitute a test of this hypothesis. CTL clones of wild-type origin were stimulated in primary limiting dilution cultures against the bm11 mutant. It was reasoned that the wild-type responder would be tolerant of all K^b determinants retained by the bm11 mutant and, therefore, such clones should specifically recognize new determinants attributable to the bm11 mutation. Each clone was tested for cross-reactive recognition on a panel of targets which included the wild type B6, six other K^b mutants, and the allogeneic D2.GD target (K^d, D^b). Where known, the positions of the amino acid substitutions in each of these mutants is as follows: bm1, 155, and 156; bm3, 77 and 89; bm8, 23; bm9, 116 and 121; bm10, 165; and bm11, 77 (ref. 16).

Results obtained from panel analysis of 58 B6-anti-bm11 clones independently derived from 11 individual B6 responders are presented in Table 1. Positive recognition refers to cross-reactive lysis which represents at least 60% of the value obtained on the bm11 target as indicated in the legend to Table 1. As expected, none of the B6 clones demonstrated specific recognition of the syngeneic B6 targets. Also, as expected on the basis of a shared mutation at amino acid position 77, the vast majority of bm11 specific clones (83%) also recognized the bm3 target. It is likely that the antigenic determinants recognized by the 17% which did not recognize bm3 are obscured or disrupted on the bm3 molecule as a result of the second mutation at position 89. Most interesting, however, is the observation that the majority of clones (62%) recognized not only targets which bear the mutation in position 77, but also recognize at least one of the other K^b mutants such as bm8, bm1 and bm9 which are identical to the wild type K^b in position 77, having their substitutions elsewhere. Moreover, of these 26 clones, 24% recognize at least two such H-2K^b mutants.

In Table 2, these data are presented as the fraction of clones that recognize each of these targets. The fraction of clones that cross-react on the third-party alloantigen, K^d on D2.GD, is comparable to the level of third-party reactivity usually seen in conventional allogeneic responses[3-5] (5–10%). In contrast, some of the mutants, bm8, bm1, bm9, are recognized by a significantly greater proportion of clones than is usual for third party recognition. Based on these results, it may be concluded that different and often distal amino acid substitutions in an H-2 molecule can fortuitously result in antigenic determinants which if not identical, are at least similar enough to permit comparable T-cell recognition as reflected in the comparable degree of lysis of different mutant targets.

In view of the disparate positions of most of these mutations, it would appear unlikely that two different mutants could demonstrate significant cross-reactivity on the basis of a common 'foreign' determinant. The only candidates for a non-self antigen as perceived by the strain of origin would be determinants that encompass the substituted residues and it is unlikely these are cross-reactive since they would correspond to a different position on the molecule for each mutant. Therefore, these results strongly support the hypothesis proposed above, that conformational alterations of self H-2 antigens can result in immunogenic determinants which do not include the

B6 splenic CTL precursors were stimulated *in vitro* under limiting dilution culture conditions in V bottom microtitre wells containing 5×10^5 irradiated B6 'helper' spleen cells, 5×10^6 irradiated bm11 stimulator cells, and varying numbers (1,000–6,000) of B6 responder cells in 0.2 ml of culture media as previously described[12]. After 6 days in culture, a 60 μl portion of each well was tested for cytolytic activity against conA stimulated bm11 targets. Such target cells were prepared and labelled with ^{125}I-iododeoxyuridine[12] and 1×10^4 cells were added to each well in 140 μl of culture media containing 10% fetal bovine serum and 3% rat-T-cell growth factor which was a necessary addition to maintain maximum viability of these target cells during long assays (18–20 h). CTL clones obtained using responder cell numbers resulting in 20% or fewer positive wells were expanded[12] and tested for lytic activity against ^{51}Cr-labelled bm11 target cells. Successfully expanded clones were assayed in duplicate on each of the indicated target cells. A clone was considered positive or negative for recognition of a particular target if its value for lysis was either >60% or <25% respectively of its value for lysis on bm11 targets. Clones which did not meet these criteria on all targets were considered ambiguous and not recorded above.

amino acid substitution responsible for the alteration.

Based on these results, it is further proposed that the interaction of foreign antigens with H–2 encoded molecules can similarly result in conformational changes which may be immunogenic. A similar hypothesis has recently been proposed by Ohno[20]. In order to conform with our views of restricted recognition, such interaction would need to fulfil the following requirements: (1) the same antigen should always result in the same conformation change in H–2, and (2) this interaction should be sufficiently stable to permit binding and triggering of T receptors that recognize the resultant novel H–2 conformation. It would then be possible to explain the appearance of antigen specificity and MHC restriction even though the receptor actually recognized 'altered self' and not antigen.

There are several observations which are consistent with such a model. First, there is much evidence for stability of H–2 antigen interactions as measured either by co-capping or co-purification of these two molecules[21–25]. Second, it has proven much easier to block antigen specific CTL or MLC using anti-H-2 antibody reagents as opposed to using antibody specific for the foreign antigen *per se*[26–29]. This is most consistent with an indirect role for antigen in receptor recognition. Third, it has been reported by several laboratories that influenza specific CTL are more cross-reactive than influenza specific antibody[30–32]. This is again most readily accommodated by a model which predicts that only some foreign determinants potentially contribute to the specificity of a CTL response, in particular, those which effect the interaction between H–2 and the foreign molecule. Finally, this model presents a structural basis for the well documented cross-reactivity against allo-antigen of antigen specific T cells, since both types of recognition would involve altered-self MHC determinants[33–36].

The implication of this hypothesis which may be most difficult to accept is the burden placed upon the H–2 molecule by the fact that the diversity of all possible H–2 determinants would have to be sufficient to account for antigen specificity. However, if the low frequency of CTL precursors specific for non-MHC antigens, such as virus and minor antigens[5,37], reflects a correspondingly small number of different determinants created by an antigen H–2 interaction, then the chances that a second antigen would create the same determinants may be relatively slim. In contrast, in essentially all responses where the H–2 antigen is itself structurally altered, many new determinants are created, thereby greatly increasing the likelihood of cross reactivity. This would account for the observation presented in this report.

These studies were supported by NIH grant nos AI 15710 and CA 25803.

Cytogenetic mapping of the duplicated segment of chromosome 12 in lymphoproliferative disorders

G. Gahrton*†, K.-H. Robert*, K. Friberg†, G. Juliusson*, P. Biberfeld† & L. Zech†

* Section of Clinical Hematology and Oncology, Department of Medicine, Huddinge Hospital, S-14186 Huddinge, Sweden
† Institute of Medical Cell Genetics, Medical Nobel Institute and Department of Pathology, Karolinska Institute, S-10401, Stockholm, Sweden

Recently, an extra chromosome 12 has been reported to occur with high frequency in peripheral blood lymphocytes from patients with chronic B-cell lymphocytic leukaemia (B-CLL)[1,2]. Here we report a unique chromosomal abnormality, which suggests that the segment q13 to q22 on chromosome 12 carries the important genes that are duplicated in those lymphoproliferative disorders characterized by trisomy for this chromosome.

Cytogenetic studies were performed on peripheral blood lymphocytes, bone marrow cells and spleen cells from a 56 year-old man with a lymphocytic non-Hodgkin lymphoma. The lymphoma was found in the spleen, bone marrow, and peripheral blood. The white blood cell count was 9.3×10^9 per litre and a differential count showed that 74% of the cells were lymphocytes. Surface membrane immunofluorescence studies revealed a monoclonal B-cell proliferation with a phenotype $\mu\kappa$ when tested with fluorescein-conjugated $F(ab')_2$ fragments of goat anti-human μ, γ, δ, κ, and λ antisera. Microscopy of the spleen and small lymph nodes showed a mixed lymphocytic–histiocytic lymphoma (Rappaport classification[3]) or polymorphic immunocytoma (Kiel classification[4]).

Table 1 Metaphase analysis of lymphocytes from a patient with chronic B-cell lymphocytic leukaemia

Material	Mitogen	No. of metaphases analysed	No. of abnormal metaphases	Karyotype
Peripheral blood	EBV	17	2	46XY;
	LPS	11	3	46XY, t(10;10)
	PHA	21	1	(pter; q24),
Bone marrow	EBV	6	2	dup(12)
Spleen	EBV	5	4	(q13—q22)
	LPS	3	1	
Total		63	13	

0028-0836/82/230513—02$01.00

Mitogenic stimulation of isolated peripheral blood lymphocytes was performed with Epstein–Barr virus (EBV), lipopolysaccharide (LPS) from *Escherichia coli*, and phytohaemagglutinin (PHA)[1]. Cultures for cytogenetic analysis were collected on day 4. Metaphase preparations were prepared by conventional methods and the preparations stained according to the Q-banding technique[5]. The results of the cytogenetic analyses are shown in Fig. 1 and Table 1. Of 63 metaphases, 13 had the same chromosomal abnormality. One chromosome 12 had an extra part attached at band 22, which was identical with the part q13 → qter of a normal chromosome 12. The other chromosome 12 was normal. Thus, the region q13 → q22 was duplicated. In addition to this abnormality, a balanced reciprocal translocation between the two chromosomes 10 was found in all metaphases carrying the abnormal chromosome 12.

As shown in Fig. 2, the observed abnormality of chromosome 12 has probably arisen through chromatid exchange. It is probable that a breakpoint occurred on one chromatid of one chromosome 12 at q13 and another breakpoint on the other chromosome 12 at q22. The two chromatids were then exchanged. Alternatively, there may have been three breakpoints, two on one chromatid of one chromosome 12 at q13 and q22, and one on q13 or q22 on one chromatid of the other chromosome 12. The chromatid part, q13—q22, on the first chromosome was then inserted at the breakpoint of the second chromosone 12. Of the possible abnormal karyotypes that can appear, irrespective of the mechanism, only alternative *b* in Fig. 2 was found. Normal karyotypes were also found, but these were probably due to the presence of normal nonmalignant lymphocytes in the peripheral blood[1].

The results show that the essential genes that tend to be duplicated during leukaemogenesis leading to lymphoproliferative B-cell disorders characterized by trisomy of chromosome 12, are probably located on the seqment q13 → q22.

Other experimental work on murine lymphomas has also indicated that only part of a trisomic chromosome is crucial for the neoplastic transformation[6]. Mouse T-cell lymphomas are characterized by triosmy 15, but only genes located distal to band T6 are important for leukaemogenesis. Furthermore, in certain human myeloproliferative disorders characterized by trisomy of chromosome 1, there are indications that only the segments q23—q25[7,8] or q25—q32[9] are associated with disease. Thus, in lymphoproliferative disorders (and probably also other haematopoietic diseases) characterized by trisomic chromosomes, the important genes to be duplicated for disease development are probably located on a very small, specific part of the chromosome. In human lymphoproliferative disorders characterized by trisomy 12, these genes seem to be located on the segment q13—q22. So far mapping of chromosome 12 has only located the loci for a few enzymes and antigens to the long arm of this chromosome, that is mitochondrial synthetase, serine hydroxymethyltransferase, branched-chain amino acid transferase-1, and surface antigen 8 (ref. 10). Further studies of these enzymes in lymphoproliferative B-cell disorders may elucidate whether any part of the q13—q22 region on chromosome 12 is also involved in patients where no gross cytogenetic abnormalities are found.

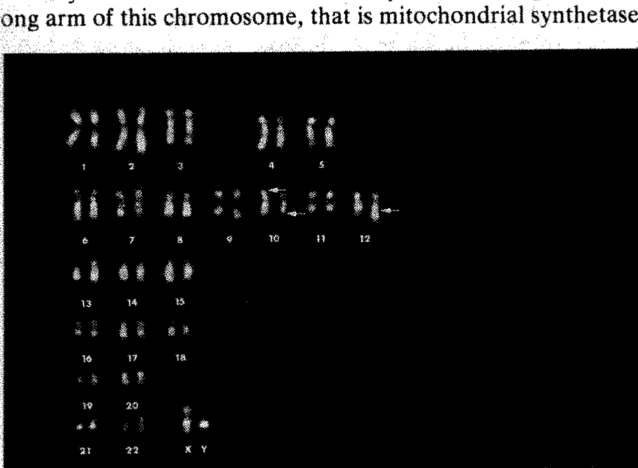

Fig. 1 Karyotype of a peripheral blood lymphocyte stimulated by EBV, showing duplication of the seqment q13–q22 on chromosome 12. There is also a reciprocal balanced translocation between the two chromosomes 10.

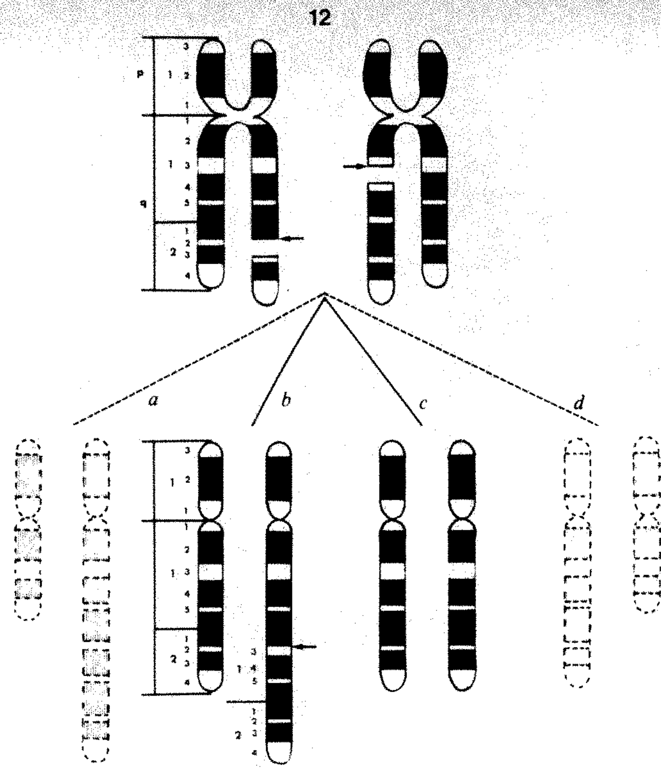

Fig. 2 Possible mechanism of development of the chromosomal abnormality. Only alternatives *b* and *c* were found.

Two distinct forms of surface antigen gene rearrangement in *Trypanosoma brucei*

Phelix A. O. Majiwa, John R. Young, Paul T. Englund*, Stuart Z. Shapiro & Richard O. Williams

International Laboratory for Research on Animal Diseases, PO Box 30709, Nairobi, Kenya.

African trypanosomes express different surface antigens sequentially in their mammalian hosts[1]. Expression of different variable surface glycoprotein (VSG) antigens is associated with rearrangements of genomic DNA[2-5]. Several laboratories have reported that expression of some VSG genes is accompanied by the appearance of a duplicated copy of the genes at a new location in the genome[3,4]. However, in a series of sequentially related *Trypanosoma brucei* clones from a different stock we were unable to detect duplication of one VSG gene (ILTAT 1.2, B) in expressing clones. Two copies of this gene were found

in expressing and non-expressing clones. Apparent insertions and deletions occurred near the 3′ ends of both gene copies, but could not be correlated with expression[2,5,6]. We report here the observation of both types of rearrangement for different VSG genes in the same series of trypanosome clones. Thus the different types of rearrangement are not a function of different trypanosome stocks, but of different VSG genes within a stock.

The trypanosome clones used in this study were derived from a single clone (clone A, expressing VSG A) from *T. brucei* stock 227 (ref. 7). Clone B was derived from a relapse infection of clone A and clones C and D were cloned from the first-relapse populations in normal mice infected with clone B. Trypanosomes grown in lethally irradiated rats were checked by immunofluorescence for homogeneity of VSG expression[7] before isolation of RNA or DNA.

The construction and identification of plasmids pcBB1 and pcBC1 containing mRNA sequences encoding VSGs B (ILTAT 1.2) and C (ILTAT 1.3), respectively, have been described elsewhere[8]. Plasmid pcBA1 was constructed and initially identified in a similar manner. That pcBA1 contains VSG A coding sequences is substantiated by two further criteria: it contains 3′-coding and non-coding sequence homologies with other VSG mRNAs[9], and hybridizes to RNA found only in trypanosome clone A. This is shown in Fig. 1, where pcBA1 was hybridized to total RNA from trypanosome clones expressing VSGs A, B, C and D (ILTAT 1.4). The inserted sequences of pcBA1 are present only in the trypanosome clone expressing VSG A. The only known clone-specific mRNA is that encoding the VSG expressed[10]. In addition to the major band at 2 kilobases (kb), the expected size of mature VSG mRNA, pcBA1 also hybridizes to three faint bands of 3.2, 3.6 and 4 kb, in clone A RNA only. As electrophoresis was done in stronger denaturing conditions[11], these bands may represent incompletely processed precursors of the VSG A mRNA. Such precursor RNAs have not been described previously for other VSGs.

The experiment shown in Fig. 2 characterizes the rearrangements affecting the genes for VSGs A, B, and C. Complementary DNA sequences encoding each of the VSGs

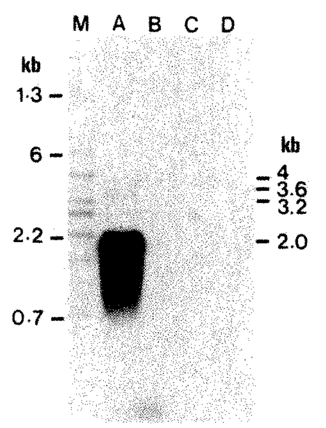

Fig. 1 Clone specificity of the cDNA sequence in pcBA1. Total RNA from four trypanosome populations homogeneously expressing different VSGs (A, B, C and D) was prepared by dissolving 10^{10} trypanosomes in 10 ml of 60% guanidinium thiocyanate, 50 mM sodium citrate *p*H 7.0, 0.5% sarcosyl. This was layered over 1.5 ml cushions of 5.7 M caesium chloride containing 50 mM EDTA *p*H 7.5, and centrifuged at 30,000 r.p.m. for 6 h in a Bechman SW 50.1 rotor. DNA remained at the interface and RNA was recovered from the pellet after careful removal of the supernatant and cushion; ~2.5 μg from each clone was denatured with glyoxal, electrophoresed, transferred to nitrocellulose, and hybridized with radioactive pcBA1 as described by Thomas[11]. The filter was washed twice in 0.1×SSC, 0.1% SDS at 50 °C for 15 min before autoradiography. The mRNA band was deliberately over-exposed to show the complete specificity of hybridization at this stringency, and to reveal the three faint high molecular weight bands in clone A. Molecular weight markers are shown under column M.

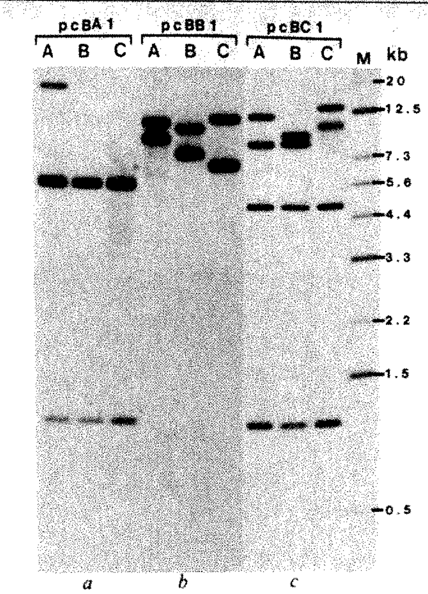

Fig. 2 Comparison of rearrangements affecting the genes for VSGs A (ILTAT 1.1), B (ILTAT 1.2) and C (ILTAT 1.3). DNA from trypanosome clones expressing each of these VSGs was digested with *Hin*cII (for hybridization to pcBA1 and to pcBC1) and *Sal*I (for hybridization to pcBB1). These enzymes do not have cleavage sites in the cDNAs to which their digests were hybridized. Fragments were separated by electrophoresis on a single gel and transferred to nitrocellulose in 20×SSC as described elsewhere[14]. Cut sections of the filter were hybridized, in conditions described elsewhere[14], to plasmids pcBA1 (*a*), pcBB1 (*b*) and 1,100-bp 5′ fragment of pcBC1 (*c*), which had been labelled with ^{32}P by the procedure of Rigby *et al.*[15]. The markers (M) are fragments of known size which hybridize to pBR322 sequences in the pcBC1 probe. The filter sections were washed twice in 0.1×SSC, 0.1% SDS at 65 °C for 1 h, dried, and then realigned for exposure to X-ray film.

were hybridized to DNA from trypanosome clones expressing the three antigens. The enzyme used in each case did not cut the cDNA sequence of the VSG probe used. Thus, if there are no introns in the gene, each hybridizing band visualized implies a distinct region that is homologous with the probe.

For pcBA1, hybridizing fragments were identical in size in each clone except for the presence of an extra, larger fragment in DNA from clone A. A different result was seen for the other two probes. There was no additional fragment in the DNA from the cell clones expressing VSG B or C, as there was neither an extra band nor an increase in relative intensity of any band. Although the number of fragments hybridizing to each cDNA was the same for all trypanosome clones, there were large differences in the sizes of two of the hybridizing fragments, even when DNA from two non-expressing clones was compared.

Gene rearrangements were observed for all three cDNAs studied. Where an extra gene fragment was detected in the clone expressing the VSG encoded by the probe sequence (A), the remaining copies of the gene did not undergo rearrangements in different clones (Fig. 2). These characteristics of the VSG A gene rearrangement parallel observations by others using different VSG genes which are duplicated and transposed when expressed[3,4].

The experiment shown in Fig. 3*a*, using another enzyme that does not cut the cDNA, also demonstrates an extra fragment hybridizing to pcBA1 in clone A. This fragment hybridizes strongly to probe fragments from either end of the cDNA, indicating that it contains both ends of the cDNA sequence.

For other VSG genes which are duplicated and transposed when expressed, the duplicated segment extends from a point within the 3′ end of the mRNA sequence to a point beyond its 5′ end[12]. When enzymes cutting inside a transposed segment were used to observe duplicated genes, single bands were visualized with increased intensity. For VSG A, this was demonstrated

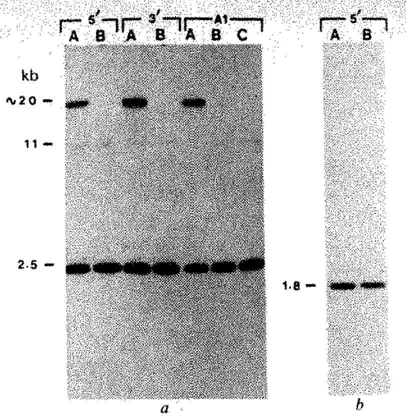

Fig. 3 Confirmation that the extra fragment hybridizing to pcBA1 contains intact most of the VSG A mRNA sequence. *a*, Hybridization of 5' and 3' fragments of pcBA1 to *Eco*RI digests of DNA from trypanosome clones expressing (A) and not expressing (B, C) VSG A, compared with hybridization of the whole cDNA. The 5' fragment contains 150 base pairs (bp) of the 900-bp cDNA sequence; the 3' fragment contains 380-bp, and includes part of the poly(A) tail. Both ends of the cDNA sequence are detected in the extra *Eco*RI fragment in clone A. *b*, Hybridization of the same 5' probe to *Pvu*II-digested DNA from clones A and B. The same *Pvu*II fragment, which contains most of the VSG A mRNA sequence, is produced from the extra copy unique to clone A and the copy present in non-expressing clone. Restriction enzyme fragments of pcBA1 were isolated by the procedure of Maxam and Gilbert[16]. Labelling of probes, electrophoresis and filter hybridization are described in Fig. 2 legend.

with enzyme *Pvu*II, (Fig. 3*b*). In clone A, an increase in intensity was observed in a 1.8-kb enzyme fragment, which was produced by the *Pvu*II site in the cDNA and another 1.8 kb towards the 5' end of the mRNA. Thus we suggest that the duplicated copy of the VSG A coding sequence is an intact copy of the cDNA sequence. It is reasonable to conclude that we are observing the same kind of duplication–transposition event as reported for other VSG genes.

Figure 4 shows that there are sequence differences between the basic copy and the duplicated extra copy of the clone A gene. We know from the published sequence of the clone A cDNA[9] that the coding sequence for the A antigen is not cut by *Bam*HI. As seen in Fig. 4, the extra copy of the clone A gene was not cut, whereas the basic copy in all cell clones was cut by this enzyme. A comparison of the cDNA sequence with the basic copy sequence showed that a point mutation has occurred at base position 1,700, resulting in the loss of a *Bam*HI site in the cDNA and therefore presumably in the duplicated extra copy of clone A (see ref. 13).

In previous descriptions of this type of gene rearrangement for the VSG B genes[2,5,6], we suggested that the differences between our observations with this gene, and those of others

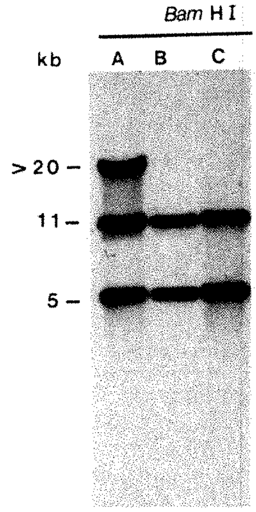

Fig. 4 Restriction enzyme site difference between the extra fragment and the basic copy of the clone A gene. pcBA1 was hybridized with *Bam*HI digests of DNA from expressing (A) and non-expressing (B, C) trypanosome clones. The probe recognizes two fragments (11 and 5 kb) in all clones and a fragment >20 kb in the expressing clone alone. When used as probes, the fragments from extreme ends of the cDNA (as in Fig. 3) show that the 11 and 5 kb fragments are respectively 5' and 3' portions of the basic copy (data not shown). This indicates the presence in the basic copy of a *Bam*HI site which is absent from both the cDNA and the additional, larger fragment unique to the expressor.

with other VSG genes, might be due to the use of different trypanosome stocks. This explanation cannot hold, as both types of gene rearrangement affect different VSG genes expressed within one sequentially derived series of trypanosome clones. It is evident that the 'expression-linked copy' model for VSG gene expression, as proposed by workers who observed extra copies of VSG genes in expressed states[3,4,12], does not describe the expression of the VSGs B and C in this series of trypanosome clones. Therefore, there must be some other mechanism controlling expression of these genes.

VSGs B and C are frequently expressed in relapse populations in animals infected with other ILTAR 1 clones (J. J. Doyle, personal communication), whereas VSG A is only rarely observed in relapse populations. This difference in VSG expression may be related to the different types of nuclear DNA rearrangements described here.

We thank Dr J. J. Doyle for providing trypanosome clones, Dr G. Matthyssens for critical reading of the manuscript and Ms Catherine Munyua for typing.

Post-translational modification of tubulin dependent on organelle assembly

Karen J. Brunke, Philip S. Collis & Donald P. Weeks

The Institute for Cancer Research, The Fox Chase Center, Philadelphia, Pennsylvania 19111, USA

Microtubules are involved in a wide variety of cellular functions[1–3] and are major components of many subcellular structures (for example, the centriole, mitotic spindle, cytoskeleton and flagellar apparatus). The ability of microtubules to serve in such a diversity of functions may be accounted for, at least in part, by heterogeneity in the constituent types of α- and β-tubulin subunits[4–10] in different microtubules. Higher eukaryotes generally possess several tubulin genes and this may account for part of the heterogeneity of tubulin subunits[11–13]. However, the unicellular eukaryote, *Chlamydomonas reinhardii*, has only two α- and two β-tubulin genes[14–16], which suggests that some of the variation in tubulin subunits seen in this organism[5,8] may arise as a result of post-translational modification. This notion is supported by the experiments of Lefebvre *et al.*[8] who compared flagellar tubulins with those produced by *in vitro* translation of tubulin mRNAs. Here we show that a form of α-tubulin subunit apparently confined to the *Chlamydomonas* cell body is converted, post-translationally, into a flagellar form of α-tubulin and that this modification is dependent on flagellar assembly. We discuss possible mechanisms for these modifications and their implications for the generation of unique types of microtubules having specialized functions within the cell.

0028-0836/82/230516—03$01.00

When flagella are removed from *Chlamydomonas* gametes, the regeneration of a new set of flagella begins after ~10–12 min[17]. The initial rate of outgrowth is quite rapid[17] (~0.5 μm min^{-1}) but diminishes exponentially as the flagella lengthen. The new flagella approach their final length by ~90 min. During flagellar outgrowth, the synthesis of tubulin, the major structural protein of the flagellum, is rapidly induced[14,18,19]. Our studies have demonstrated that the synthesis of α- and β-tubulin subunits begins in less than 10 min after deflagellation and then rapidly increases to maximal rates in ~30–40 min. The autoradiograph shown in Fig. 1 illustrates this; it also reveals that in the SDS-polyacrylamide gels chosen for these experiments, the α-tubulin subunits produced from 10 to 90 min after flagellar excision can be resolved into two discrete bands. We have designated the upper band as α_f as it co-migrates with the predominant species of α-tubulin in the flagellum (see track 8 and also Fig. 2). The lower band co-migrates with the α-tubulin subunit species found exclusively in the cell body (see Fig. 2). Production of the α_f tubulin subunit is detectable neither during the first 10 min after flagellar removal nor beyond the time (~90 min) when flagellar outgrowth has been completed. The fact that α_f does not accumulate in the body of the cell and is produced exclusively during the period of flagellar assembly suggests that a portion of the newly synthesized α-tubulin subunits is converted to a modified form in a process associated with flagellar outgrowth. The results of the following experiments support this conclusion.

If mRNA is isolated from cells 45 min after deflagellation, when the production of α_f is at its peak (Fig. 1), and then translated in the wheat germ *in vitro* translation system[18], an α-tubulin polypeptide is produced which co-migrates with the α-tubulin of the cell body (Fig. 2a, lanes 4 and 7). There is no detectable synthesis of a polypeptide having the same electrophoretic properties as α_f (Fig. 2, lane 4 compared with lanes 3 and 5). These results suggest that either a mRNA encoding α_f exists but is not translatable *in vitro* or all cellular α-tubulin mRNAs are translated faithfully *in vitro* and produce α-tubulin which is identical (or almost identical) to the α-tubulin synthesized and stored in the cell body. If the latter is the case, then α_f could only arise as a result of post-translational modification. This interpretation is consistent with that of Lefebvre *et al.*[8] who performed similar *in vitro* experiments using the rabbit reticulocyte translation system. Nevertheless, the possibility still exists that a putative α_f mRNA does exist and that neither the wheat germ translation system nor the reticulocyte *in vitro* system is capable of translating it into a mature polypeptide. To establish that α_f is indeed the product of post-translational modification, we performed two additional sets of experiments.

In the first, we took advantage of the fact that tubulin induction following deflagellation is not dependent on subsequent flagellar outgrowth[17]. Flagellar regeneration was blocked in this experiment by treating deflagellated cells with colchicine. A comparison of tubulin species produced by deflagellated cells in the absence (Fig. 2*b*, lane 1) and presence (lane 2) of colchicine revealed that the α_f subunit was produced by the non-treated cells but not by a sample of the same cells treated with colchicine immediately after flagellar excision. As both samples were labelled for the same time period after deflagellation, these results also indicate that the appearance of α_f is dependent on flagellar outgrowth. (To ensure that the load size of protein in any of the samples did not influence the relative migrations of α- and α_f-tubulin subunits, radioactive proteins from flagella or cell bodies were combined with appropriate samples of non-radioactive proteins from the same sources as described in Fig. 2 legend, and run in Fig. 2*b*, lanes 3, 6 and 7.)

In the second experiment, cells were deflagellated and allowed to produce tubulin subunits for 120 min (Fig. 2*c*, lane 1) during which time flagella were regenerated (lane 4) and reserves of radioactively labelled tubulin accumulated in the cytoplasm (lane 6). At 120 min, cycloheximide was added at a concentration of 10 μg ml^{-1} which blocks essentially all protein synthesis on 80S ribosomes in *Chlamydomonas* (ref. 17; Fig. 2*c*, lane 3). The cells were then deflagellated[20], rapidly chilled, and centrifuged to separate out the labelled flagella. The pelleted cell bodies, which were free of contaminating flagella as judged by microscopic examination and by the lack of α_f-tubulin subunits (lane 6), were resuspended in fresh medium and allowed to regenerate flagella for 1 h. As expected[18,21], the cytoplasmic reserves of flagellar proteins allowed the regeneration of flagella that were on average 4–5 μm long (compared with 12–15 μm for full-length flagella). These short flagella were removed and separated from the cell bodies. Examination of the α-tubulin in the flagella regenerated in the presence of cycloheximide revealed that α_f-tubulin subunits were produced even in the absence of new tubulin synthesis (Fig. 2*c*, lane 5). None of the radioactively labelled α-tubulin that was converted to α_f during regeneration in the presence of cycloheximide was found in the body of the cell; α_f was found only in the flagella.

Taken together, these data provide strong evidence that the major α-tubulin subunit of the flagellum is the product of post-translational modification and, more importantly, that this modification is coupled to flagellar assembly. Two mechanisms can be envisaged to account for the close coupling of post-translational modification of α-tubulin and flagellar outgrowth. In the first, α-tubulin is modified in the cytoplasm only during periods of flagellar elongation and, once modified, is rapidly and quantitatively transported into the growing flagellum. The second, and perhaps more attractive hypothesis, is that

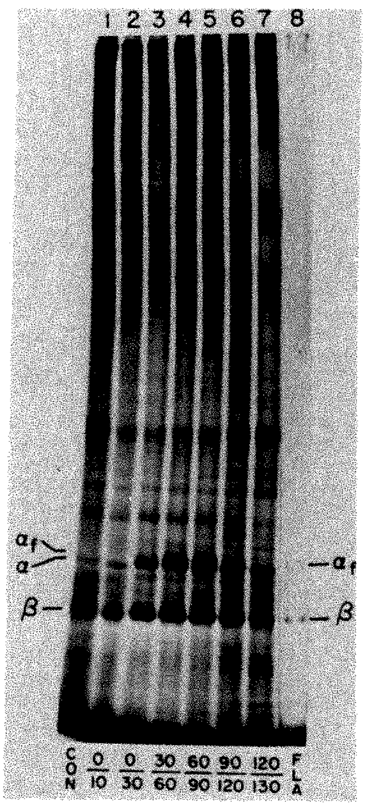

Fig. 1 Tubulin induction following flagellar excision in *C. reinhardii*. Autoradiograph of a SDS-polyacrylamide gel containing $H_2{}^{35}SO_4$-labelled proteins produced at various times before and after flagellar excision. Preparation of gametic cells by transfer of vegetative cells to nitrogen-deficient media and deflagellation of these cells by *p*H shock were performed as described previously[17]. Gametic cells were pulsed with $H_2{}^{35}SO_4$ before deflagellation (CON) and for the 10- or 30-min periods after flagellar removal shown below each track (for example, 30/60 denotes labelling from 30 to 60 min after deflagellation). Labelling conditions were as previously described[17] and included the use of chloramphenicol (250 μg ml^{-1}) to prevent the synthesis of chloroplast proteins. Samples having ~2×10^6 c.p.m. were loaded on to each track of the 15 cm-long 8% polyacrylamide gel and the proteins separated by their differential electrophoretic mobilities[18]. α Designates the α-tubulin subunit which migrates as a protein with an apparent molecular weight of 56,000; α^f, the predominant α-tubulin subunit of the flagellum; β, the β-tubulin subunit of molecular weight 53,000. Track 8 contains radioactively labelled flagellar markers (2×10^5 c.p.m.).

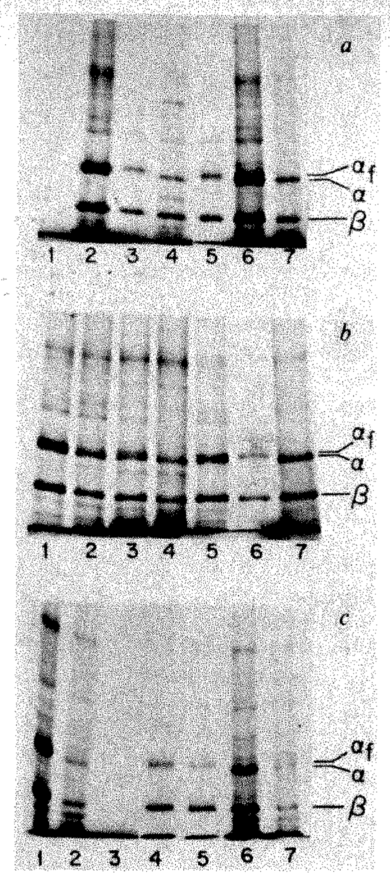

Fig. 2 Analysis of α- and α_f-tubulin subunit production. Autoradiographs of 8% polyacrylamide gels (containing 0.1% SDS) in which samples from cells and flagella labelled *in vivo* and samples of *in vitro* translation products ($\sim$1–2 $\times 10^5$ c.p.m. per track) have been separated by electrophoresis. *a*, Comparison of tubulin subunits from deflagellated cells labelled *in vivo* with ^{35}S-methionine-labelled products from the *in vitro* translation of *Chlamydomonas* mRNA. Procedures for the isolation of polyadenylated mRNA from deflagellated cells and its translation *in vitro* in the wheat germ translation system were as previously described[18]. *In vitro* translation reactions were performed in the absence (track 1) or presence (track 4) of mRNA isolated from fully-induced deflagellated cells. For comparison of these *in vitro* translation products with radioactive proteins produced *in vivo*, tracks 2 and 6 contain samples of cells that were deflagellated and labelled for 60 min with $^{35}S\text{-}H_2SO_4$. An aliquot of these same cells was deflagellated and flagella and cell bodies separated by density gradient centrifugation[20] to allow further comparison of flagellar tubulin (tracks 3 and 5) with tubulin contained in the body of the cell (track 7). The electrophoretic migration of the tubulin subunits produced *in vitro* and *in vivo* was not influenced by differences in protein load sizes as demonstrated by the following combinations of components: track 2, a mixture of the *in vitro* translation components of track 1 with proteins from deflagellated cells labelled *in vivo*; track 3, a mixture of the *in vitro* translation components of track 1 and flagella labelled *in vivo*; 5, unlabelled cell bodies and labelled flagella; 7, unlabelled flagella and labelled cell bodies. *b*, Effects of colchicine on the production of α- and α_f-tubulin subunits by deflagellated cells. Gametic cells were deflagellated and labelled with $^{35}S\text{-}H_2SO_4$ for 60 min in the absence (tracks 1 and 5) or presence (track 2) of colchicine at a concentration (1.5 mg ml^{-1}) which prevents flagellar regeneration. Control and marker samples were as follows: 4, proteins from labelled, non-deflagellated cells; 3, labelled non-deflagellated cells plus labelled flagella; 6, labelled flagella plus unlabelled cell bodies; 7, labelled cell bodies plus unlabelled flagella. *c*, Conversion of pre-labelled α-tubulin subunits into α_f-subunits during flagellar regeneration in the presence of cycloheximide, a protein synthesis inhibitor. Gametic cells were deflagellated and labelled with $^{35}S\text{-}H_2SO_4$ for 120 min (track 1). Non-deflagellated cells were similarly labelled in the absence (track 2) or presence (track 3) of cycloheximide (10 μg ml^{-1}). At the end of the labelling period, cycloheximide was added and a sample of the cells which had regenerated flagella were again deflagellated in order to allow separation of labelled flagella (track 4) from labelled cell bodies (track 6) by density gradient centrifugation. The pelleted cell bodies were resuspended in fresh medium containing cycloheximide and allowed to regenerate new flagella for 60 min in the absence of protein synthesis, then the cells were once more deflagellated to separate flagella (track 5) and cell bodies (track 7). In this case, after the cell bodies and flagella had been separated by centrifugation, the flagellar fraction was centrifuged at 30,000 r.p.m. for 45 min in a Beckman SW 40.1 rotor (as opposed to the usual centrifugation at 16,000 r.p.m. for 30 min in a Sorvall SS 34 rotor) to ensure the complete recovery of the short flagella regenerated in the presence of cycloheximide.

unmodified tubulin subunits move into the flagellum and are modified at or near the site of active microtubule assembly. In the latter case, localization of the enzymes responsible for tubulin modification might be accomplished by their binding to structures closely associated with the growing tips of the axonemal microtubules (for example, the distal filaments described by Dentler[22]).

The present and earlier[6,23] observations of flagellar-specific tubulins suggest that, in general, the ability of microtubules to perform a specific function in a particular subcellular structure may be influenced by the types of tubulin subunits they contain. Differences in the tubulin composition of microtubules can, in turn, be influenced by either genetic variability between different tubulin genes in the cell or post-translational modification of tubulin subunits. The presence of multiple tubulin genes in several higher organisms[11,12] indicates at least the potential to generate subunit diversity at the genetic level. However, two observations raise some question as to the role of genetic variability in the production of different classes of microtubules within a single cell. First, in *Aspergillus*, a heat-sensitive mutation in a single β-tubulin gene[24] seems to have pleiotropic effects on several microtubule-mediated functions—suggesting that tubulin produced from a single gene can be incorporated into most, if not all, of the microtubules of the cell. Secondly, in *Drosophila*, a mutation has been found in the structural gene for a β-tubulin that is expressed only in testis tissue[7]. The variant tubulin produced from this 'specialized' tubulin gene is apparently not confined to a particular type of microtubule, but rather has wide ranging detrimental effects on various microtubule-containing structures within the cell. Therefore, if the existence of organelle-specific tubulin subtypes is widespread, the production of these subtypes may well have to depend on the kinds of post-translational modifications reported here for the α_f-tubulin subunit of the *Chlamydomonas* flagellum.

Finally, one hypothesis that may be drawn from our results is that the enzymes required for flagellar α-tubulin modification may be located close to the site of axonemal microtubule assembly. In a broader context, this hypothesis suggests that the enzymes which modify tubulin subunits and thereby tailor microtubules to perform the specialized functions of a particular organelle may not be scattered throughout the cytoplasm but may be in close and perhaps exclusive association with the microtubules of that organelle.

These studies were supported by NSF grant PCM-80-03438, NIH grant CA-06927 and RR-05539, and by an appropriation from the Commonwealth of Pennsylvania. K.J.B. is a recipient of funds from the NIH (CA-09035).

BOOK REVIEWS

A new nuclear holocaust

John Maddox

IN 1962, Mrs Rachel Carson discovered the harmful effects of pesticides in the pages of the *New Yorker*, and life has not been the same since for the chemical manufacturers. Earlier this year, Mr Jonathan Schell used the same vehicle to announce his personal discovery that nuclear weapons also have harmful effects, and in the process helped to fuel the influential campaign in the United States for a "nuclear freeze". Like *Silent Spring, The Fate of the Earth* is a republished collection of the magazine articles.

The result is compulsive reading but not necessarily a compelling book. The first half is the simpler and the more arresting, written as it is with restrained passion, suppressed rage perhaps. Yet Schell is not an out-and-out scaremonger but rather a cautious one. His "nuclear predicament" is his way of referring to people's indifference to the threat embodied in the nuclear arsenals — "the world has declined, on the whole, to think about them very much". Properly and persistently he reminds his readers that uncertainties must abound in attempts such as his to show what would happen in an all-out nuclear attack on the United States. Would more people be killed by prompt radiation from an airburst weapon than from fire or blast? Only time, says Schell, could tell.

But how can it be possible to write vividly about a topic, the destruction that might be caused by a nuclear attack, when thousands on thousands of words have already been cast in type? Schell succeeds for two reasons, one less creditable than the other.

The meaner trick is the assumption of discovery:

> We have lived in the shadow of nuclear arms for thirty years, so it does not seem too soon for us to familiarize ourselves with them . . . .

or

> a description of a full-scale holocaust seems to be made necessary by the simple but basic rule that in order to discuss something one should first know what it is.

There follows a list of the technical reports that Schell has referred to, but there is no acknowledgement of other writers in the same genre — Robert Junk with his *Brighter than a Thousand Suns,* for example. One's first reaction is resentment: why should Szilard, for example, rate a mention in Schell's account only as one "who called on a number of

The Fate of the Earth. By Jonathan Schell. Pp.244. UK hbk ISBN 0-224-02064-1; UK pbk ISBN 0-330-26915-1; US ISBN 0-394-52559-0. (Jonathan Cape/ Picador/Knopf: 1982.) Hbk £7.95, $11.95; pbk £1.95.

colleagues to keep the discovery [of fission, not then of the bomb] secret from the Germans"? Was he not the Manhattan Project man who wore his conscience most conspicuously on his sleeve? But charitably, one quickly comes to terms with Schell's assumption. To discover the prospective awfulness of the holocaust is more likely to catch the attention than to recount what has been told already. Schell is in any case properly diffident about his knowledge of distant historical events (using the phrase "it is reported" to describe what happened during the Cuban missile crisis of 1962); and then, perhaps, each generation that lives with the bomb needs its own prophet.

Schell's second trick, his literary skill, gives him a good chance of being that. His account of what the holocaust might be like *is* original, almost fresh. Fission, as fusion, is the exception that proves Einstein's rule that mass can be converted into energy. The novelty in fission is that the strong nuclear force was for the first time manipulated by people. One gram of uranium destroyed Hiroshima, but the bomb weighed four tonnes.

The literary rehearsal of the holocaust takes off effortlessly from this point. Schell says that in "this unique endeavour", "foresight is asked to perform a task usually reserved for hindsight". He is only a reluctant futurologist. He takes comfort from the circular slide-rule distributed with copies of Glasstone and Dolan's book *The Effects of Nuclear Weapons* to ground his calculations in someone else's reality, and he does his best to follow the *New Yorker's* precept that the whole world has an absorbing interest in what happens in Manhattan by exploding his mercifully hypothetical one-megaton weapon above the Empire State Building; all the buildings between Battery Park and 125th Street would be knocked down, the fireball would set the city alight. "From Greenwich Village up to Central Park, the heat would be great enough to melt metal and glass."

Schell, of course, is telling the truth. He is probably also right in his guess of what would happen if the existing stock of Soviet nuclear warheads were fired at a representative set of targets throughout the United States. Communications systems would be put out of action. Most cities not flattened would be burning. The few survivors would be either beastly or indifferent to each other, and hampered in their efforts to restart some kind of primitive society by their load of genetic defects and consequent somatic transformation. The critical question, for Schell, is whether the result would be to extinguish the human species or to make life on the Earth impossible, perhaps by the removal of the ozone cover, for all except a few plants and radiation-resistant insects. He acknowledges that the outcome is uncertain, but although there is "all the difference in the world" between the chance and the certainty of extinction, "morally they are the same".

Peroratively, half-way through his book, Schell remarks:

> In weighing the fate of the earth and, with it, our own fate, we stand before a mystery, and in tampering with the earth we tamper with a mystery. We are in deep ignorance. Our ignorance should dispose us to wonder, our wonder should make us humble, our humility should inspire us to reverence and caution, and our reverence and caution should lead us to act without delay to withdraw the threat we now pose to the earth and to ourselves.

This purple passage is the climax to the book. Tract though it may be, it is a well-intentioned tract. Its naivety can be forgiven as innocence. Its neglect of the agonies that have exercised people of all kinds since 1938 is less easily forgiven, but Mr Schell has an important point to make.

At this high point in his book, with only half the pages turned, readers are bound to wonder what can come next. An account, probably ironical, of the attempts that people have been making over the years to negotiate arms control agreements? A discussion of the danger of nuclear proliferation, and of the wayward policies of the nuclear suppliers in this regard? The answer, it turns out, is nothing like that but a chapter called "The Second Death", a kind of essay on the theme that even in strictly personal terms there is something worse than being killed — the whole species might be eliminated.

Nobody will quarrel with the conclusion. Did not even St Augustine, for whom the objective of every human being was to arrive safely in Heaven, acknowledge that even quite ordinary people could be fixated on the terrestrial future by their regard for their children and their children's children?

But Schell skates on thin ice in getting there.

Thus he asserts that scientific knowledge is different from other knowledge in that it cannot be forgotten. Really? And that

> a disturbing corollary of the scientists' inability even to foresee the path of science, to say nothing of determining it, is that while science is without doubt the most powerful revolutionary force in the world, no-one directs that force.

But Schell's real objective is to contrast and compare the notions of death and extinction, one personal, the other for the species. He rightly and evocatively finds a parallel between the extinction of wagon-loads of people in the concentration camps and the feared extinction of whole species. It is an ethical goal, he says, to seek to avoid extinction. Yet living as we do on top of a nuclear stockpile, we are "living with a lie".

The core of Schell's final essay is a comment on the doctrine of deterrence, a popular target these days. If the objective is to build a weapons system so powerful that the destruction of an adversary can be assured, how can success be made convincing without a demonstration? But detente is no good either: look at the way the Soviets made "crimes against detente" punishable, and how President Nixon pleaded exemption from the laws of the United States for the sake of a peaceful world. The real bugbear, Schell says, is sovereignty (but his book was written before the Falkland Islands conflict).

> . . . just as those who favour the deterrence policy . . . must in all honesty admit that their scheme contemplates the extinction of man in the name of protecting national sovereignty, so must those who favour complete nuclear and conventional disarmament, as I do, admit that their recommendation is inconsistent with national sovereignty . . . .

Read as a piece (and it does not take long), Mr Schell's book is thus an extraordinary let-down. "I have not sought to define a political solution to the nuclear predicament" but "I have left to others those awesome urgent tasks . . .". There's generosity for you; some other author, another four-part series in the *New Yorker*, perhaps?

What Mr Schell has forgotten (apart from the precursors whom he fails to mention) is that the simplest explanation of his opening conundrum — why are we mostly so indifferent? — is not a failure to imagine what nuclear war would do to us but a failure to devise political procedures for its sure avoidance. People have seen the difficulties and have sometimes lost heart. Mr Schell's recipe, if taken seriously, can only further depress them, for in his eloquent way he is saying that the problem would be manageable if only the world were an entirely different place. For a book that makes so much of people's ethical responsibilities, that is not merely a disappointing conclusion but an irresponsibly airy recipe for conduct. □

John Maddox is Editor of Nature.

Journals' review issue 1982

On October 7th *Nature* will publish a second review supplement devoted to science journals. Last year's supplement, covering journals first published between January 1978 and May 1980, appeared in *Nature* **293**, 341-369; see p.343 of that issue for details.

Criteria for inclusion of a journal in the 1982 issue are that:

- the first number appeared, or the journal was re-titled, between June 1980 and May 1981;
- it is published at least three times a year;
- the main language used is English.

Broadly, periodicals of professional interest to scientists will be considered for review, with the exception of abstracts' journals.

In addition it is hoped to cover publicly available newsletters, first published between January 1978 and May 1981, in that issue.

Publishers and societies are invited to submit four sample issues of periodicals satisfying the above criteria, ***including the first and most recent numbers***, to the Review Editor, *Nature*, 4 Little Essex St, London WC2R 3LF, England (London 836 6633 ext 2570) as soon as possible.

Affinity for industry and biomedicine

P.G.H. Byfield

Affinity Chromatography and Related Techniques: Theoretical Aspects/ Industrial and Biomedical Applications. Analytical Chemistry Symposia Series, Volume 9. Edited by T.C.J. Gribnau, J. Visser and R.J.F. Nivard. Pp.584. ISBN 0-444-42031-2. (Elsevier Scientific: 1982.) Dfl.195, $83.

AFFINITY chromatography has marched out of the research laboratory and into the world. That was to be the message of the symposium held in June of last year at Veldhoven, of which this book is a record, and the organizers emphasized it by bringing together similar numbers of participants from industry and academia. Meetings based on the discussion of a technique run the risk of being boring since the wide range of possible applications may contain only little of interest to an individual. The organizers overcame this by concentrating the contributions around biomedical applications and relevant industrial processes. This theme penetrated also into the contributions on theoretical considerations and developments in supports and chemistry; many of these were based on biomedical or industrial needs.

By far the most exciting current application of affinity chromatography is indeed to the biomedical field. Even the ability to simplify the isolation of useful compounds from biological sources will open up new possibilities in patient treatment and management. Several contributions describe the commercial production of proteins from human plasma by this technique, others indicate the way to future products, while one author laments that only lack of knowledge of their function inhibits the isolation of more plasma constituents — perhaps the physiologists will take up this challenge. Exploiting the high specificity of antibodies in therapy, as reagents and as affinity ligands, has often been hindered by difficulties in their isolation due to the high interaction energies between antigen and antibody. The successes described here in the fractionation of antisera and in the purification of vaccines will help many, particularly when combined with the practical conclusions in the theoretical paper by van Oss.

Some disquiet was expressed at the meeting that ligand leakage might contaminate products intended for clinical use with hazardous compounds, especially where organic dyes are the ligands. These problems should be easy to overcome. After all, what is affinity chromatography about if not to remove small quantities of a substance from large quantities of other material?

One forward-looking section of three papers considered the use of affinity systems directly in therapy, for the delivery of drugs to specific sites *in vivo* and for the extracorporeal treatment of blood to remove toxins, drugs and so on. Although there is a long way to go, these approaches to more specific treatment of disease are surely to be encouraged.

It is rare to read of an affinity chromatography system that is not based on cyanogen bromide-activated agarose, yet most meetings include sections on new supports and coupling methods. Why is this? One answer was evident at Veldhoven. Both large-scale work and the new high-pressure liquid affinity chromatography systems need robust supports such as the glass, silica and polymers described by several speakers.

Many good posters were shown at the meeting and it is a pity that, tantalizingly, only the titles, not their abstracts, have been published in the book. Nonetheless those interested in using the technique rather than in studying the phenomenon will find much of value in this volume; even the theoretical section contains advice which will be of much practical use. □

Peter Byfield is a Scientific Officer in the Endocrinology Research Group at the Clinical Research Centre, Harrow, Middlesex.

Uneven depths in marine geology

Philip Weaver & Lindsay Parson

The Oceanic Lithosphere. Edited by Cesare Emiliani. Pp.1,738. ISBN 0-471-02870-3. (Wiley: 1982). £110, $195.

SINCE the inception of the Deep Sea Drilling Project, which has played a major role in providing data from previously unsampled horizons in both sediments and the basaltic basement, marine geology has emerged from infancy and into an exciting period of discovery. More recent work using manned submersibles has proved invaluable for the precision sampling of specific areas of interest. Investigations have not been restricted to these data, however, and bottom sampling and geophysical work outside the DSDP are providing the basis for new studies, such as the extensive use of gravity and piston core sampling in the investigation of Quaternary sediments (for example in the CLIMAP project).

The Oceanic Lithosphere, the seventh volume of *The Sea* series, attempts to bring together some of the new discoveries and to provide reviews of the major fields of research. Its scope is therefore enormous, and no one book could hope to cover all aspects fully. The subject matter of the 35 chapters falls naturally into two sections, the first dealing with upper mantle and crust, the second with the sedimentary record.

It is noteworthy that a number of the review articles — such as those on heat probe and on magnetics, and on the composition and evolution of the ocean crust — constitute works of equal, if not greater value to researchers of a general geological or geophysical bent seeking broad appraisals of the ocean basins than to the specialist oceanographers to whom this book claims to be directed. In contrast, or perhaps as a balance, a number of detailed discussions — such as those considering helium isotope work and radiogenic gas retention — will be of far more limited appeal, and may have been included at the expense of swelling an already impressively over-large tome.

Nevertheless, valuable contributions are made in the form of studies of ophiolite suites and their role in the understanding of the evolution of present-day oceanic crust. Petrological analyses of oceanic basement are well represented, and in particular the review by Fox and Stroup provides a comprehensive synthesis of work on oceanic crust with its discussions of composition, seismic structure, heat flow results and magnetism.

The section on marine sediments covers a range of topics from sediment composition and origin to the evolution of ocean basins. Apart from red clays, most oceanic sediments are biogenic in nature, and analysis of their microfaunas enables us to understand past climates and ocean circulation patterns, and to identify changes in the normal sedimentary regime such as hiatuses, anoxic intervals and periods of mass extinctions. *The Oceanic Lithosphere* necessarily devotes several chapters to reviews of the various microfossil groups, providing comprehensive summaries of the particular group, their present-day and past distributions, and their value to oceanography. These are followed by chapters reviewing the deep-sea record and the dynamics of the Earth's sediment system as a whole.

One of the areas of particular interest at the moment is the study of sedimentary processes. Identification of sediment drifts, submarine slides and erosional channels, and the mapping of turbidite flows shows us that the ocean floor is not necessarily stable. Regrettably, this area of research is not covered in the book and readers seeking an overview of the subject could be left with the misconception that the oceanic sedimentary record consists of a layered sequence of undisturbed sediments.

Taken as a whole the volume offers a somewhat patchy review of the oceanic lithosphere. It would have been more logical to produce it as two separate parts as with other volumes in this series, and perhaps to add a few more topics to each part. Largely as a result of the amalgamation of these two parts, *The Oceanic Lithosphere* appears destined for the reference collection kept on a sturdy shelf. □

Philip Weaver and Lindsay Parson are at the Institute of Oceanographic Sciences, Wormley, Surrey.

All round the world of algae

Brian Whitton

The Ecology of Algae. By F.E. Round. Pp.653. ISBN 0-521-22583-3. (Cambridge University Press: 1981.) £60, $130.

PROFESSOR Round has presented us with the type of book which is becoming rarer and rarer, a major monograph written by just one person. Algae are a decidedly heterogeneous group of organisms, so the author has faced up to a challenge which would daunt most editors of multi-author symposium proceedings. *The Ecology of Algae* has well over two thousand references integrated into the text, so it approaches in scope such famous works as F.E. Fritsch's *Structure and Reproduction of the Algae* (Cambridge University Press; 1935, 1945) or one of the volumes of G.E. Hutchinson's *A Treatise in Limnology,* published by Wiley. The question, then, is just how well has the author succeeded in covering this vast topic.

Professor Round has himself published papers on freshwater and marine environments, and has travelled and researched in many countries. The book obviously benefits from this, as both types of environment are given equally sympathetic treatment and examples are chosen on a world-wide basis. There is only one specifically marine chapter, on coral reefs. Throughout the rest of the book the algal ecology of freshwater, subaerial and marine environments is brought together, usually in adjacent sections, but sometimes in a single integrated account. This approach is often very successful in showing similarities between different environments, particularly among the phytobenthos communities which were the subject of much of the author's earlier research. As far as I can judge, most topics are dealt with thoroughly and competently, but in comparison with the space given to the behaviour of algae, treatment of the environment is brief. Information on nutrient cycles is particularly sparse and rather uncritical.

The text steers a reasonable course between the summary of numerous case studies and synthesis; there is none of the nonsense associated with the glib generalizations of several modern algae textbooks. A great deal of information is packed into each section, so the text often requires hard concentration; many readers will probably use the book more as a means of finding their way into the literature than as one from which whole chapters are read in a single sitting. I enjoyed especially Round's own comments on the state of particular areas of research. Such asides can be decidedly annoying, but Round's often show considerable insight and are so sensible that I found them most helpful.

The book is well produced, with numerous figures, useful summaries at the end of each chapter, few printing errors and accurate references. An appendix summarizes the current state of algal systematics, though (to quibble) I would disagree with the inclusion of the Prochlorophyta as a phylum. The main text reviews a large body of literature with a sweep that few, if any, other phycologists in the world could attempt. Research on ecology dates much more slowly than that on physiology and biochemistry, so *The Ecology of Algae* is likely to remain an important text for at least the next decade. I hope librarians will find the money to buy this book, whatever the state of their finances. □

Brian Whitton is Reader in Botany at the University of Durham.

Ape reproduction: science and ethics

Alison Jolly

Reproductive Biology of the Great Apes: Comparative and Biomedical Perspectives. Edited by Charles E. Graham. Pp.437. ISBN 0-12-295020-8. (Academic: 1981.) $52.50, £34.80.

THIS is an unusual book: it achieves just what it sets out to do. It is a handbook that summarizes existing knowledge of ape reproduction, and in the process also raises new ideas which will shape future research. And yet, for those few people who read the entire volume, the clearest impression is not the zoological synthesis the various authors achieve, but an ethical chasm which divides them.

To be sure, the synthesis is impressive: studies of ape reproductive tracts, secretions, hormonal control, pregnancy and birth, endocrine development, sexual behaviour in laboratory or field, as well as conditions of caging and handling for different studies, are brought together and analysed thoroughly. The book shows that the field observations do correlate with laboratory studies of anatomy and physiology; one can indeed illuminate the other. This volume will thus be an essential reference source.

But how do these ape studies apply to human beings? Here we reach the gulf between the indoor and the outdoor scientists. Each of the physiological articles ends by saying that ape reproductive parameters are much closer to those of human beings than to rhesus monkeys'. Each then concludes that we must conserve the great apes for use in medical experiments unethical with human beings, though most add that both ethics and commercial good sense mean limiting damage to such "models" to a minimum.

The field workers, instead, want apes conserved for their own sake and for the scientific and aesthetic pleasure they give us. Perhaps they even share my distaste for calling a living animal a "model", which implies that it exists only as a human surrogate. They certainly emphasize conservation of wild habitat with its mothers that dote five years on one infant before bearing the next, instead of "rational" rearing in nurseries. Battery ape production means removing infants from the mother at birth, if destined for experimental use, so that mothers skip lactational amenorrhea and get on with the next pregnancy. At present, a breeding nucleus of infants must be left for two years with the mother before removal if they are to become emotionally capable of adult sexual intercourse. Later perfection of artificial insemination might remove any "need" for either ape sex or ape motherhood.

I exaggerate, but only slightly. Understanding ape reproduction is desperately important to maintain the captive populations: 1,000 chimpanzees in the United States; far fewer gorillas and orang utans. In Great Britain and Ireland, as of January 1980, zoos held 167 chimpanzees, 63 gorillas and 61 orang utans, few of them breeding adults. We may argue cynically that we shall not pay to support these creatures and their remaining wild cousins unless we selfishly think of them as "models", or we may frankly argue that they should be preserved for other reasons. Of the physiologists who have contributed to this book, only R.V. Short has the courage of his logic as well as his convictions to conclude:

> Humans not only are more available, but also infinitely more cooperative than apes; human reproductive biology is more likely to be pioneered in the human, and it is seldom that the basic facts will first be revealed in an ape, and subsequently extrapolated to man . . . If the only great apes to survive in the 21st century are to be found in zoological gardens and laboratories, we will have lost forever many of the vital behavioral clues which explain why these animals are built the way they are. The great lesson of evolution is that form reflects function. Bequeathed only a caged, or worse still, a stuffed gorilla, we would have no way of determining the adaptive significance of any of its anatomical features . . . if we can begin to correlate form with function in our closest relatives, then by analogy we can gain new insights into the selective forces that have made humans what they are today.

Knowing one's place

R. H. S. Carpenter

Human Visual Orientation. By Ian P. Howard. Pp.697. ISBN 0-471-27946-3. (Wiley: 1982.) £25, $59.95.

OUR senses provide us with two distinct kinds of information: *what,* and *where.* Neurophysiologists, beguiled by the complexities of *what,* have tended to neglect *where;* yet the location of stimuli is far from being the simple matter one might at first suppose.

Objects can only be localized relative to the organ that senses them; if this is itself moveable, then we need to know not just where the object is relative to the sense organ, but also where the sense organ is relative to the body. In the case of vision, we have a highly mobile eye mounted on a freely turning head, attached to a flexible body which can be moved about with the feet. Add to this the large number of degrees of freedom enjoyed by our arms and hands, and it can be seen that even an

action as simple as picking up a pencil demands the complex processing of information not just from our eyes, but from sense organs in our muscles, skin and joints, from the vestibular receptors that tell us about the motion and attitude of our head relative to gravity, and from the stored expectations that we have of the way the world is structured.

To a very large extent, this integration of various kinds of information must be learnt: unlike a surveyor's theodolite, our senses do not come to us ready-calibrated in degrees and minutes of arc, but must be scaled by our own brain through its experience of the way in which one kind of sensation tends to be correlated with another. If we wear prisms that deviate our sight to one side, though at first we reach out for visual objects at the wrong place, after only a few trials our brain adjusts itself to the new situation and no errors are made. This aspect of sensory location has stimulated a great deal of interest over the past few years, for it enables one to make attractively quantitative measurements of the learning processes involved. The advantage of studying sensorimotor coordination rather than perception is that we then work with a system with a clearly defined output as well as input; in the latter case there must always be some doubt as to the nature of whatever it is that is doing the perceiving.

Behind a deceptively modest title, *Human Visual Orientation* hides a wealth of detailed and remarkably up-to-date information about nearly all aspects of this very wide subject. Particularly welcome, in a field where slipshod terminology can easily lead to tangled confusion (how, for example, does one rigorously define the direction of gaze?), are the author's succinct definitions of technical terms, and his clear and intelligent reviews of salient facts in an area in which many important observations date back to the nineteenth century. Many topics which the title of the book might not lead one to expect — the neurophysiology of eye movements, for one — are summarized with equal clarity and expertise.

In other respects, however, the author has perhaps been too modest in his aims: his explicit omission of motion perception and other dynamic aspects of orientation, and perhaps especially his suspicion of model-building and his reluctance to synthesize and integrate on more than a moderate scale, may leave some readers unsatisfied. But this does not detract significantly from what is otherwise a first-rate book, a richly-veined mine of information that will undoubtedly become a standard work of reference and provide much to ponder upon for many years. □

To whom does the United States belong?

Lynton K. Caldwell

The Land Use Policy Debate in the United States. Edited by Judith I. de Neufville. Pp.269. ISBN 0-306-40718-3. (Plenum: 1981.) $29.50, £18.59.

TO UNDERSTAND the land use policy debate in the United States one must first recollect its historical context. During the colonial era, and for decades thereafter, settlers were drawn to the New World by the prospect of free land unburdened by the feudal legacy of taxes and servitudes. And whereas general English common law regarding ownership and tenancy of land was brought to North America, specific restrictions were left behind. Moreover the early years of colonization occurred at a time when English landowners were shaking off feudal exactions. In any event, controls by government were largely unenforceable on the frontiers of settlement. Then, as public authority and jurisdiction were extended to unappropriated lands, the guiding object of public policy was to move ownership as rapidly as possible into private hands.

For a century after independence, speculation in the purchase and sale of public lands was one of the principal roads to wealth in the United States. And the most respected figures in public life, not excepting George Washington himself, did not hesitate to engage in it. The privatization of land was carried further in North America than perhaps in any other country in the modern world. Attempts to impose even minimal controls on the uses of land have not come easily. In 1970 the Senate of the United States considered a National Land Use Planning Act, which was intended to encourage states and localities to adopt forms of democratic planning that would avoid at least the worst conflicts and demonstrable misuses of land. Endorsed by President Nixon, this measure passed the Senate on three occasions but never reached the floor of the House of Representatives, being blocked by a combination of land speculators, developers, farmers and ordinary citizens who feared that the government was about to take away the right to do as they pleased with the land that they owned.

Against this background, one may better understand the 20 essays that make up this book. They evolved out of a colloquium held in 1977 under the sponsorship of the Lincoln Institute of Land Policy at Cambridge, Massachusetts. In view of the long history of frustration in land use planning in the United States, it was appropriate that the focus of the colloquium was on latent values in land use policy. It should be apparent that a significant measure of change in popular understanding and attitude will have to occur before rational land use policy will become effective in the United States.

The scope of the colloquium, and the book, includes considerations of land use as affected by economic, social and environmental policy, the role of markets, the law and public participation. Finally, the authors raise the possibility of a new

The geologist's wife

TO HER HUSBAND SETTING OFF
UPON AN EXCURSION

Adieu then, my dear, to the Highlands you go,
Geology calls you, you must not say no;
Alone in your absence I cannot but mourn,
And yet it were selfish to wish your return.

No, come not until you have searched through the gneiss,
And marked all the smoothings produced by the ice;
O'er granite-filled chinks felt Huttonian joy,
And measured the parallel roads of Glenroy.

And if, in your wanderings, you chance to be led
To Ross-shire or Moray, to see the Old Red,
Oh still, as its mail-covered fishes you view,
Remember the colour is love's proper hue.

Such being your feelings, I'll care not although
You're gone from my side — for a fortnight or so;
But know, if much longer you leave me alone,
You may find, coming back you have two wives of stone!

These verses, four of the eight in *The Geologist's Wife* — written by the anonymous but evidently love-lorn "Susan" in 1847 — are taken from *The Poetry of Geology,* recently published by George Allen & Unwin. The anthology is edited by Robert M. Hazen and costs £4.95, $9.95.

land ethic and identify a series of problems relating to political control of land use. The editor of this volume, who is a member of the Department of City and Regional Planning of the University of California at Berkeley, pulls together the principal themes and viewpoints of the authors in a final essay.

Four general policy positions emerge in the discussions, although not all of the viewpoints are shared by all authors. The first is that the test of good land use policy is the procedure by which it was adopted. This opinion divides between those who emphasize participatory democracy and those who advocate market processes. The second position is that a policy is good if it truly represents the public interest. This view of "goodness" depends less upon what people think than upon ostensibly objective assessments of the implications — economic, ecological and ethical — of particular land use decisions. A third position is that a good land use policy is one that is allied with technological or problem-solving criteria. From this viewpoint land use capability, as assessed by technological and economic possibilities, is the significant factor in determining the land's best and highest use. Fourth, and final, is the notion that good land use policy must be "socially just", correcting, or at least not aggravating inequalities of wealth and power in society.

Although the viewpoints taken in this collection of essays are not new, they seem to require periodic restatement in a country in which deep-rooted emotional and psychological problems inhibit the development of any consistent or rational policy regarding land. Ann L. Strong, the most widely known of the authors, is surely right in her contention that in the United States there has always been an ultimate public interest in the care and custody of land. No less a libertarian than Thomas Jefferson made this explicit. But the myth of absolute and uninhibited private ownership has dominated public policy even to the demonstrable detriment of most private land owners.

The principal value of this collection of essays is that it reiterates the terms of the debate and keeps the discussion going at a time when the prospects for the reforms that most of the authors advocate appear unpromising. I agree with Ann Strong in the title of her essay, "Land As A Public Good: An Idea Whose Time Has Come Again", but I recall that the idea of a national land ethic implemented through public law has come among Americans before, and has not been received. I believe that the force of circumstances will inevitably cause the concept of land as a public good to be generally accepted, but I am not yet persuaded that that time is now. □

A waste of time for everybody?

Susanna Millar

Animal Play Behavior. By Robert Fagen. Pp.684. Hbk ISBN 0-19-502760-4; pbk ISBN 0-19-502761-2. (Oxford University Press: 1981.) Hbk £21, $29.95; pbk £10.50.

THE cover notes and preface to this book declare that Fagen has broken new ground by adopting an evolutionary approach to play, and that he has solved an important biological paradox. This is a somewhat inflated claim. With the single exception of behaviourism, now long outmoded, there is no theory of play, and no developmental theory, that has not assumed an evolutionary context or has operated in a biological vacuum since Spencer first tried to account for play, and Darwin started child watching. The introduction explains that only analyses based on sociobiology and behavioural ecology count. Fagen anticipates that this will cause offence. It is not at all clear why, except that the aggressive, polemical style seems to invite it. Muted hope, that the proposals will justify the claims made for them, is a much more likely response.

Fagen does, nonetheless, make a worthwhile contribution; more to method than to theory, but potentially all the more useful for that. He proposes to apply formal modelling techniques to play, using assumptions based on current genetic and evolutionary ideas. Formal mathematical and computer models, designed to simulate behaviours of complex systems, can be used to investigate the properties of the systems and are widely used in research in biology, genetics and psychology. Fagen's examples of possible model fitting with questions related to play, given mainly in appendices, are much the most interesting parts of the book and provide clear pointers to what could be done.

The main problem about play, according to Fagen, is that animals geared to survival apparently "waste time" by playing. Actually, this is more a terminological quibble than a biological paradox. The "useful/useless" dichotomy depends on the system of classifying behaviour by the outcome, goal or end-state which is obvious to the observer. It is arbitrary and, therefore, provides no reason against analyses of play in terms of survival value; or against applying the theory of frequency-dependent natural selection of genetically based variations to play behaviours. But there is also a genuine difference between play and behaviours such as sex and aggression, which here gets rather lost. This is the paradoxical relation between play activities and the contexts (outcomes) in which they occur. It poses no problem for biological principles, and the "useful/useless" distinction is irrelevant to it. But the relation between activity and context does differentiate play from other behaviours, and it deserves rather more attention than it is accorded by Fagen.

By far the largest part of the book is devoted to the assumptions that Fagen has selected to explain play. These are given as chapter and section headings for his arguments. Since we do not as yet have the results of independent tests, these arguments carry no more weight than any other explanation based on observational and experimental studies. Fagen argues that play is an innate general tendency to prepare for later versatility, with possible connections to art and science. This view is not new. More importantly, it is not implied by evolutionary principles. The fact that it is, of course, unlikely that play behaviours would occur if they did not help with "fitness" and species survival in various ways does not by any means logically imply that all types of play must have the same function, or depend on a single mechanism. As Fagen is aware, such issues require testing rather than rhetoric. The eventual results of the modelling studies he proposes should certainly be of interest.

The book is meant to educate everybody. There is a lively chapter of descriptions, mainly of play-fighting, and one giving a brief account of some biological principles. Non-specialists may find it difficult to follow some of the arguments as they dart between assumption, assertion, findings and interpretation. In addition there are overstatements and inaccuracies. For instance, Fagen shows that cost–benefit tables can, in principle, be set up for play with various criteria of "fitness". But there are methodological difficulties in outcome studies that are passed over rather too lightly. The relaxed "play-face", which is a signal for social play in many species, is sometimes observed in solitary object and locomotor play. Fagen treats this as important evidence for the unity of play; but the observations are quite insufficient to decide whether the "play-face" in that case acts potentially even as a sign for others, let alone that it has the same signalling function as in social play. Piaget's theory is outdated; but to state that it considers play merely an epiphenomenon is rather a howler.

In all, there is an air of haste and of conducting a jihad which does a disservice to scholarship and to the subject. Nevertheless, students who already know something about the subject should find the book stimulating. □

Cloud over French science plan

The French minister for research and technology's plan for future expansion may be delayed by the parliamentary process. But there is in any case a need to think about it more carefully.

The fall of the French franc on Sunday, which brings its devaluation against the German mark to something like 20 per cent in the past 12 months, may concentrate the attention of French parliamentarians wonderfully next week on a key point of the new research law, which is to be debated in the Assembly on Monday: its cost.

The *loi d'orientation et de programmation* for research and development is intended to be the principal instrument of the minister of state for research and technology, M. Jean-Pierre Chevènement. Almost everything hangs upon it: the restructuring of organizations such as the Centre National de la Recherche Scientifique, their stronger linkage with the economy, modifications in contracts of employment and — not least — the outline of a four-year budget. Under the terms of the bill, the government civil research and development budget, effectively Chevènement's budget, would grow in real terms by 17.8 per cent per year on the average as part of a strategy to bring total research and development expenditure in France to 2.5 per cent of Gross National Product by 1985. All basic research is guaranteed at least 13 per cent but high technological priorities (including biotechnology) would get increases of more than the 17.8 per cent. The absolute size of these annual increases is staggering — the best part of one National Science Foundation each year.

This ambitious plan was conceived in the early dreamier days of the present government. Even if the figures are agreed next week at the Assembly, it is doubtful whether they will be faithfully reflected in the 1983 budget, presently subject to horse-trading in the council of ministers. The problem is the overall French budget. The government planned a deficit of FF95,000 million in 1982, but the latest projections give a deficit of FF125,000 million largely because the French economy has not begun to grow at the expected rate of 3 per cent a year, so that tax returns are not covering expenditure. Moreover, increased social welfare benefits and the raising of the minimum wage have pushed up consumer spending but French industry has not been ready to respond, so that consumers have spent their money on imports instead. The government, alerted to the problem, has followed a well-trodden path in France and elsewhere in Western Europe and has imposed a classic squeeze: a four-month freeze on prices and incomes, combined with devaluation. So whither to grand plan now?

President François Mitterrand, speaking only a few days before the squeeze was announced — no doubt to prepare the ground — appeared to be phlegmatic. "We follow the same politics" he said. We are just in its second phase." His government's chief economic objective has been to reconquer the home market. In 1974, 24 per cent of French consumer spending went on imports, but the proportion had risen to 35 per cent by 1981. Part of the government's strategy has been priority for investment in nationalized industry (Mitterrand promised FF25,000 million in 1983) and for industrial innovation. But so far the President has refrained from mentioning a figure for research for 1983.

The research ministry is putting a brave face on this turn of events, but even if the government endorses its hopes for future budgets, trouble in the Assembly about other than financial matters could mean delay. The bill has in any case been badly mauled in the Senate, so that it will be for a joint Senate/Assembly committee eventually to pick up the pieces of Chevènement's grand plan — and to reassemble them as if into a jigsaw puzzle. If the job cannot be done before 1 July, the bill will have to wait until the winter.

The moral in this potentially disappointing tale is general and not specific. The present government of France was elected just a year ago on an optimistic programme of reform and renewal. Neither President Mitterrand nor M. Chevènement has exactly echoed Mr (now Sir) Harold Wilson's British pre-election speech of 1963 about the social benefits of "white-hot technology", but they have both been edging in that direction. The promise is valid, but the performance cannot be guaranteed. This is why the British experience in the 1960s should be studied in France. After the 1964 election, money was indeed thrown at a variety of technical projects but without much lasting effect. (An aluminium smelter built at that time in the Scottish Highlands was shut down only a few weeks ago, the predicted victim of the arithmetic of economics but a social catastrophe nonetheless.) In the end, the inflationary consequences of over-optimism precipitated the stagnation of the British science budget which has persisted ever since (Mr Edward Heath's intervening essay in what is now called Reaganomics notwithstanding). This is why other Europeans are distrustful of what the French have embarked on in the past year. The objective of spending more on research and development is entirely admirable, but nothing will be achieved if the bills have to be paid by printing money. For then it will be recognized that public expenditure on research and development is politically discretionary, and the tap will be turned off.

Who follows Slaughter?

Mr X, the next director of the US National Science Foundation, could spell trouble.

President Ronald Reagan has an unexpected opportunity for putting his own mark on the conduct of US science with the resignation of the director of the National Science Foundation (NSF), John B. Slaughter, whom President Carter appointed in 1980. Slaughter is ending his six-year term of office early, he says, only because he cannot resist an offer to become chancellor of the University of Maryland at College Park, the large state school with a high-quality science and engineering faculty. One of his aims is to integrate the university, which has always been an also-ran to its famous neighbour, Johns Hopkins University, more into the intellectual life of the Washington area. Slaughter says he also wants to attract top quality black students from the region to the university, instead of letting them be lured to other institutions elsewhere in the country. This ambition is understandable. Slaughter is one of the few black scientist-administrators in the United States, and one whose rapid rise has never been tainted with tokenism. (He was an assistant director of NSF, then vice-president and provost of the University of Washington before returning to NSF as director.) But another motive for his decision is the need to pay for his children's college education, and the Maryland job offers not only a pay rise but a free house. Similar reasons were given by another competent Administration figure, Admiral Bobby Inman, when he announced he would leave as deputy director of the Central Intelligence Agency, saying he would have to take a job in business. Must we conclude that the

0028-0836/82/240525-02$01.00

cost of college tuition is now so high that only business executives and university presidents can afford it?

Slaughter denies that being a Democratic appointee in the midst of the Republican Administration has caused problems, or that there is some particular disagreement behind his decision to leave. (The resignation is effective from 31 December.) This denial must be taken with a pinch of salt: the Administration has slashed NSF's science education programmes, particularly close to Slaughter's heart. But it is also true that he worked closely with the incoming Republican team to prevent NSF from being the target of serious cuts in the hard sciences. Is this why NSF has not been the butt of the broadsides of Dr Jay Keyworth, the President's science adviser, against the uselessness of the national laboratories or of planetary science?

In his brief term at NSF, Slaughter has made some important changes, along the lines of his early much publicized call to have NSF sponsor more applied research. He established a directorate of engineering, co-equal with the other directorates that run NSF's basic research. The new directorate, a combination of scattered programmes and some new things, now commands some 10 per cent of NSF's annual budget of approximately $1,000 million. Slaughter has and the National Science Board had a hard job persuading the basic research community to support the engineering directorate. At first, he says, they were "agnostic" about it (read "unenthusiastic"). Basic researchers in the hard sciences tend to regard NSF as their exclusive patron and historically have resisted its forays into public policy, engineering, social sciences and other matters. It is unfortunate, therefore, that Slaughter will not be around to follow through on the move. Past attempts to integrate engineering into the basic research agency have been conspicuously unsuccessful. Unless vigorously and carefully promoted, Slaughter's new directorate could yet founder. Presumably the job of promoting the engineering directorate will fall to Donald N. Langenberg, NSF deputy director, who had the job before Slaughter arrived.

Slaughter has also, with the help of the National Academy of Sciences, established a commission to develop a national policy on science and engineering education, especially urgent in the present crisis in technical education in US elementary and secondary schools (see *Nature* 6 May, p.9). Congress may yet give the commission funds to develop and implement a national plan. Slaughter says that the establishment of the commission is his single most important act as director of NSF. One of his merits is that these changes have been undertaken carefully, in consultation with NSF's traditional constituency, basic researchers in the hard sciences.

Mr X, the highly political candidate whom President Reagan might appoint to succeed Slaughter, could be a very different animal. Reagan is midway through his term of office, and is under fire from his original supporters, the extreme conservatives. If, to placate them, he appoints somebody (probably an industrialist) with fixed and preconceived views about the absolute merits of private enterprise, the result could be disaster. Mr X might well urge that NSF should get out of education policy and social sciences (both hotbeds of liberalism in the extreme conservative view) and no longer give seed money to small businesses doing basic research. NSF could finish up by being stripped down to its core mission — sponsoring basic research in universities — while its other more tentative but important roles, such as its recent brokerage in university–industry partnerships, vanish.

The effect of such a Mr X on the academic science community in the United States is easy to foretell. As a group, academic scientists tend to be paranoid about Washington's designs on their grant monies, and Mr X would strengthen their fears. The community would then pull back from its tentative experiments with industry, its unwilling acceptance, as Slaughter says, that "engineering is also important to the nation", and retreat to its ideological trenches. So it is to be hoped that Mr X will remain just what he is, a figment of the imagination, a hypothetical second-rater, whose *curriculum vitae* may be pressed on the President but whom the President will wisely decide not to appoint to the job Slaughter is vacating.

Nuclear plant and prices

The new chairman of the British electricity industry has a chance to make sense of the nuclear industry.

Dr Walter Marshall, chairman of the United Kingdom Atomic Energy Authority for the past year, is clearly once again the British government's favourite scientist. Last weekend he was made a knight, that peculiarly British public honour which requires that those whom he hardly knows should address him by his first name. A week before that, he was appointed chairman of the Central Electricity Generating Board, the principal owner of commercial nuclear power stations in the United Kingdom and the most likely source of further orders for nuclear plant. Much has plainly changed since 1978, when Marshall as chief scientist at the Department of Energy was for all practical purposes fired by his minister, Mr Tony Benn.

The most obvious change is the change of government (in 1979). But it is also clear that Marshall, whose reputation was previously that of a talented theoretical physicist who had succeeded by deftness and ebullience in carrying the Harwell establishment through hard times in the early 1970s, has used the interval to good effect. His most conspicuous success in the past year has been to persuade the engineers who will be working for

him from 1 July that it is possible to build pressurized-water reactors in Britain at less than twice the cost that obtains elsewhere. The absorbing question now is what Marshall's arrival at the generating board will mean for the British nuclear industry.

The precedents are not uniformly encouraging. Sir Christopher (now Lord) Hinton, who built the first dozen or so nuclear reactors in Britain as well as the separation plant at Windscale (now called Sellafield) maddened his ex-colleagues when, as chairman of the generating board, he insisted that the only significant difference between nuclear electricity and other kinds of electricity is the relative cost. Logically, that view is unshakeable, but it does not thereby follow that the customers (especially monopoly customers) for nuclear plant are without influence on the costs that they must pay. For too much of the past two decades, the generating board has been too passive a customer for nuclear plant, looking to the government to be told when to build reactors, putting up compliantly with the publicly created suppliers' monopoly (called the National Nuclear Corporation) and, more generally, behaving limply.

Marshall, fortunately, is far from limp. The most likely immediate consequence of his translation to the generating board is that this huge nationalized industry will become less dull. The chance of putting the British nuclear industry on a sound commercial footing — or at least of telling conclusively whether such a goal is feasible — is higher now than ever. But in the end what matters is that there should be an asssured supply of electricity at the lowest possible cost. Nuclear power undoubtedly has an important part to play, but so too does the elimination of high cost (oil-fired) and excess capacity from the board's network of generating plant. Pure reason, alas, is not sufficient. Marshall's imaginativeness will help. So too will his capacity to make even those whom he has talked down think well of him.

Political interference at FDA?

New policy raises fears of meddling

Washington

For the second time in as many months, the Reagan Administration is being accused of injecting politics into the selection of scientists for independent advisory panels. According to an official at the Food and Drug Administration (FDA), appointment authority over its scientific advisory panels is gradually being taken away from the FDA commissioner and given to the Department of Health and Human Services (HHS). What worries FDA officials is that HHS recently suggested at least two scientists whom FDA believes are unqualified and who were proposed for political reasons.

Earlier this year, the Department of Agriculture admitted that it had been running security checks and "political" checks on scientists nominated for peer-review panels to evaluate proposals for its competitive grants programme but the political checks have since been dropped.

The troubles at FDA, however, seem more serious. Although the secretary of HHS has always had authority to appoint the advisory panels at FDA, that function has traditionally been delegated to FDA itself. One FDA official said that although HHS has given general directions on the numerical balance of the committees; approval by HHS was generally a formality.

Over the past several months, however, HHS has rewritten the panels' charters as they come up for renewal, retracting FDA's delegated control over them. Although FDA is still being asked to identify possible candidates it is also, for the first time, being told to furnish a list of alternatives. And the final decisions are apparently now being made in the office of HHS secretary Richard S. Schweiker.

Of even greater concern to FDA is that the secretary's office has begun to offer suggestions of its own. According to a report in the *Washington Post* last week, which was confirmed by FDA, these suggestions included a woman psychiatrist who was a founder of the "California Pro-Life Council," an anti-abortion group. She was suggested by HHS as the consumer representative on a panel that evaluates contraceptive and abortion drugs. FDA told the secretary's office that she was unqualified, but whether FDA's opinion will be considered is still uncertain.

The *Washington Post* also reported that HHS suggested a California physician whose main qualification, according to FDA scientists, was apparently that he listed Dr Loyal Davis — Nancy Reagan's stepfather — as a reference.

The Department of Health and Human Services claims that it is doing nothing improper. An HHS official said the department is merely continuing the centralization of appointment authority begun under President Carter. The official also denied that the secretary's office was making its own recommendations for committee positions, and said it was simply passing on to FDA all names that it receives from congressmen and senators of both parties.

That interpretation was contradicted by an FDA official, who said that while names had occasionally been passed on before, what was happening now was quite different. The official said that HHS was coming back with new names *after* FDA had submitted its list of candidates, and was specifically asking if these new names were qualified for specific positions. Mr Garret Cuneo, the HHS official now apparently in charge of the selection process, refused to comment on the matter.

The effects of the new appointment policy remain to be seen; no obviously political appointments have been made so far. But even if political manipulation does not occur, FDA is worried that the new procedures will make putting together an advisory panel even harder. The aim in the past has been to get not only leading scientists in a range of specialities, but also to have different geographical regions and women and minorities represented on each panel. FDA officials wonder how these goals can still be met when it is cut out of the process and when it is limited to saying whether the HHS candidates are qualified or not.

Meanwhile, at the Department of Agriculture, the dust seems to have settled. According to the office of Agriculture Secretary John R. Block, the decision to run political checks on scientists nominated for peer-review panels was really the result of a misunderstanding. Political checks are normally run on policy advisers; last autumn, the Office of Management and Budget ordered the department to bring the peer-review panels under the same federal act that governs policy panels. Agriculture department officials then assumed that political checks would have to be run for them as well.

After disclosure of the political checks on scientists, Block ordered them to be stopped. The scientists who had not yet been cleared by Block's office were then all approved at once. Block's office maintains, however, that none of the information

NIH urged to act on germ war

Washington

In response to rumour that the US Army and Navy are seeking to develop "defensive biological weapons systems" using recombinant DNA techniques, two American biomedical scientists have called on the National Institutes of Health (NIH) specifically to prohibit such work.

Dr Richard Goldstein of Harvard Medical School and Dr Richard Novick of the Public Health Research Institute of New York City are proposing an amendment to the NIH recombinant DNA guidelines to ban "the construction of biological weapons by molecular cloning". The proposal will be considered at the next meeting of the Recombinant DNA Advisory Committee on 28 June.

According to Dr Goldstein, several scientists have recently been approached by the military about the possibility of using cloning techniques to produce biological warfare agents. The United States signed the 1982 Biological Weapons Convention, agreeing "never in any circumstances to develop, produce [or] stockpile" biological agents for other than peaceful purposes. But Dr Goldstein says the military apparently interprets this as not covering the development in the laboratory of suitable organisms for "defensive" — by which is meant deterrent — purposes.

In a statement describing their proposed amendment, the scientists argue that "the use of molecular cloning for the deliberate construction of biological weapons is, *per se*, the most serious biohazard imaginable for this technology", and that "it constitutes an egregious misuse of scientific knowledge".

Although the NIH guidelines strictly apply only to researchers working under NIH grants, the Defense Department has so far agreed to follow them. But the amendment's sponsors say that even if their proposed ban is not binding on military research, it would "provide automatic public support for a refusal of the scientific community to participate in the development of biological weapons and it may convince governments that the 1982 prohibition should be construed as applying to laboratory research".

Under the recent relaxation of the DNA guidelines (see *Nature* 29 April, p.793), the previous ban on cloning of toxin genes and on release of recombinant organisms into the environment was lifted, although permission from NIH is required before proceeding with either. The amendment would restore the ban in these two areas when the aim is construction of biological warfare agents, and extend it to previously unregulated activities such as the cloning of viruses for this purpose.

Stephen Budiansky

0028-0836/82/240527-02$01.00

obtained in the political checks was used.

The department will continue to run nominees' names through an FBI security check which it calls "routine", although neither the National Institutes of Health nor the National Science Foundation follows this practice.

Professor Joe Key of the University of Georgia, a director of the competitive grants programme under President Carter, wonders if the checks were an attempt to cause trouble for the four-year-old programme, which is still small and fragile and viewed with some suspicion elsewhere in the department. The bulk of agricultural research (some $1,500 million a year, of which $15 million is for competitive grants) is funded through land-grant colleges and state experimental stations, which receive government funds according to an automatic allocation formula. This latest incident did little to help the competitive programme's vulnerable position.

Stephen Budiansky

West German environmentalists

Greens' delight

Heidelberg

The Hamburg elections on 6 June have left the environmentalist "green" party in a powerful position. While the conservative Christian Democratic Union (CDU) won one more seat in the Hamburg Senate than the Social Democrats (SPD), the greens (Grün-Alternativ-Liste) won nine seats and now hold the balance of power.

In Hamburg, CDU leader Walther Leisler Kiet is now trying to form a non-party "citizens' senate". If he fails, Mayor Klaus von Dohnanyi of SPD will have to ask the greens for their support. The greens have set their faces against coalition and have said that they will cooperate only on strict conditions, including Hamburg's abandonment of nuclear power.

The aftershocks of the Hamburg election continue to reverberate in all political strata in West Germany. The personal intervention of Chancellor Helmut Schmidt and Foreign Minister Hans Dietrich Genscher failed to turn the tide in favour of the Social Democrats, while the Free Democrats, the lesser partner with the Social Democrats in the Bonn coalition, again failed narrowly to reach the 5 per cent threshold necessary to qualify for a seat.

The polarized vote in Hamburg reflects the shakiness of the Bonn coalition as well as the strength of the green-left. If the Social Democrats lose only one more *Land*, the Christian Democrats will have a clear two-thirds majority in the Bundesrat and could block all government legislation. Rumours are now rife that the Free Democrats will leave the coalition after the Hesse election on 26 September, perhaps joining with the Christian Democrats. The deepening green intrusion into West German politics is at least partly responsible.

With seats in five parliaments, the greens have become the third strongest party. The abrasive challenge they offer to the assumptions of the established social industrial system is proving hard for even the Social Democrats to meet. They are concerned that "integrating" green issues would further alienate the traditional working class base without necessarily keeping ecologically-minded young voters. Indeed, there are wide differences between the Social Democrats and the greens except on individual issues such as the Rhine-Danube canal or the protection of wildlife.

The central goals of the greens are the realization, by means of a social welfare state, of the recommendations of Global 2000 and of disarmament. They call, for example, for radical change to a no-growth society, the use of alternative technologies and energy sources, conservation, economy and peace. They oppose the "compromise politics" of the Social Democrats.

Voters are mainly young and well educated and the focus is often local: cauliflower cancers of eels from the polluted Elbe and the discovery of tonnes of nerve gas in a ramshackle chemical factory near the city centre were important at Hamburg. The parties are autonomous at every level, so that there are no declared leaders and the small new national party controls neither the policies nor the attitudes towards coalition of the *Länder* parties. To ensure the five per cent vote, the Länder-Grünen have often joined with other groups, some of whom have made uncomfortable allies.

Their anarchic demands for Rousseauesque self-determination, their use of violence and frequent threats to make West Germany ungovernable if minority demands are not met raise spectres of the Weimar Republic.

In September, the Hessen greens will go it alone, campaigning especially against the extension of Frankfurt Airport and plans for four local reprocessing plants for atomic waste. They expect a 10 per cent vote, a Christian Democrat parliament and a defeat for the Social/Free Democrat alliance that would indeed have national repercussions.

Sarah Tooze

European science policy

Give and take

Brussels

The second report on European science policy by Crest, the Committee on Scientific and Technical Research, tells the familiar story of how, after 15 years of trying to bridge the technology gap with the United States, Europe still lags behind in the latest technologies. Of the million or more European scientists — representing 20 per cent of the world's total — 350,000 are researchers, and science in Europe cost $35,000 million in 1980. The new report, which has still to be published, goes beyond its predecessor in comparing the national research and development policies of the ten EEC member states.

Energy research, which since 1974 has been a priority, accounted for a smaller share of the research and development budget at 11 per cent in 1980 than in either the United States (12 per cent) or Japan (25 per cent). Nuclear (fission) research has seen its importance slump, particularly in West Germany and France.

Allocations to industry research grew by 15 per cent a year in the Community as a whole between 1978 and 1980 but are thought to have returned to pre-1974 levels only last year. The increase has been marked in Italy and the United Kingdom, but UK spending is still below the 1974 level.

Space research, where international cooperation is at its most developed in Europe, shows France and West Germany sharing more than two-thirds of the spending, worth $860 million in 1980. Curiously Italy and Belgium, recent years have contributed the greatest proportion of their budgets to space research.

Agricultural research turns out to play the biggest role in the smaller member states. In Ireland and Greece a quarter of public research and development money goes on agriculture, which is equivalent to only 3.7 per cent of the EEC's total spending. Agriculture is also important in Denmark and the Netherlands which spent $3.7 and $6.8 per head respectively compared with an EEC average of $2.7, and $3.1 in the United Kingdom. Italy's outlay seems small at $0.9 per inhabitant, considering agriculture's social and economic importance in the country.

International cooperation is still important but its share of public budgets has fallen by as much as 25 per cent since 1978. Between 1974 and 1978 it was constant at 10 per cent but now there are wide differences among the member states. Britain's contribution, for example, has increased by 25 per cent since 1970.

The ten members of the EEC also differ in the response of their companies to the technological challenge. The role of the state in industrial research is greatest in the United Kingdom (30 per cent), France (22 per cent) and West Germany (20 per cent), but less than 10 per cent in the rest. Measuring research in companies as the proportion of expenditure on research and development to the value added of the manufacturing puts British companies first. The proportion of research expenditure is 4.7 per cent followed by West German companies (3.9 per cent), French companies (3.5 per cent) and Dutch companies (3.3 per cent); in the United States though, the average is 5.7 per cent. But if a distinction between public expenditure and companies' own funds is made, the picture changes. US companies spend the most (3.8 per cent) followed by the Japanese (3.4 per cent).

The report argues that many of the

0028-0836/82/240528-02$01.00

member states are not pulling their weight. Germany, France and the United Kingdom share 80 per cent of Community research and development expenditure while the combined efforts of Belgium, Denmark, Ireland and Greece amount to as little as 6 per cent. The conclusions are being studied in preparation for the next EEC science council of ministers on 30 June.

Jasper Becker

Monsanto hands out $23.5 million

St Louis

The Monsanto Company has awarded $23.5 million to the medical school at Washington University in St Louis, Missouri, for five years of research into how proteins and peptides affect cell regulation. The grant, announced on 3 June, approximately doubles the research funds from non-federal sources at the medical school for that period, and is one of the largest from a single company to a university.

Monsanto's award is an obvious boon to the university's research programme: two-thirds of the money will go to applied research and one-third to basic research. Work will be selected by an eight-member committee — four university faculty members and four people from Monsanto — headed by Dr David M. Kipnis, head of the department of internal medicine at the university medical school. University researchers will be at liberty to publish the results of work funded under the grant, but if the material contains potentially patentable technical developments Monsanto can review it, and request a short delay before submission for publication. Monsanto will have exclusive rights to any licences arising from patents on the work, but patents will be the exclusive property of the university, which will be able to receive royalties from Monsanto licences. Royalties will go to the university's research and education programmes — not to individual researchers.

Meanwhile, as many as "a couple of dozen" Monsanto scientists may work at the university and some may spend several years there. Monsanto's move clearly shows an interest in medical products, and Dr Howard A. Schneiderman, Monsanto's senior vice-president for research and development, says that while the company does not now market health-care products, it hopes to do so in future.

Monsanto launched a $1.8 million project with Washington University earlier this year for research using monoclonal antibodies for diagnostic work. The company is also working with Dr Mary-Dell Chilton, of the university biology department, on genetic engineering in plants. Schneiderman did not, however, confirm rumours that a major new grant from Monsanto was imminent to support Chilton's research.

Karen Freeman

Luxembourg in space

TV plan delay

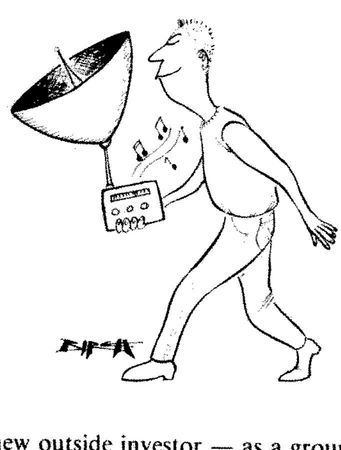
Luxembourg is falling behind in the race to provide the first satellite broadcast for Europe. Unresolved wrangles about the relative sizes of French, Belgian and West German shareholdings in the projected £200 million Luxembourg system have now put back the earliest possible launch date until late 1986.

By then, the national satellites planned jointly by France and West Germany will probably have been up for a year. Also by late 1986, the new all-British Unisat, with two BBC channels, might be aloft.

Radio Tele-Luxembourg (RTL), the commercial company in charge of all broadcasting in Luxembourg, insists that its satellite project is a matter of when, not if. It plans to beam three channels of films, news, entertainment and advertising to a wide swathe from Benelux to Bavaria, and possibly to south-east England. It knows, however, that this ambition represents a big gamble for a small country. RTL, whose current radio and television programmes reach a weekly audience of 40 million in Europe, contributes 5 per cent (about £25 million) of the annual income of the Luxembourg government. Commercial broadcasting has been a major source of revenue for the 50 years since Luxembourg, accustomed to living on its wits, recognized that its central location, plus national sovereignty over its broadcasting policy, permitted it to send radio advertisements and popular music into countries whose governments prohibited one or both by their own broadcasting organizations. It was in 1932 that Radio Luxembourg began spoiling the determination of Lord Reith, the BBC's first director-general, that the British people should have no light radio entertainment on Sunday.

Now, however, with commercial radio and television sprouting all over Europe and eroding its audience, RTL must find a new service to sell or see its profits and contribution to the national purse atrophy. But even if its satellite succeeds in pulling in audiences and advertising revenue, the heavy costs of depreciation of the start-up years is going to hurt Luxembourg's economy, already in trouble with its first unemployment since the Second World War.

RTL cannot proceed, however, until it decides upon a new financial structure to accommodate the necessary infusion of new capital. Although the company is registered in Luxembourg and has, by law, a majority of Luxembourg nationals on its board, its largest shareholder is predominantly Belgian. Also, French investors, notably in the form of Havas-IP, Compteurs Schlumberger and Paribas, are in a strong if not controlling position. RTL's problem now is how to introduce a



big new outside investor — as a group of West German publishers (which does not include the giants) has offered about £50 million — without disrupting the delicate Franco-Belgian balance of power. The French hope to avoid excessive dilution of their own influence. But they, and the whole board, know that the matter will have to be sorted out next month if further delay is not to occur.

Once the go-ahead is given, RTL will invite tenders for the system (two satellites plus a spare). It will also decide whether to devote one of the three television channels to broadcasting in English. Any deregulatory move by the Hunt committee now inquiring into the expansion of cable television in Britain would undoubtedly sway the decision. Elsewhere, RTL insists, a vast expansion of cable television in Europe is not necessary to the success of its plan. It expects half of its audience to buy a rooftop dish to receive its programmes.

Brenda Maddox

Jobs and automation

US faces facts

Washington

The effect that new electronic technology is having on jobs, which has been an issue of intense debate in Europe, is now a cause for concern in the United States.

A new study by the government's General Accounting Office (GAO) suggests that the recent revolution in electronics will be felt not just in manufacturing — the sector most affected so far by automation — but also in office and service jobs. And even within manufacturing, the spectrum of fixed automation introduced in the 1950s, and the initial applications of robots lately have tended to be in tasks that were considered menial, or monotonous or unsafe, for human workers. Spray painting

0028-0836/82/240529-02$01.00

of automobile bodies is an example. Now, with microprocessors that can be incorporated into virtually every machine, even skilled and previously immune occupations such as tool-and-die making may be affected.

The critical question is the validity of what has been a traditional assumption: that technological progress brings with it more jobs. Several witnesses scheduled to testify next week before a House subcommittee investigating the issue doubt that assumption still holds. "We can't count on expansions in the white-collar or service areas, which is what saved us in the fifties and sixties", says William Bittle of the International Association of Machinists and Aerospace Workers.

An annual employment forecast issued by the Bureau of Labor Statistics (BLS)* confirms that employment in at least some office and service occupations is being hit by electronic technology. "We do see some jobs disappearing", says Ronald Kutscher, assistant commissioner of BLS for economic growth and employment projections. Key-punch operators, telephone operators and virtually all the printing trades will be hard-hit, for example.

The other open question, though, is how many jobs will be created by the new technologies directly. Workers will be needed to build, install, adjust, and repair automated equipment. The GAO study found virtually no evidence that could answer this question, however.

The trade unions have apparently accepted that jobs will be displaced by automation. But the critical issue to them is whether enough time will be allowed for workers to find new positions. In Norway, unions have negotiated contracts that set a gradual rate for the introduction of new technologies. The possibilities of such contracts being agreed to in the United States seem much smaller. A common complaint by American trade unions is the tendency towards secrecy on the part of management and the absence of the sort of cooperation and consultation practised in Europe and Japan.

The House subcommittee hearings may be a small step towards some government action on the problem. Representative George Miller, who is holding the hearings, has introduced a bill (HR 5820) that would provide for vocational retraining of displaced workers in new occupations created by automation. The unions, however, tend to dismiss government-supported training as a subsidy for industry and an inefficient substitute for on-the-job training. More to the point may be another concern of Miller's: he points out that the government spends nearly \$2,000 million a year on labour-saving devices. **Stephen Budiansky**

Advances in Automation Prompt Concern Over Increased U.S. Unemployment (General Accounting Office, May 25, 1982). *Occupational Outlook Handbook* (U.S. Department of Labor Bureau of Labor Statistics, April 1982).

GM cancer prizes

Rules to be bent

Although this year's General Motors Cancer Research Prizes have been duly awarded (see below), leaving Dr Howard Skipper, Dr Denis Burkitt and Dr Stanley Cohen each \$100,000 better off, the awards committees are clearly running into difficulties in selecting an annual trio of winners while sticking to the rules. Only four years after the awards started, the biggest worry is that of finding each year someone worthy of the prize "for the most outstanding recent contribution to the prevention of cancer, including environmental factors".

The rules of the prizes were set in 1978 when General Motors, disturbed by the number of its directors who had become victims of cancer, put \$2 million (just doubled) into a General Motors Cancer Research Foundation. The prizes are large enough to invite comparison with the Nobel awards; the rules, however, differ in interesting ways.

One rule, intended to eliminate fortuitousness, is that a prize winner should have made more than one major discovery. Their discoveries must have been made within the previous fifteen years unless their importance has been recognized only more recently.

One prize (Kettering) is for diagnosis and treatment of cancer, another (Mott) for prevention and the third (Sloan) for a contribution to basic science. Winners are chosen by a process that resembles that used for the Nobel prizes. From a list of 25,000 prominent scientists, about 6,000 each year are asked to nominate candidates. Three subcommittees, one for each prize, first pare the nominations to twelve. Last year, they had to sift through 114, 40 and 91 nominations respectively. By the second meeting, each committee member has to report on the merits of two of the twelve candidates, eight of whom are then eliminated. At a final meeting the committees rank two of the four remaining candidates in order of preference. Finally the awards assembly has to decide whether to follow the committee's advice.

This year the assembly argued whether it should award the Mott prize for prevention. Nobody seems to have doubted the importance of Dr Burkitt's discovery of the childhood cancer that now bears his name (Burkitt's lymphoma) and his perceptive suggestion that it is transmissible (it later became clear that a virus is involved). Nor is it in doubt that he pioneered the chemotherapy of "his" lymphoma. But that was all more than fifteen years ago and in any case cannot strictly be considered a contribution to the prevention of cancer.

Turning a blind eye to those problems, the relevant committee and the assembly also had to grapple with the question whether Dr Burkitt's advocacy of the importance of dietary fibre in the prevention of cancer, the topic that has most occupied him in the past fifteen years, is more than a provocative hypothesis. In the end, it was not taken into account.

The choice of Dr Howard Skipper for the Kettering prize for diagnosis and treatment ran into much less opposition, although again the rules have obviously been stretched. Skipper is widely acknowledged as a pioneer of cancer chemotherapy. For 35 years he has influenced clinical chemotherapy by extensive studies on animal and cell models. His discoveries have influenced which drugs are used, in what combinations and their dosage and timing. It is, however, not easy to point to two major discoveries of Skipper's within the past fifteen years. His most recent work bears on the understanding of drug resistance in tumours.

Even for the least disputed of this year's prizes — that to Dr Stanley Cohen — an elastic interpretation of the rules is evident. There is no doubt that he put epidermal growth factor on the map and that it is relevant to cancer research. Cohen's earlier and very important work on nerve growth factor is not a contribution to cancer, and so the characterization and the biological effects of epidermal growth factor have had to be considered separate discoveries.

Perhaps prize rules are made to be stretched. Certainly as Robert Burton once said: "No rule is so general, which admits not some exception". But when the exception is the rule it may be time to change them. **Peter Newmark**

General Motors Cancer Research Prizes 1982: From left to right: Professor Stanley Cohen of the department of biochemistry at Vanderbilt University School of Medicine; Dr Howard E. Skipper, recently retired president of Southern Research Institute, Birmingham, Alabama; and Dr Denis Burkitt, honorary senior research fellow, St Thomas's Hospital, London.

Awaiting the gypsy moth

Washington

Spring in New England, with its green-shaded campuses, tall shadowy and seemingly endless deciduous forests, and country villages with white church spires set against rolling green mountains, used to be one of the natural glories of North America. But as spring advances in New England this year, so will the gypsy moth (*Lymantria dispar*). During June and July the moths will emerge from their pupae and begin their destructive predatory march that now covers most of eleven states from Maine down to Maryland, munching away at the entire foliage of white, red, black and scarlet oaks, and in infested areas of the grey birch trees, the apple trees, American beeches, red maples and even conifers including the common white pine. In areas of heavy infestation, the upper ridges of mountains become so entirely denuded of tree canopy and ground cover that they are ashen and apparently lifeless, reminiscent, as one New Haven scientist said last week, of an experiment that Brookhaven National Laboratory ran in the 1950s to see what a forest would look like after irradiation by nuclear weapons.

The plague of the gypsy moth in the United States is a genetic experiment run wild. In 1869, L. Trouvelot, a French astronomer and naturalist who lived at 27 Myrtle Street, Medford, Massachusetts, imported some gypsy moths from Europe to help found a silkworm industry in New England, then the centre of the textile industry. Some of the eggs were lost, and by 1889 they had multiplied enough to provoke an outbreak in the town of Medford. The following year the state legislature awarded $25,000 for control.

Things have got worse since. The larvae hang on silk threads they have spun, so that air currents can carry them to new trees in which to hatch. Prevailing winds encouraged the spread through northern New England. In 1923 the government established the north–south flowing Hudson River as a natural "barrier zone" to contain the spread south. The Second World War interrupted control efforts, but brought an apparent remedy: DDT. The 1950s saw uncontrolled spraying which checked the infestation in some places, but did not control the spread. In 1958, when DDT was banned, a less effective substitute Sevin was introduced and the government finally started a research programme to control the beasts.

Each year, the front of infestation moves westwards and southwards away from New England. Last year an estimated 13 million acres were defoliated, double the area in 1980. Estimates for the summer of 1982 are that yet another 13 million acres will be defoliated, that is, 50 per cent or more of the canopy will be destroyed by gypsy moths. Carried by vehicles, gypsy moths have been found in Ohio, North Carolina, South Carolina, Virginia, West Virginia, Wisconsin and Michigan and outbreaks have been reported in Salem, Oregon, and Santa Barbara, California. New England forests are not lumbered extensively any more, but as forests in the south and west become infested, the economic costs of the gypsy moth plague will grow.

The battle against the gypsy moth has been hindered by two things. One is the fact that no major industry is affected — thus in Maine, for example, the localized infestations are less important politically than the spruce budworm infestation, which has hurt that state's timber industry for some years. A second impediment is that the US environmental movement, with its power to express issues forcefully, and arouse public opinion, has been lukewarm to the gypsy moth issue. Many environmentalists are more concerned about the potential toxicity of Sevin, a spray commonly used against the gypsy moths, than they are about the forest damage *per se*. Moreover, the fact that lesser infestations do not destroy a forest completely and that most of the trees affected are only "ornamental", gives the environmentalists grounds to argue that the problem is not so urgent. One suspects that they may also hesitate to decry the gypsy moth because if the plague were indeed extensive is it not only a few logical steps to argue that we should return to the only known substance that combats it — DDT? Many environmentalists may not want to start down that slippery road.

So far, the gypsy moth story is one of the failure of science and technology. As the old saying goes, if we can go to the Moon, why can't we beat the gypsy moth? The chief microbial pathogen used so far, BT (*Bacillus thuringiensis*), is not nearly as effective as DDT: it must be sprayed over a large area requiring that an entire neighbourhood should get together and spray at once; if rain or other weather changes interrupt the spraying, it does no good. The other remedies tried so far have been of little effect, partly because, by now, the infestation is so severe. Research has recently focused on pheromones and other specific chemical lures, but the results are not yet broadly applicable.

The biology of the gypsy moth raises several interesting biological questions. The population dynamics of the gypsy moth are not understood, with rises of population followed by collapse, perhaps because of the weather. The physiology of the single American species may throw light on its susceptibility to parasites, perhaps the best hope for control. The relative scarcity of *Lymantria* species in Europe as compared with East Asia suggests that the genus originated in the Far East. The hope is that the work now under way will suggest a species-specific pesticide for a pest that the US Department of Agriculture acknowledges to be uncontrollable. The chemical company that first finds a cure will make a fortune. The search for parasites effective against gypsy moths has now turned to East Asia.

Upland oaks in New England heavily defoliated by the gypsy moth.

The pest also haunts Europe, but because the forests are less dominated by oak and are smaller and more precisely managed, it has not become the plague it is in the United States. Moreover, in Europe, the parasites that limit the gypsy moth population survive the winter whereas, when introduced into the United States, they die for lack of a suitable winter host.

China is the only part of the world that has not been thoroughly investigated for parasites that could solve the problem in the United States. It is to be hoped, therefore, that the Chinese government will be as cooperative as possible with the teams from the US Department of Agriculture which are there now, and plan to go again next year, to investigate gypsy moths in China, particularly in allowing parasites to be taken out of the country.

It is also to be hoped that the Reagan Administration will produce a better research policy on the gypsy moth than its parsimony so far suggests. The research programme begun by the Department of Agriculture in the 1970s may for practical purposes be abandoned as a consequence of the budget cuts. Aid to affected states on research and control, to which the federal government used to contribute 43 per cent, was cut for the present fiscal year to 12.5 per cent, although the Administration relented three weeks ago, and raised the proportion to 25 per cent. But in the coming financial year the Department of Agriculture will not be allowed to embark on any joint programmes with the states, although it may continue with some research of its own.

As New Englanders sit on their porches this spring, musing on how much the gypsy moth will devour of scrub oak or aspen trees on the West Coast, they can take some morbid pleasure in reminding themselves that their President thinks this is a local problem, and that his science adviser, for all his talk about the importance of science's interface with society, does not think the gypsy moth is of any priority for science.

CORRESPONDENCE

Herczynski's arrest

SIR — Many of your readers will have been dismayed to learn from Vera Rich's note (*Nature* 20 May, p.172) that Dr Ryszard Herczynski has been arrested in Warsaw for passing to two attachés from the US Embassy "materials damaging to the interests of the Polish state". Herczynski's numerous friends in this country know him as a vigorous and fearless critic of attempts by the authorities in Poland to inject political considerations into the conduct of scientific and academic affairs. That he has been critical of action taken under the present martial law, we can be sure; and it is probable that the materials alleged to be damaging to the interests of the Polish state were simply documents expressing such criticisms. Nevertheless, he could be sentenced to between three and five years' imprisonment (not internment) under martial law, with no appeal. This would be a terrible injustice.

Expressions of support for Herczynski from Western scientists may dissuade the Polish government from treating him harshly. It would be helpful to convey to those concerned that the essentially non-political causes defended by Herczynski — respect for the truth in scientific and academic matters and maintenance of the integrity of scientists — are also our causes, and that we do indeed care what happens to him. Quick action is desirable since Herczynski's trial may be held soon.

A letter of protest has been sent to the Polish authorities, signed by 25 scientists.

Japanese IQ

SIR — Reading Alun Anderson's comments on the study of IQ in Japan (*Nature* 20 May, p.180), the surprising find is not that it has improved with better nutrition, urbanization, improved social conditions and so on, but that under conditions comparable with those in the United States and Europe, it is 10–15 per cent higher. If this difference is genuine, I could offer an easily testable explanation.

It is well known that coaching can improve IQ results by 5–10 per cent. My conjecture is that every Japanese child undergoes a sort of coaching when (s)he learns to read and write his own language. Apparently it is so complex that only by the age of eleven can they be regarded as fully literate. Of course, the ideal IQ tests are language neutral, but my point is that the mastering of a difficult language plays a general IQ boosting role. This hypothesis is easily testable: one should compare the IQs of immigrant Japanese groups in the United States, say, who are literate in their language and matching groups who are not. Also, if the hypothesis is true, other members of the Chinese-related cultures should show higher IQ, under similar social and economic conditions.

Finally, competent linguists could perhaps find other languages of comparative complexity, the speakers of which could then be included in such inter-nation IQ comparison.

G. MAGYAR

Abingdon, Oxon, UK

Drugs and safety

SIR — I assume that the attack by M. Weatherall (*Nature* 1 April, p.387) on the toxicological testing of drugs was designed to provoke a response and was not intended to celebrate its publication date.

To propose the substitution of patient surveillance for toxicological testing is at first sight attractive because it places the emphasis firmly on men and women and not rats or bacteria. There is, moreover, undoubtedly a kernel of truth in some of his concern about unthinking and invalid testing, yet in selecting genetic toxicology to bear the brunt of his criticism he has chosen unwisely. His arguments show ignorance of current attitudes among thinking toxicologists and regulators. Moreover, the effects under consideration are, as I shall show, almost completely refractory to conventional surveillance.

Genetic toxicologists aim to detect potential mutagens and initiators of carcinogenesis. They would not expect that the result of a bacterial mutagenicity test alone could be extrapolated directly to man. Properly thought-out tests carried out early in the development of a drug can give an alert to possible problems ahead, problems that may be averted by chemical modification or that may require specialized tests to be undertaken when the drug is first given to humans. It would, of course, be verging on the criminal to give young patients with benign disease a drug known to be a potent mutagen in a wide variety of systems (including whole animal tests). Nevertheless, weak mutagens, or those active only in certain rather special situations, may well have a clinical future when all relevant circumstances have been considered. It is here (at the regulatory level) that the common sense advocated by Weatherall should be seen to operate.

To argue for surveillance and against testing for mutagenicity is particularly inappropriate since the deleterious effects of DNA damage are in general so long delayed that they would fail to be detected. Although sensitive techniques are now being developed that would enable the presence of DNA damage and other markers indicative of DNA damage to be detected in treated patients, their use is justifiable on economic grounds only where mutagenicity tests indicate possible risk.

Weatherall is right to try to educate the public and their regulatory bodies not to expect absolute safety from drugs any more than from surgical operations, but the surgeon introducing a new technique will have spent many hours experimenting on animals and will have a fair idea of possible risks before his first operation on a patient.

Back to basics

SIR — Many American scientists may be unconvinced that "Europe leads on (nucleotide) sequences" as suggested by your correspondent Robert Walgate in his article on the European Molecular Biology Laboratory (EMBL) computer library of nucleic acid sequences (*Nature* 15 April, p.596). American molecular biologists have for several years been successfully using several similar data banks including the Nucleic Acid Sequence Data Base organized by Margaret Dayhoff's group at Georgetown University Medical Center. This sequence library, in addition to containing several programs for sequence analysis, currently includes 746,000 nucleotides (compared with the 600,000 reported in your article for the EMBL library).

Apart from the issue of nucleotide quantity, the sample entry provided in your article, while perhaps not typical, does not reflect favourably on the EMBL library as regards quality. The entry gives no indication that the MOPC41 kappa gene sequence presented was not determined by the authors of the entry reference; the sequence was in fact copied by them in their paper to compare with a sequence of another gene which they had determined. In transcribing the MOPC41 sequence these authors erroneously inserted a nucleotide (position 189) which now appears in the EMBL sequence. This trivial error illustrates the importance of relying on original sources of sequence data, a policy of the Georgetown data base. The correct sequence is included in the corresponding entry from the Georgetown data base (see below) along with the correct primary reference (Seidman *et al. Nature* **280**, 370; 1979).

Female mate choice and runaway sexual selection

from Paul H. Harvey and Stevan J. Arnold

IN *The Descent of Man and Selection in Relation to Sex*[1], Darwin explained how various traits usually found in only one sex — such as the peacock's tail or the deer's antlers — might have evolved. He thought that such traits resulted from one of two selective processes that favour access to mates: either selection for weapons used in combat between males, or selection for adornments used to attract females (Figs 1, 2). Darwin observed that the adornments are most clearly seen in males of species, for example, birds of paradise, where females choose from a group of displaying males. But Darwin was aware of a difficulty in his theory that has never been fully resolved: the characters favoured by females often appear to hinder the survival of males. Why should females choose to mate with those males least likely to be favoured by natural selection? Recent analytical work formalizes a model suggested by R.A. Fisher and shows how selection can favour female mating preferences for characters that actually lower male viability, even to the point of driving a population to extinction.

Fisher[2] described a simple model for female choice which had a surprising outcome — male characters which impair survival could be selected for and maintained in a population simply as a consequence of female choice. He considered species with heritable variation for both a male character, say tail size, and female preference for choosing mates on the basis of tail size. If environmental change led natural selection to favour an increase (or decrease) in male tail size, then, over the generations, male tail size would change. However, so would female preferences. The important idea here is that males with longer tails would tend to be mated by females who prefer longer-tailed males. The male offspring of those females will not only inherit their fathers' long tails and be favoured by natural selection but will also inherit their mothers' preference genes and pass them on to their daughters, thus causing an increase in the frequency of those preference genes. This genetic covariance or linkage disequilibrium is a result (not an assumption) of Fisher's model. Modification of male tail size will, therefore, proceed under the influences of both natural selection and sexual selection.

Ultimately a balance between the forces of natural and sexual selection might be expected to lead to an equilibrium male tail size, but Fisher[2] argued that "as long as there is a net advantage in favour of further plumage development, there will also be a net advantage in favour of giving to it a more decided preference". Fisher termed this process 'runaway selection' and went on to assert that in the absence of "severe counterselection . . . *it is easy to see* that the speed of development will . . . . increase with time exponentially, or in geometric progression" (our italics). He suggested that the process might only be checked when males had tails so long that they would be extremely unlikely to survive and females preferring to mate with them would be left without a mate.

Fisher never published a formal population genetic model of the runaway process and, since his writing style was never lucid, later workers have often chosen to add assumptions to the model. One common variant[3,4] claims that the runaway process is a consequence of females choosing males on relative rather than absolute criteria — for example, from one extreme of the distribution of observed male tail sizes in the contemporary population rather than males with particular sized tails.

There has been a clear need for explicitly formulated models that would describe the joint evolution of male characters and female choice and that would, at the very least, specify some conditions under which the runaway process does or does not operate. In a series of papers published in the 1960s and 1970s and summarized in a book[5] published in 1980, O'Donald examined several models which incorporated genetic loci coding for male characters and female choice. These two-locus diploid systems cannot be treated analytically, but computer simulations show that the runaway process would occur. However, Fisher "describes the

Fig. 1 (right) Strepsiceros Kudu. One category of sexually selected characters confers a direct advantage in male–male combat over access to mates. Darwin was aware of numerous examples and had no difficulty in explaining them. Male weaponry is often more markedly developed among polygynous species. **Fig. 2** (below) A second category of sexually selected characters is particularly evident in males of lek species, such as the bird of paradise, where females choose from among a group of displaying males. The males play no part in defending the nest or feeding the young. But why do females appear to choose to mate with males whose plumage must be disadvantageous in terms of natural selection?

evolution of mating systems in terms Darwin himself might have used"[5] and not all his claims are validated in O'Donald's population genetic treatment of his model — the runaway process does not increase at a geometric rate.

Working with a haploid two-locus analytical model and diploid two-locus simulations, the recent treatments by Kirkpatrick[6] also demonstrate the runaway process. But it is evident from Kirkpatrick's treatment that both Fisher and O'Donald were wrong to conclude that "preferences start to evolve only if females prefer those male phenotypes that are advantageous in natural selection"[5]. Indeed, female preference genes that favour more viable males do not necessarily spread through the population, and neither do the more viable males! Why should this be so? The key to the answer lies with Kirkpatrick's finding that when the male trait gene frequency is plotted against female choice gene frequency then there is a line of genetic equilibria: for every frequency of preference there is a frequency of the male trait at which the system is in equilibrium. There is not a single equilibrium point because any viability loss experienced by long-tailed males can, with some female preference, be exactly balanced by a mating advantage. When females preferring long-tailed males are common in the population then sexual selection will maintain a high frequency of the long-tailed males. When the preference gene is not at fixation, however, a low frequency of shorter-tailed males may be maintained in the population to service those females who prefer mating with them. The process is clearly frequency dependent.

What this means is that when the same male fitness and female choice functions are used while initial trait and preference frequences are varied then different points on the line of equilibria are reached. Once populations reach the line there is a prospect for additional indeterminate evolution — genetic drift can carry small populations along the line of equilibria. Finally, it is clear from the models that females need not choose males on relative rather than absolute criteria (see above and ref. 7) for the male's tail to evolve to a maladaptive size.

Kirkpatrick's analysis independently followed a treatment of the problem by Lande[7] which, more realistically, assumed that both male traits and female mate preferences are under polygenic control. Lande modelled such a system with male traits and female preferences treated as normally distributed variables. Although we might expect selection to deplete heritable variance in both traits, Lande points out that this is not necessarily so[8]; at some point depletion by selection will be balanced by enrichment of variation by mutation and recombination. If we assume that variances in male trait and female preference metrics remain the same

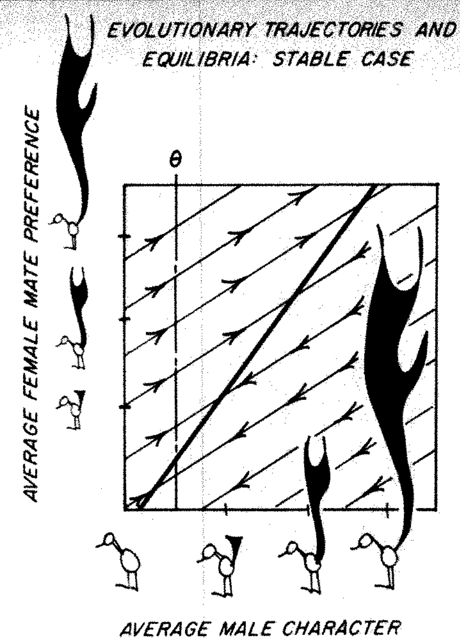

Fig. 3 Females choose mates on the basis of tail size. The light lines depict possible trajectories for the joint evolution of male tail size and female preferences, and the arrows indicate the direction taken. (The male tail size that is optimal for viability is indicated by the symbol θ.) The heavier line connects the equilibrium states at which the males tail length and the females mating preference cease to undergo evolutionary change (other than by random drift along the line). Whether the evolutionary process leads to stable or unstable equilibria depends on genetic parameters and the strength of viability selection.

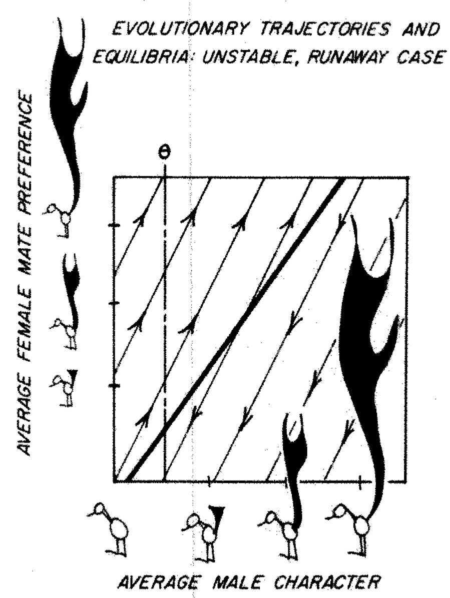

between generations, but that character averages change as consequences of natural and sexual selection, then Lande's models also reveal a line of equilibria. For any strength of female preference there is a male trait size such that the system is in equilibrium. Lande demonstrates the line of equilibria in three models assuming quite different rules of female choice. Again, there is no direct selection on female mating preferences, which evolve as a genetically correlated response to selection on males.

Lande's formulation allows a different interpretation of what Fisher meant by runaway selection. With the two-locus models, populations perturbed slightly from the line of equilibria always return there (although not necessarily to the same point) and the runaway process ends. However, in Lande's models, evolutionary trajectories may lead away from the line of equilibria so that both male trait and female preference can evolve "away from the line at a geometrically increasing rate" (Fig. 3), as Fisher originally claimed. The qualitative conditions for the line of equilibria to be unstable are that females show much heritable variation in mate preference and that there is weak natural selection on the male character. Lande points out that his models help to explain why males of closely related species may differ in a "substantially nonadaptive and random pattern" while the females are phenotypically similar, and also that "random genetic drift may be an important factor promoting speciation by sexual isolation and the evolution of sexual dimorphism".

The similar conclusions reached by models with such dissimilar genetic assumptions underscores the generality of the conclusions. Lande's model, in particular, is general in terms of its assumptions yet clear predictions follow from it[9]. One other idea based on females choosing bizarre males precisely because the male traits constitute handicaps to survival[10] has gained questionable credence among some ethologists who seem not to understand that population geneticists have been unable to model the process successfully. O'Donald[5] presents a detailed analysis of the topic.

The model first sketched by Fisher 67 years ago[11] is only now becoming understood and its widespread implications appreciated. There is no reason why the runaway process should be restricted to plumage characters — vocalizations or pheromone production are other possible candidates. Shortly we might expect relevant parameters to be measured and the efficacy of the theory to be tested. In any event, the finding that, under a variety of circumstances, sexual selection can result in a decline of male viability and thus contribute to population extinction is an important one for evolutionary biology. □

'Style' in prehistoric artefacts

from Paul Mellars

VARIATIONS in the forms of hunting weapons have always held a peculiar fascination for archaeologists. In North America, for example, the whole taxonomy of the 'Palaeoindian' cultures depends heavily on the elaborate patterning in the various forms of stemmed and fluted projectile points, whilst in Europe the same preoccupation can be seen in the classification of a wide range of industries from the Upper Palaeolithic period to the Bronze Age.

The tacit assumption underlying these studies has always been that the patterning represented in the projectile point forms reflected in some way the social groupings of the human communities themselves — that the archaeological 'cultures' bore at least some resemblance to the kind of ethnic or cultural groupings which a modern ethnographer or anthropologist might recognize. From the archaeological evidence alone, of course, any correlations of this kind must remain essentially a matter of faith, and it is only with the recent surge of interest in 'ethno-archaeological' studies that the prospect of testing these correlations has emerged.

By far the most important study to date was reported by Polly Wiessner, of the Max Planck Institut für Humanethnologie, at the recent annual conference* of the Prehistoric Society. For several years Wiessner worked among a number of bushman groups (collectively known as the 'San') who still live predominantly by hunting and gathering in the northern and central parts of the Kalahari Desert. Her main aim was to investigate 'style' as expressed in the material culture of these groups, focusing particularly on how far stylistic variation in the different types of artefacts could be correlated with the various linguistic divisions and other forms of social groupings of the present bushman communities. The analysis was conducted at several levels, ranging from variation between individual craftsmen, through the successively larger 'band' and 'band-cluster' groupings, to the level of the three major linguistic divisions (the !kung, G/wi and !xo) which represent the most discrete and ancient social divisions within the societies studied.

From an archaeological perspective, the most instructive results were obtained from a detailed study of the metal-tipped hunting arrows, which are not only among the most highly valued possessions of the bushmen, but are also still used to secure much of the daily food supply. Most important was the discovery that whilst the forms of these arrows showed a good deal of variation from one hunter to another (and sometimes between different batches of arrows manufactured by the same hunter), it was only at the level of the major linguistic grouping that any consistent and statistically significant patterns of variation could be observed. Curiously, variation at this level was apparent not only in relatively minor details of the shapes of the arrow points, (for example, the convexity of the sides or the precise form of the barbs) but also in features that might be expected to have a significant effect on the function of the arrows. Thus, the arrowheads manufactured by the !kung were consistently smaller than those made by the other two groups, whilst those produced by the !xo had distinctively broader, flatter tips. In these features there was no detectable overlap in the forms of the arrows manufactured by the three groups, so individual arrows could easily be visually assigned to one group or another. Despite these variations, the different forms of arrows were used to kill almost exactly the same species of game in all the societies examined.

Most archaeologists would probably argue that these results conform exactly to expectations — that the element of style in the form of the arrow points was serving to differentiate clearly separate social groupings which would have meaning not only to an anthropologist but also to the bushman groups themselves. Wiessner clearly regards this as one of her most important findings, and has referred to this form of patterning as 'emblemic style', that is, the use of stylistic variation as a symbol or 'emblem' which serves to link the individual with some specific, clearly defined social group.

One of the most intriguing implications of her study, however, is that in certain other spheres of material culture, style can operate in a totally different way. The clearest illustration of this was provided by her analysis of the elaborate beadwork used by bushman women to decorate clothing and other personal possessions. In contrast to the clear patterning observed in the arrow-point forms, the patterns of beadwork showed surprisingly little clear-cut variation from one bushman group to another, and instead displayed a bewildering array of variation in the products of the individual women within each group. In other words, style in this case was focused much more at the personal level, than at the level of the local or regional group. Wiessner has therefore referred to this form of highly individualistic style as 'expressive style'.

Wiessner suggests that much of the contrast between the two forms of style can be explained in terms of the particular functions which the different categories of artefacts served in bushman life. The items decorated with beadwork were largely personal possessions which rarely changed hands between individuals and which appeared to play little part in the social relationships maintained between different bushman groups. Arrows, on the other hand, had a much more dynamic role in social life. Not only were arrows frequently exchanged between individual hunters, but the forms of the arrows could potentially be used as a guide to the ownership of killed or wounded game. As Wiessner points out, the ownership of killed game has virtually no significance at the level of the individual hunter, since the strongly egalitarian ethic of bushman society demands that meat from any animal should be widely distributed between members of the local residential group. Even at the level of the separate bands or band-clusters, the question of ownership is of limited relevance, since most of the bands within each major linguistic group maintain a close alliance in economic matters which allows relatively free access to the territories (and therefore food resources) of other groups, and which frequently leads to the movement of individual hunters from one band to another. At these levels of organization, therefore, there is little need for any clear identification of ownership of killed animals, and indeed the uniformity in the form of the arrows could be viewed as an important way of symbolizing and reinforcing the economic and social ties between the different groups. At the level of the linguistic groups, however, social divisions are much more sharply defined. Social or economic exchanges taking place across these boundaries are generally more formalized, and more dependent on a clear recognition of the rights and affiliations of the groups or individuals involved. Wiessner suggests that the clear differentiation in the arrow forms at this level could be important not only economically (by clarifying the ownership of wounded animals) but also in identifying the sources of any aggression or personal conflict across group boundaries. The clear messages encoded in the forms of the arrows thus become an important element in the patterns of 'boundary maintenance' between the societies involved.

Clearly, the archaeological implications of this study need to be treated with caution. Bushman societies have undergone radical transformations in recent years and it is inevitable that many aspects of both bushman life and bushman technology are still adjusting to these changes. Nevertheless, there are several lessons implicit in the bushman data to which the archaeologist should take heed. As a number of authors have recently emphasized (for example, Wobst in *Univ. Michigan Mus. Anthrop., Anthrop. Pap.* **61**, 1977; and Hodder in *The Spatial Organization of Culture*, Duckworth, 1978), 'style' is not a simple univariate

*A conference on 'The Archaeology of Hunter-Gatherers' was held in London on 20–21 March 1982.

P.A. Mellars is in the Department of Archaeology, University of Cambridge, Downing Street, Cambridge CB2 3DZ.

0028-0836/82/240535-02$01.00

phenomenon which can be equated in a simple, one-to-one way with the extent of 'interaction' between separate groups or individuals; it can clearly operate very differently in different social contexts, and can lead to a variety of contrasting and interacting patterns in different spheres of material culture. Variations in the forms of hunting weapons may after all provide one of the most sensitive indicators of group affiliation among prehistoric hunting and gathering communities, but to assume that this would necessarily be true in all social contexts would be stretching the evidence too far. Only by clearly understanding the social mechanisms by which these variations in material culture come into being can we reliably interpret the data from the surviving archaeological record. It is in this context, of course, that the ethnoarchaeological studies carried out by Wiessner and others are of central importance to the understanding of human behaviour in the past. □

Total eclipse of June 1983

from A.D. Fiala

NEXT June 11, nature will provide one of her most spectacular sights, a total eclipse of the Sun. The eclipse will be of long duration and visible from accessible land sites where there is every prospect of good weather — a favourable combination that has not occurred since June 1973 and will not occur again until July 1991. The path of totality will cross land mostly in Indonesia, but also in Papua New Guinea and a few small islands. Maximum duration of totality will reach over 5 minutes 15 seconds, at a point midway between the islands of Java and Sulawesi. However, on both islands duration in excess of five minutes will occur, with the Sun well up in the sky.

The path of totality will start in the south Indian Ocean at sunrise. For the first hour the umbra will sweep over water, then fall upon Christmas Island. It will then travel the Indonesian archipelago, crossing the centre of Java, the south of Sulawesi and the south of New Guinea, with Ujung Pandang and Port Moresby lying nearly on the central line (see the map). On Java, several large cities lie in the path, including Jogjakarta, Surabaya and Semarang. Bosscha Observatory, the closest to the equator of the world's major observatories, will lie outside the path of totality, however, and will see only 97 per cent partial phase.

The weather prospects for the eclipse are excellent, according to Canadian meteorologist Jay Anderson (*Newsletter of the Bull. R. astr. Soc. Can.*, June 1981). Monsoon conditions give a probability of clear sky of over 65 per cent on the north-east coast of Java and south-west coast of Sulawesi, and nearly 90 per cent at Port Moresby. The sunspot cycle will be midway between maximum and minimum, so intermediate coronal structure and activity may be expected. The eclipse will last long enough for the sky to darken, making it easier to see faint features, particularly from high altitude.

Many astronomers and physicists are laying provisional plans as, indeed, is the Indonesian Government, which is hoping to attract tourists to both the eclipse and the hundredth anniversary of the eruption of Krakatoa that falls at the same time. Experiments are being planned to measure the size of the Sun, to probe the composition and structure of the solar atmosphere and to look for solar effects on the Earth's atmosphere and on the behaviour of living organisms.

A collaborative team from the US Naval Observatory, the Computer Science Corporation, NASA Goddard Space Flight Center and the Astronomical Society of Canberra plans to man at least one station near each edge of the path, in order to measure the solar diameter. This procedure has been carried out at many eclipses, since the original measurements in 1715 by Halley. So far, the results indicate that there is a variation in the size of the Sun, but too few measurements have been gathered to distinguish between monotonic and pulsating variation. The long duration of this eclipse should give the opportunity for observing an extraordinarily large number of small limb features. The observations are not at all difficult, requiring only careful timing and concentration.

Nowadays at any major eclipse there are several airborne observers. NASA's Kuiper Airborne Observatory may be flying along the track over the Indian Ocean, using the Moon as a high-resolution image dissector along the limb to study the limb brightness variation in sub-millimetre wavelengths.

On the ground, several US experimenters hope to be present. A team led by D. Landman, Institute of Astronomy, Hawaii, hopes to continue spectrophotometry of the weak emission lines and continua of ordinary prominences to provide tests of theoretical models. Investigative teams from Kitt Peak, Sacramento Peak and Williams College would like to study in different ways the motion of material in the inner corona, while a group from Iowa State University would study the motion of dust in the outer corona.

Turning the Sun 'off' for several minutes should produce some significant effects in the Earth's atmosphere in the wake of the eclipse path. At least four teams from the US are hoping to study these effects. Two of them would attempt to refine our knowledge of the atmospheric turbulence causing shadow bands and another would look for effects of the wake as far away as India. Observing teams are also expected from Japan and Australia, and quite likely from India, Europe and Canada as well. Indonesia has created a national committee on the eclipse.

This eclipse is the first of three total eclipses to occur in the region over a five-year period. Interestingly, the second is also the next total eclipse, on 22–23 November 1984, and its path intersects with the 1983 eclipse in the Gulf of Papua. However, no experiment has yet been proposed which would make use of this circumstance. The third eclipse will be on 18 March 1988 over Sumatra and Borneo.

The path of totality of the total eclipse of June 1983.

Ionospheric hole caused by rocket engine

from Michael J. Rycroft

AMONG the most interesting of the wide variety of active experiments[1] that can be carried out to study the tenuous upper atmosphere and ionosphere are those that are 'accidental'. One such experiment, perhaps better termed an 'experiment of opportunity', is the operation of a rocket engine at heights above 200 km. The Saturn V launching of Skylab on 14 May 1973, which halved the total electron content of the ionosphere for three hours[2,3], created considerable interest in the effects of rocket exhaust gases on the ionosphere. Further measurements of an artificially induced 'ionospheric hole' were made during the Atlas-Centaur launch on 20 September 1979 of HEAO-C[3,4]. Michael Mendillo and Jeffrey Baumgardner, of Boston University, report[5] the first results of the latest experiment of this type, that for the Atlas-F launch of the NOAA-C weather satellite on 23 June 1981. Launched from Vandenburg Air Force Base, California, at around 03.00 local time, the rocket engine burned to an altitude of 434 km, well into the topside F-region of the ionosphere.

Because the rocket exhaust gases contain highly reactive molecules such as H_2, H_2O and CO_2, reactions with atomic oxygen ions (which are dominant in the F-region) produce molecular ions such as H_2O^+ and H_3O^+. The rates of the reactions are between a hundred and a thousand times faster than those which normally occur with ambient atmospheric nitrogen and oxygen molecules. Thus the atomic ion plasma is rapidly converted to a molecular ion plasma which then recombines quickly with ionospheric electrons, removing ionization and creating the local ionospheric hole. As the rocket proceeds and the plume of exhaust gases diffuses through the atmosphere, the electron content of a column through the F-region, both bottomside and topside, is depleted. The dissociative recombination reactions of the molecular ion plasma, which create the hole, produce oxygen atoms in the singlet D excited state. As these fall into triplet P states, red airglow is emitted, primarily at a wavelength of 630 nm. The position where the airglow is emitted is determined by the time scale of the diffusion of rocket exhaust species through the atmosphere.

The two important quantities to be observed in such experiments are the airglow and the total electron content (TEC) of the ionosphere. In the June 1981 experiment, the TEC was found by measuring the Faraday rotation of the plane of polarization of 136 MHz radio beacon signals from the ATS-1 geostationary satellite over the Pacific Ocean, the groundsite for such observations being chosen such that the ray path passed through the rocket's exhaust plume at 350 km altitude. Four minutes after launch, the TEC decreased rapidly, and reached a steady value some three minutes later; the TEC was found to decrease by 1.7×10^{17} electrons per m^2. From the same site narrow-band optical observations were made using a low-light level image-intensified photographic system with a 60° field of view. As the TEC decreased, an expanding shell of airglow with an intensity of several kiloRayleighs was observed; in the horizontal plane, this appeared rather like a 'smoke ring' with a radius of up to about 1,200 km. As the shell expanded more, its intensity decreased on a time scale of several minutes.

What can be deduced from such observations of the expanding shell of rocket exhaust molecules? First, the diffusion coefficient can be estimated to be $3 \times 10^7 m^2 s^{-1}$. This is consistent with the lightest species of exhaust gases (H_2) diffusing through an ambient atomic oxygen atmosphere, with a temperature of 1,000K at 350 km altitude. Second, knowing that the Atlas-F rocket ejects 10^{27} H_2O molecules per s (about 50 kg s^{-1}), the observation that the airglow emission was maximal two minutes after the initiation of the hole can be interpreted. It is found that 14 per cent of the plasma recombinations yield oxygen atoms excited in the singlet D state. Also, it is shown that, to first order, quenching of the excited oxygen atoms by molecular species is not important.

Further analysis of this and similar experiments can be expected in the future, and other chemical release experiments are planned, for example from the Space Shuttle. Even the operation of the Shuttle's engines or the dumping of water produced by its fuel cells could lead to interesting results. Such active space plasma experiments conducted in the ionosphere are not only of scientific interest, but also have practical significance for various aspects of radio communications. □

Coastal plants take to the road

from Peter D. Moore

IT has long been recognized that the spreading of salt on roads in Britain during the winter is having a progressive influence on the vegetation of our roadside verges[1]. A similar problem has been described from the United States back in 1969, when it was estimated that 6×10^6 tons of salt were applied annually to roads in the northern states[2]. Up to 10^6 tons are used annually in Britain[3], and locally this often means that salt is being added to the soil of these verges at a rate of 3–4 kg m^{-2} yr^{-1} (in the United States, values of up to 6 kg m^{-2} yr^{-1} have been recorded[2]).

If we compare these figures with those obtained from studies of natural salt spray on coastal vegetation, such as maritime cliff grasslands, then the ecological impact of the salt input can be appreciated more fully. In his studies of the Lizard peninsula, Cornwall, Malloch[4] determined the annual 'salt' (Na, K, Mg, Ca, Cl) deposition in rain gauges to be approximately 0.07 kg m^{-2} yr^{-1}. In only one location did he record a value as high as 0.86 kg m^{-2} yr^{-1} of sodium, which is approximately equivalent to 2.6 kg m^{-2} yr^{-1} of total salt. The results are in keeping with those from sites in western Ireland 15 km from the sea[5] (0.04 kg m^{-2} yr^{-1}), in Lancashire 2 km from the sea[6] (0.01 kg m^{-2} yr^{-1}) and in Cheshire 40 km from the sea[6] (0.004 kg m^{-2} yr^{-1}). It is evident, therefore, that our roadside verges are receiving a considerably greater (often by a factor of 50) input of salt than our most exposed cliff grasslands, and it is not surprising that the effects of such treatment are being increasingly felt.

The application of salt to soil has a strong influence on its structure, and leads to clay flocculation and consequent loss of aeration. It also, naturally, raises the osmotic potential of the soil water, making it difficult for plants which lack physiological adaptation to absorb water. There are two main consequences for the vegetation: first, there will be a strong selective pressure against those individuals within populations that lack the requisite adaptations; and second, halophytic, maritime plant species will be able to invade these inland habitats.

Relatively little data are available on the effects of salt application upon the general

Peter Moore is in the Department of Plant Sciences, University of London King's College, 68 Half Moon Lane, London SE24 9JF.

0028-0836/82/240537-02$01.00

balance of grassland species but it seems that white clover (*Trifolium repens*) and meadow grass (*Poa pratensis*) may suffer more than red fescue (*Festuca rubra*), rye grass (*Lolium perene*) and crested dogstail grass (*Cynosurus cristatus*)[7]. Selection of specifically adapted genotypes within populations is difficult to demonstrate in the field, but experimental studies suggest that this will be an active process[8].

The second conseqùence — the invasion of typically coastal species of plant — is more obvious to the observer and hence has been studied in more detail. In 1976, Mathews and Davison[9] surveyed the Newcastle-upon-Tyne area and found several such species (such as *Aster tripolium, Puccinellia distans, Plantago maritima* and *Sueda maritima*) on roadside verges as much as 13 km from the sea. The salt marsh grass (*Puccinellia distans*) has now been recorded on verges extensively throughout northeastern England, in the Midlands, East Anglia and Kent[10]. Other species have not kept up with the rapid spread of *Puccinellia,* though the sea plantain (*Plantago maritima*) and the sea spurrey (*Spergularia marina*) are still advancing gradually. The sea aster (*Aster tripolium*), however, appears to have failed in its bid for a place in the new saline grasslands; seed set has been poor and populations are contracting rather than expanding. Seed dispersal techniques could be the key to success in this invasion. *Puccinellia, Plantago* and *Spergularia* are low-growing plants and their seeds could easily be carried in the mud adhering to vehicle tyres, while *Aster* seeds are produced well above the ground and rely on wind dispersal.

A survey of roadside vegetation in Norfolk has also recently been conducted by Bull[11]. Permanent recording plots were set up five years ago and the species present recorded annually since then. Both extinctions and immigrations have been observed during this time and Bull regards many of the new immigrants (for example, *Polygonum aviculare, Artemisia vulgaris* and *Rumex obtusifolius*) as salt tolerant. The difficulty in interpreting this kind of data is the number of variables involved (frequency and time of mowing in particular); controlled experimental studies are evidently needed.

The invasion of our roadside verges by halophytes is thus proceeding in much the way that the 'railway flora' developed during Victorian times[12]. One difference is that the nature of the current change will be less conspicuous. Extinctions may be more abundant than immigrations, but these are less easily noticed by casual observers, and genetic modifications within our roadside plants may also be overlooked. We may be sure, however, that there are subtle changes afoot in our 1,500 km² of roadside verges[13]. □

Seawater under extreme pressure

from Michael Whitfield

UNTIL recently, the experimental difficulties involved in performing precise measurements at high pressures have ensured that relatively little information was available about the properties of seawater and the reactions of its constituents in ocean conditions. The available information has been scattered throughout the literature, uncorrelated and accessible only to the *cogniscenti.* Two recent publications[1,2] indicate that this picture is changing rapidly.

Most experiments are carried out at atmospheric temperature and pressure, but it is a harsh reality that mean ocean conditions lie closer to 4°C and 200 atm, and more extreme conditions are not uncommon. The pressure generated by the overburden of water has a significant influence on the density of seawater and hence on the stability of the water column and the direction and rate of water movement. Furthermore, minerals such as calcium carbonate and silica, generated in surface waters by biological processes, become progressively more soluble as they settle through the ocean, encountering waters at increasing pressures. Consequently the recycling of these minerals and the many trace elements associated with them is strongly dependent on the pressure sensitivity of the dissolution reactions. The solubility of calcium carbonate in the deep oceans is of particular concern since the dissolution of this mineral is likely to provide the final sink for the excess carbon dioxide currently being injected into the atmosphere by the combustion of fossil fuels. Another reason for growing interest in these measurements is the discovery of rich and diverse communities of organisms surrounding warm hydrothermal oases along the mid-oceanic ridges which are subjected to pressures of several hundred atmospheres.

To appreciate the significance of the recent developments one must look first at the problem of defining the equation of state for seawater, which enables the density of seawater to be calculated at a particular temperature, pressure and salinity. These parameters can be accurately measured and the calculated density fields then used to elucidate oceanic circulation patterns.

To establish the new equation of state for seawater, techniques were developed for the precise measurement of solution density over a wide range of temperature and pressure. Density measurements at atmospheric pressure for solutions of individual electrolytes found in seawater can be used to estimate the contributions made by the component ions to the solution volume (the ionic molal volumes). Similar measurements made at high pressure provide estimates of the ionic molal compressibility. The influence of pressure on a chemical reaction can be estimated from the accompanying volume change — a reaction which produces a decrease in volume being favoured by the application of pressure.

Millero[2] has taken advantage of recent density measurements at atmospheric pressure and at high pressure to compile data on ionic molal volumes and compressibilities over the temperature and pressure range of interest to oceanographers (0–50°C, 1–1,000 atm). Using this information he has calculated the effect of pressure on the solubility of a range of mineral phases (including silica, strontium carbonate and calcium carbonate) and shown that the calculated values are in good agreement with available experimental data. Furthermore, by taking into account the molal compressibilities he was able to show that, for the minerals he considered, there was no need to invoke the presence of structurally altered zones at the surface of the solid phase to explain the observed pressure dependence. However, molal volume measurements over a wider temperature and concentration range will be needed in order to estimate the effects of pressure on reactions in the geothermal brines produced along saline spreading centres on the ocean floor. It is now becoming apparent that the reactions occurring at these sites may be responsible for fixing the concentration of many seawater components, and that the more spectacular deep-ocean vents may be surrounded by rich mineral deposits whose formation and stability require further investigation. □

The impact, transmission and evolution of infectious diseases

from Robert M. May

OVER the past ten years and more, the World Health Organization (WHO) has increasingly placed its emphasis in the Third World on primary health care — paradigmatically exemplified by 'barefoot doctors' in villages — rather than on heroic technology and large hospitals[1]. I think this is very sensible, as many of the afflictions that combine to make life spans in the Third World markedly shorter than those in the developed countries can be countered by relatively inexpensive and simple measures; rehydration treatments for infants with diarrhoea or public health practices that help lower parasite burdens give better value for each dollar expended than do CAT scanners.

In designing programmes of primary health care, insights into the overall transmission and maintenance of infections within host populations are valuable. This fact has paradoxical aspects, for to some the 'flute music' (Simon Levin's phrase) of mathematical epidemiology must seem like the most baroque manifestation of Western cultural imperialism, even less relevant to village paramedics than is open heart surgery. Motivated partly by the idea that theoreticians and practitioners have interesting things to say to each other in this area, a recent Dahlem Conference* brought together ecologists, population biologists, epidemiologists, veterinarians and a variety of medical people to examine the overall population biology of infectious diseases. Taking several background papers as read, the conferees divided into four groups to focus on the impact of diseases on human and other animal populations; the factors influencing transmission and maintenance of infection; the possibilities for control or eradication of infections; and the broad co-evolution of hosts and pathogens.

Impact

As reviewed for the meeting by Holmes (University of Alberta), anecdotes abound about the devastation that diseases can inflict on natural populations of plants and animals. It is, however, much more difficult to assess the extent to which diseases are important in regulating such populations. For instance, in some species of wildfowl in North America some 80–90 per cent of the individuals not shot by hunters die of diseases each year, yet it is arguable that availability of breeding sites remains the primary factor regulating population density. The discussion made it plain that the various causes of deaths are hard to disentangle in most vertebrate populations, and left the impression that regulatory mechanisms may often depend on the interplay of several factors. Thus in those parts of Europe where rabies is now endemic in fox populations, the fox density may be significantly depressed below the disease-free level, which is set by territorial considerations; the present densities appear to depend on both the disease and territory size.

Holmes advanced the suggestion that invertebrate populations may more typically be regulated by infectious diseases and parasites than are vertebrate ones. Although some empirical evidence points in this direction, a systematic study is lacking. Theory suggests[2] that host populations are more easily regulated by infectious diseases if there is little or no acquired immunity (typically making the regulation of invertebrates, which lack such acquired immunity, easier than of vertebrates), and if the intrinsic rate of growth of the host population is not too large.

In any assessment of the impact of disease on natural populations, *Homo sapiens* must be considered as a special case. This is not out of respect for Bishop Wilberforce and his spiritual heirs, but because the patterns of explosive growth of human populations over the past century and more are without parallel elsewhere in the animal kingdom.

Changing life expectancies in human populations, particularly over the past two centuries in the developed world and since World War II in the developing world, are almost wholly due to reduced mortality from infectious diseases[3,4]. Although these diminished mortality rates and their demographic consequences are clear, the relative importance of the contributions made to them by better nutrition, improved hygiene, medical advances and other factors remains the subject of sharp and unresolved debate[3].

Transmission

Many biologists and medical people are fascinated by the intricate details that make each association between a host species and a virus, bacterium, protozoan or helminth unique. But underlying this richness and peculiarity of detail — which must be kept in sight as one moves towards control programmes — are some common themes.

A lot of discussion centred around the extent to which R_0, the 'intrinsic reproductive rate' of the parasite[5-8], can be used to characterize particular host–parasite associations. Calculation of R_0 itself involves classifying parasitic infections according to their overall dynamics rather than their conventional taxonomy. For microparasites, which broadly are those with high rates of direct reproduction in the definitive host (as typified by most viral and bacterial, and many protozoan, infections), R_0 is the average number of secondary infections produced when one infected host is introduced into an uninfected population. For macroparasites, which broadly are characterized by having no direct reproduction within the definitive host (as is typified by most helminth infections), R_0 is the average number of adult offspring established in 'second generation' hosts that one adult parasite produces in an essentially uninfected host population. In either case, R_0 depends both on the basic biology of the host–parasite interaction, and on the environmental and social factors that influence transmission rates.

An accurate estimate of R_0 for microparasites can be made if good serological studies are available. Failing this, rough estimates can be made from the approximate formula[6] $R_0 = 1 + (L/A)$ where L is the average life span of the human or other host, and A the average age at which infections are acquired when the disease is endemic. Estimation of R_0 for macroparasites is more difficult, and involves knowledge of the average parasite burdens, of the way in which parasites are distributed within the host population (almost invariably in a clumped or 'overdispersed' manner, rather than independently, randomly or uniformly), and of the way egg output and adult parasite survival depend on the number of parasites in a host.

In addition to attempting to estimate R_0 for a selection of microparasites and macroparasites, the conferees also catalogued some of the difficulties inherent in the concept. For one thing, not all infections lend themselves to ready classification in this binary scheme. For another, some microparasites have two or more qualitatively distinct categories of host. For example, while typhoid usually runs a relatively short course of infection from which the host either recovers or dies, a few hosts ('Typhoid Marys') will be asymptomatic yet will carry and can transmit the infection for a relatively long time, possibly even lifelong; it is not obvious which is more important in transmission, the much larger number of much shorter infections, or the small number of long and asymptomatic infections. Gonorrhoea and some other infections may be primarily maintained by a core of 'superspreaders'[9-12]. Such refinements can be embraced within the definition of R_0, but they complicate its estimation.

Control

Control is a term often used loosely to describe any reduction in the incidence of an infection. Clearly, eradication of the infection is a limiting case. Whatever the

*The Dahlem Conference on the 'Population Biology of Infectious Diseases' was held in Berlin on 15–19 March 1982. The proceedings will be published as a book by Springer Verlag, later this year.

Robert M. May is Class of 1877 Professor of Zoology at Princeton University, Princeton, New Jersey 08544.

0028-0836/82/240539-02$01.00

degree of control being attempted, the goal will tend to be relatively easier if R_0 is small. It was remarked by Molineaux (WHO, Geneva) that the WHO success in the global eradication of smallpox and the failure in efforts to eradicate malaria from large parts of Africa may be partly because for smallpox in developing countries R_0 is $\sim$ 3 or 4, while for *falciparum* malaria R_0 ranges from $\sim$ 50 to several hundreds.

The existence of reasonably safe and effective vaccines against many microparasitic infections provides the basis for attempts at control or even eradication. Again, knowledge of R_0 can give a rough idea of the prospects for such campaigns. Assuming the vaccine to be 100 per cent effective (which few are), eradication requires that the fraction, p, of the population protected by vaccination must exceed a critical value[6,7,13] $p > 1 - 1/R_0$. For large R_0, this can require a forbiddingly high proportion of the population to be vaccinated. Thus, although the aetiologies of measles and smallpox are in many ways similar, with the infection always being apparent and running a relatively short course, the tentative estimate that R_0 is probably around 10–20 for measles in developing countries may make its global eradication much more difficult than was the case for smallpox with its R_0 of 3–4.

For macroparasites, there was discussion of the distinction between infection (having one or more parasite) and disease (having a parasite burden sufficiently high to produce illness). Especially if parasite burdens are highly overdispersed, as they usually are, relatively few hosts may carry burdens high enough to induce illness, even though essentially everyone is infected. There can thus, as emphasized by Warren[14] and others, be a real distinction between 'infection' and 'disease', and it may make sense to target control measures against the heavily infected hosts.

The concept of a 'breakpoint', first introduced by Macdonald[15] in his thinking about control of schistosomiasis, is an interesting one for many macroparasitic infections. If the parasite has a sexual stage in the definitive host, as many macroparasites do, then there can be two alternative stable states for the host–parasite association above the threshold at $R_0 = 1$: if the parasite population is present at densities above the 'breakpoint' level, the chances that female parasites in a given host will be mated is high, and the parasite population will be able to realise its intrinsic reproductive rate and establish itself; but if the parasite population is initially at a density below the breakpoint level, the chance for a given female to acquire a mate is low, and the infection will die out (even though R_0 for mated females exceeds unity). This notion of a breakpoint is obviously attractive. It offers the seductive hope that macroparasites could be eradicated by a one-time reduction below breakpoint densities, without the environmental or social changes that are needed if R_0 itself is to be reduced below unity. This contrasts with most other parasites, where, in the absence of a breakpoint phenomenon, unremitting vigilance is necessary for parasites with high R_0, even after the infection has been eradicated from a region; the basic biology is such that the infection will tend to re-establish itself if a few infected individuals are introduced. Reviewing recent work on this subject[16,17], the conferees sadly concluded that such breakpoint densities are probably too low to be of practical significance (mainly because the patterns of parasite clumping in hosts, mentioned above, tend to make mated pairs likely even at low density).

Throughout the week, it was often observed that many of the infections that excite attention in the West are of little significance in any global league table of diseases. For example, increasing incidence of various infections associated with homosexuals in large cities is attracting considerable attention, yet [as summarized for the conferees in Paul Mann's (Public Health Laboratory, Bath) clerihue] "Malaria/Is scarier/Than catching clap/From a travelling chap".

Evolution

The notion that 'successful' or 'well adapted' parasites are relatively harmless to their hosts is set forth as the received wisdom in most medical texts, and elsewhere. The idea is, at first sight, not unreasonable: all else being equal, it is to the advantage of both host and parasite for the parasite to inflict little damage. Moreover, a certain amount of anecdotal information supports this view. In his background paper, Allison (System Research, Palo Alto) observed that, for example, in regions of Africa where trypanosomiasis is endemic, indigenous ruminants suffer mild infections with insignificant morbidity, while domestic ruminants that have been bred for a long time in the region suffer more severely, with significant morbidity and mortality, and recently imported exotic ruminants suffer virulent infections which are usually fatal if untreated.

From a theoretical point of view, it would indeed appear that parasites evolve to be avirulent, provided that transmissibility and duration of infectiousness are entirely independent of virulence. This assumption, however, is not generally valid; the damage inflicted on their hosts by most viral, bacterial, protozoan and helminth parasites is often directly associated with the production of transmission stages. Once these complications are introduced into the theoretical models[18-20], it appears that many co-evolutionary paths are possible, depending on the details of the interplay between the virulence and the transmissibility of the parasite.

Considerable discussion centred around one unusually well documented example[21,22]. In the early 1950s, the myxoma virus was introduced into rabbit populations in Australia and England. At first the disease was highly virulent, but over the subsequent decade successively less virulent strains of the virus began to appear. Since the mid 1960s, the virus appears to have come to an equilibrium with its rabbit host (in both Australia and England), with the predominant strain of the virus being one of intermediate virulence. These data can be analysed to get an approximate estimate of the relationship between the virulence and the transmissibility of the various strains of the myxoma virus[20]; the nature of this relationship is such that strains with intermediate virulence have the largest R_0, and may thus be expected to predominate.

There was discussion of other cases where the evolutionary pressures on the parasite may make for its being highly virulent. The various baculoviruses, which kill their insect hosts and effectively turn them into masses of viral transmission stages, are one such example that may be amenable to an explicit analysis of the contending evolutionary forces.

The group concentrating on evolutionary aspects of host–parasite interactions thus concluded that, although parasite 'harmlessness' may characterize many old-established associations, neither *a priori* arguments nor empirical evidence points towards its being a general rule. Several interesting questions that seem ripe for mathematical or experimental investigation were identified.

In all, most of the participants found the conference helpful both in summarizing where things stand, and in identifying directions in which we might productively move. Bryan Clarke spoke for everyone when he said:

If you're teased by a sense of unease,
We hope that this volume will please,
That the work clears the murk
From the quirks that may lurk
In the laws of the cause of disease.

REVIEW ARTICLE

The relationships of *Sivapithecus* and *Ramapithecus* and the evolution of the orang-utan

Peter Andrews* & J. E. Cronin†‡

* Department of Palaeontology, British Museum (Natural History), Cromwell Road, London SW7 5BD, UK
† Department of Anthropology, Harvard University, Cambridge, Massachusetts 02138, USA

We review here the molecular data that bear on and provide a framework for interpreting hominoid relationships. Man is shown to be most closely related to chimpanzees and gorillas among extant hominoids, with the orang-utan more distantly related to them and the gibbons more distantly still. A fossil ape, Sivapithecus meteai, *shares several characters with the orang-utan and is thus probably related to it.* S. meteai *is part of the Middle Miocene* Sivapithecus–Ramapithecus *species complex, and if this group forms a valid clade then* Ramapithecus *must also be considered as being more closely related to the orang-utan than to man. The date of divergence of the orang-utan from the African apes and man is suggested by fossil and molecular evidence to be 10±3 Myr ago.*

THE Miocene epoch (25–5.5 Myr) was the period that heralded the appearance of mammalian faunas of modern appearance. It was also the period that saw the main radiations of the hominoid primates, culminating in forms that share many of the characteristics of the living apes and man[1,2]. The specific affinities within this complex of fossil and living hominoids are still, however, subjects of much controversy[1–3], and other than recent Pleistocene forms which are obviously related to the living orang-utan[4] and gibbons[5], and the Plio-Pleistocene forms of early hominids from East Africa[6,7], no fossil hominoid has been convincingly shown to be related uniquely to any of the extant hominoids.

Foremost in this controversy is the postulated hominid affinity of *Ramapithecus*, a form found now in middle to late Miocene deposits in East Africa[1,8], Turkey[9], China[10] and Indo-Pakistan[3,11,12]. This phyletic linkage has been much debated and has been both rejected and supported on morphological[11,13] and molecular grounds[14–16]. Central to understanding this problem is: (1) the relationship of the complex of species within the *Sivapithecus–Ramapithecus* network, and (2) the relationships among the living hominoids and in particular the status of the orang-utan. To a large extent the adaptation and relationship of the orang-utan have remained substantial enigmas[14,17,18], but they are clearly pivotal to our understanding of ape and hominoid evolution.

Recently, the relationships among the living species of hominoids have been greatly clarified by macromolecular comparisons[14,15,17,19]. Although not yet definitive, these comparisons have provided a new insight into the branching sequence or cladistic relationships of the living apes and the timing of the divergence between apes and man. This evidence will be reviewed here, with particular reference to the relationships of the orang-utan with the other hominoids. Changes in morphology, particularly of the teeth and face, will be correlated with the pattern of relationships thus established.

As regards the fossils, a new fossil hominoid specimen has been recently described which sheds a substantial amount of light on the *Sivapithecus–Ramapithecus* complex. *S. meteai*, from the late Miocene of Turkey[20], shows similarities in morphology and a possible phyletic relationship to the living orang-utan. *S. meteai* clearly shares broad similarities with other Miocene *Sivapithecus*[20] forms, which in turn are closely allied to *Ramapithecus*[11]. If this linkage is correct then one segment of the hominoid evolutionary tree can be rooted through a purely palaeontological approach.

Molecular affinities among the hominoids

Each organism carries within itself a history that is encoded in the genome. Given the appropriate techniques we can decipher this codex and elucidate phylogenetic history. Such macromolecular comparisons may yield insights into both the sequence and timing of ancient speciation events. The molecular approach has long been critical to the resolution of several controversies concerning phyletic links over a wide taxonomic scale, for example, in the case of taxa such as Aves, Amphibia, Reptilia and Mammalia, particularly Primates. Such comparisons are not limited to living forms, as tissue from a frozen mammoth has supported its close molecular relationship to the modern elephant[21], and skin from the recently extinct Tasmanian wolf[21] has confirmed its affinities with the dasyuroid group of marsupials.

With respect to hominoid evolution, substantial genetic data are now available which shed light on the evolution of humans and apes. Data from immunodiffusion, microcomplement fixation, radioimmunoassay, amino acid sequencing, electrophoresis, nucleic acid hybridization, nucleotide sequence and restriction endonuclease mapping, and cytogenetics, have shown a fairly consistent pattern of the branching sequence or cladistics of the hominoids, and working within this framework one can attempt to analyse the rate and nature of morphological evolution along the specific lineages.

The biomolecular evidence (Fig. 1) argues for three clear major cladogenic events in hominoid evolution: first, the separation of the gibbon lineage from that leading to the great apes and man: second, the subsequent divergence of the orang-utan lineage from that linking the African apes and man; and thirdly, evidence from molecular comparisons that *Homo*, *Pan* (chimpanzee) and *Gorilla* share a substantial lineage before their subsequent divergence. Evidence as to which of the two extant lineages shares a period of common ancestry to the exclusion of the third is at present equivocal; evidence exists which favours pairing of *Pan–Gorilla*, *Homo–Pan* and *Homo–Gorilla* (in order of greatest preference). The difficulty in determining the sequence of divergence is primarily a result of extremely short

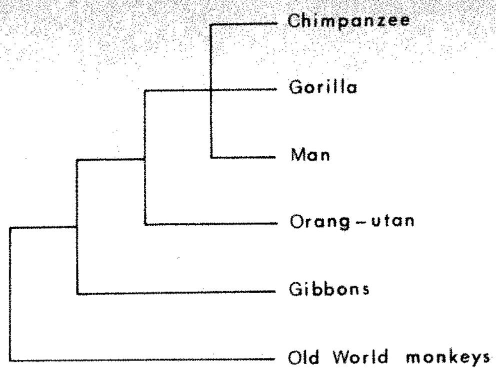

Fig. 1 A molecular cladogram of the Hominoidea incorporating data from immunological studies, electrophoretic analysis, protein sequencing, nucleic acid hybridization and restriction endonuclease analysis of mitochondrial DNA. The data are discussed in the text and in refs 22 and 23 in more detail. Molecular clock calibration of the various sequences of divergence (as calibrated in the text and in refs 15, 22 and 27) are (1) *Homo–Pan–Gorilla*, 5 ± 15 Myr ago; (2) *Pongo–Homo, Pan, Gorilla*, 10 ± 3 Myr ago; and (3) *Hylobates–Pongo, Homo, Pan, Gorilla*, 12 ± 3 Myr ago.

lineages, in a temporal sense, and of the experimental error inherent in the techniques, and so far no data have conclusively demonstrated any unique shared derived molecular changes for any pair of the lineages. However, as interesting as this issue is, it is not central to the evidence for the common ancestry of the African apes and man and to the phyletic position of the orang-utan (Fig. 1).

Molecular data demonstrate convincingly the existence of the common lineage leading to the African apes and *Homo*. Along this common lineage (Fig. 1) numerous shared molecular changes have occurred. These involve derived amino acid sequence changes in the proteins albumin and transferrin, fibrinopeptides, carbonic anhydrase, haemoglobins, myoglobin, changes in mitochondrial DNA restriction sites, 1.5% base pair substitutions (involving $\sim 10^6$–10^7 base pair mutations) in nuclear DNA, and at least one locus with electrophoretic charge changes (refs 22, 23; Table 1). Specifically determined events and inferred molecular changes clearly document the existence of this lineage, and no molecular data reverse the position of *Pongo* and *Homo* shown in Fig. 1, although some data provide more reliable results than others. The conclusion, therefore, is that, in so far as the molecular evidence reveals phylogenetic relationships, the orang-utan is removed from unique association with the African apes and is the sister group to the clade comprising the African apes and man.

In addition to the branching pattern, the molecular data may also elucidate the timing of evolutionary events. It has been hypothesized that due to their apparent approximate regularity of change, molecules may serve as an evolutionary clock to date past divergence events[14,24], and this has been used to suggest that the human and African ape lineages separated as recently as 4–6 Myr ago. Calculations based on rates of nucleic acid and serum protein evolution[15] give dates ranging from ~8.5–14 Myr for the origin of the orang-utan lineage ($\bar{x} = 9.9 \pm 1.3$, $\gamma = 1.7$). An estimate of 10 ± 3 Myr is thus quite in order, given the approximate nature of the molecular clock[25], and this agrees with the fossil evidence described here for the origin of the orang-utan lineage. Previously, the fossil evidence has appeared to indicate dates of ~15–20 Myr for this event, but the data given here suggest that the date should be close to or slightly earlier than 10–11 Myr. Precluding naive interpretations of the molecular clock[25], these results are quite compatible with each other[26,27].

Morphological affinities among the hominoids

The evidence from gross morphology generally agrees with the molecular evidence, except that it defines the relationships among the extant hominoids less precisely. The evidence must be viewed at various levels. First, there is the evidence linking the hominoids as a monophyletic group through such shared derived characters as the presence of a vermiform appendix and the loss of the tail. Second, there are the numerous characters of the postcranial and axial skeleton which link the great apes and man and exclude the gibbons[28], particularly, for example, the morphology of the wrist[29], the structure and development of the shoulder musculature[30] and the reduced lumbar region of the vertebral column[31]. Finally, there are the characters that provide evidence of pairing relationships within the great apes and man, and as these are the principal concern of this paper these characters will be examined in more detail.

Evidence exists which previously led to the grouping of the great apes as a single group containing the chimpanzee, gorilla and orang-utan. These all have a diploid number of chromosomes of 48 compared with 46 in man. They have many superficial similarities in skull morphology, such as the prognathism of the face or the enlarged nuchal area of the occiput[32], and in their postcranial morphology, particularly in their limb proportions and shoulder morphology which were thought to be functionally adapted to brachiation[32]. More recently, most of these characters have been shown to be either allometric consequences of increased body size[28,33,34] or primitive characters retained by the living great apes[35] and therefore having no relevance to the within-group relationships of the living great apes.

There is much stronger evidence linking the African apes, the chimpanzees and gorillas with each other, to the exclusion of the orang-utan, including the many anatomical specializations related to knuckle walking in chimpanzees and gorillas[36], and other characters such as the presence of the frontal sinus[37,38], a character which they also share with man. This evidence is in general agreement with the molecular data, and there is little morphological evidence that lends any support to alternative sets of relationships, for example, that the orang-utan is related more closely to gibbons[39], that it forms the sister group to the group comprising the gibbons, African apes and man[39], or that the orang-utan by contrast is more closely related to man than are the African apes[40].

The lower face of chimpanzees and gorillas has many points of similarity with the human face despite the gross differences

Table 1 Molecular comparisons among the great apes and *Homo*

Molecular comparisons	*Homo–Pongo*	*Pan/Gorilla–Pongo*	*Homo–Pan–Gorilla*
Fibrinopeptide sequence (no. of amino acid differences)[23]	2	2	0
DNA hybridization (% base pair mismatch)[40]	2.4	2.0	1.1
DNA hybridization (% base pair mismatch)[23]	—	4.5	2.4

Immunodiffusion distance (antigenic distance)[16,23]	1.6	1.6	0.8
Electrophoresis: plasma proteins[14,27]	»2	»2	~1.6
cladistic analysis based on number of electrophoretic charge changes at 23 loci[22]	8	9	7
genetic distance value based on 23 loci[17]	0.349	0.300	0.367
Mitochondrial DNA comparisons using endonuclease restriction enzyme maps of site shared[19]	1*	2†	7‡

* *Homo* shares a specific site with *Pongo* but others do not; † *Pan* and *Gorilla* share a site in common with *Pongo* but *Homo* does not; ‡ *Homo* shares this number of sites with at least one of the species of *Pan* or *Gorilla* but not with *Pongo* (or *Hylobates*).

Fig. 2 The maxilla of *S. meteai* showing the lower part of the face.

in facial height and the alveolar prognathism. Some of the characters shared between man, chimpanzees and gorillas are: the nasal aperture is broad; the subnasal plane is truncated and stepped down to the floor of the nasal cavity; the orbits are approximately square and often broader than high; the inter-orbital distance is broad; the infra-orbital foramina are usually three or less in number and are situated on or close to the zygomaticomaxillary suture; the zygomatic bone is usually curved and has a pronounced posterior slope; the zygomatic foramina (one or two) are small and are situated at or below the lower rim of the orbits; and the glabella is thickened (present in some fossil humans although not in modern man). The chimpanzee, gorilla and man also share the presence in the palate of small incisive foramina, large and oval-shaped greater palatine foramina, and large sphenopalatine fossae. Their teeth are basically similar in pattern except for the canines and premolars, and in particular the upper incisors lack a great size discrepancy between I^1 and I^2.

Many of the characters shared by man, chimpanzees and gorillas are present also in the gibbons. Where this is the case it is presumed that these characters are primitive for the Hominoidea, both because they are thus present in most extant hominoids and also because they are found in the most widely separated members of the group. (In other words, they are not present in the orang-utan, which separates the clades of gibbons and the African apes and man in Fig. 1.) In three of these characters, however, gibbons differ from the African apes and man, and these must be examined briefly to determine whether the primitive condition can be identified for them. Gibbons have a narrower oval-shaped nose, and from a consideration of other anthropoids, which generally have noses that are higher than broad, it seems likely that the primitive pattern for hominoids is a narrow oval-shaped nose as in gibbons. The infra-orbital foramina in gibbons are well removed from the zygomaticomaxillary suture, and again this is the usual condition in other anthropoids, thus it seems likely that this is the primitive condition in the hominoids. The condition of the glabella varies considerably in gibbons, from almost complete absence of thickening to fairly extensive thickening. This is true also of many other anthropoids, and it seems in fact to be size-related, therefore it is only possible to consider this character to be significant if glabellar thickening is either present on a small-bodied species or absent from a large one.

These characters have been summarized in a list (Table 2) which depicts the primitive condition in the Hominoidea. The two characters marked with an asterisk are present in gibbons, which thus retain the primitive condition, but not in the African apes and man, which thus share the derived conditions for these characters. All the other characters are shared between gibbons, African apes and man. One other character for which the polarity of evolutionary change is not yet understood concerns the presence of thick or thin enamel on the molars. The gibbons, chimpanzees and gorillas have thin enamel and man has thick enamel, and, on the face of it, thin enamel seems to be primitive for hominoids. Gibbons, chimpanzees and gorillas would thus have retained the primitive condition while man has developed the derived condition with thick enamel. Thick enamel, however, is a character that is shared with the orang-utan as well as with the fossil apes of the *Sivapithecus–Ramapithecus* group, and an understanding of the relationships between these two groups is essential to the understanding of human relationships.

Relationships of the orang-utan

The characters of the orang-utan differ in most respects from those listed in the previous section. Table 3 shows the characters of the orang-utan which it does and does not share with the fossil *S. meteai*[20] (Fig. 2). Other characters which it does not share with *S. meteai* could be added to the list, for example, the presence of wrinkling on the molar teeth in the orang-utan; but the absence of such clearly derived characters in the fossil hominoid need not be construed as evidence against an association between it and the orang-utan. Evidence for such an association comes from the list of shared characters, all of which (except where indicated) are interpreted as derived characters uniquely shared between *S. meteai* and the orang-utan. Where the fossil hominoid lacks the derived characters present in the orang-utan, this can be interpreted in terms of mosaic evolution, whereby some characters in an evolving lineage are developed before others. It would be more difficult to explain derived characters present in the fossil that are not present now in the orang-utan, but none have been observed.

No evidence exists as to whether the characters shared between *S. meteai* and the orang-utan are homologous or not. They may have arisen through convergent evolution rather than through common ancestry, but the latter is indicated by several sources. First, the characters shared between the orang-utan and *S. meteai* relate to separate functional complexes of the face and dentition. Some of the characters do inter-relate, such as the shape of the nose and the subnasal plane, or the nose and orbit shapes, or even possibly the shape of the nose and the narrow inter-orbital distance, but these characters relate directly neither to the characters of the palatine foramina, nor to two characters of the dentition, that is, the large difference in size between the central and lateral incisors and the thickness of enamel on the molar teeth. These combinations of characters can be seen as separate functional complexes that show similarities between the orang-utan and *S. meteai*, and if they are all the results of convergence it is difficult to envisage the circumstances that would lead to similarities in such disparate sets of characters occurring together in the fossil and extant forms.

Homology rather than convergence is also indicated by the metrical study of *S. meteai*[41], in which over a series of eight measurements of the palate and lower face, the extant hominoids showed a consistent and unified pattern differing

Table 2 Characters considered likely to be primitive for the Hominoidea

*Nasal aperture higher than broad, oval-shaped
Subnasal plane truncated
Subnasal plane stepped down to floor of nasal cavity
Orbits as broad as or broader than high
Inter-orbital distance broad.
Infra-orbital foramina few in number (≤3)
*Infra-orbital foramina well removed from the zygomaticomaxillary suture
Zygomatic bone curved and with strong posterior slope
Zygomatic foramina small
Zygomatic foramina 1–2 in number
Zygomatic foramina situated at or below the lower rim of the orbits
Glabella thickening which may occur on large individuals/species
Small incisive foramina
Large, oval-shaped greater palatine foramina
Upper incisors lacking large size discrepancy
Thin enamel on molars (see text)

This list is not exhaustive but concentrates on those characters that are known from the fossil record.
* These characters are present in gibbons but not in the African apes and man.

markedly from that of other anthropoids. The pattern for *S. meteai* approximates fairly closely to the great ape pattern, demonstrating both that its affinities in most dimensions are with the great apes and that, seen as a pattern, each of these characters is consistent with the others and therefore more likely to be the result of shared ancestry rather than independently acquired convergences. As for the non-metrical data, the variation in some of the dimensions, for example, palate length and nasal width, are not significantly inter-correlated and by inference are not functionally related.

Even more tenuously, it can be observed that in certain other respects the face of *S. meteai* bears strong resemblances to that of the orang-utan. The size and conformation of the zygomatic region, for example, are similar in the two hominoids, although the degree of similarity is not sufficient to distinguish them absolutely from the other hominoids. The great bizygomatic breadth in *S. meteai* is most similar to the condition in the orang-utan, but it also falls within the range of variation for male gorillas[20]. The same is true of the relatively great depth of the zygomatic region and the pronounced premaxillary prognathism[20]. The deep zygomatic region is combined in *S. meteai* with an estimated face length (nasal height measured from the estimated position of nasion[20]) that is below the range for the gorillas but within the range for the orang-utan. Thus these characters combine to produce a face shape similar to that of the orang-utan and different from comparable-sized gorillas. However, as the fossil is incomplete, it is not yet possible to quantify these characters adequately and little reliance can be placed on them except as support for the evidence given earlier.

It can be concluded from the morphological evidence given here that the orang-utan possesses a number of derived characters not present in the other extant hominoids. This is consistent with the molecular evidence discussed in the previous section (Fig. 1). We have shown that the suite of characters that distinguishes the orang-utan from other hominoids is present also in a fossil ape, *S. meteai*, and as it is concluded that these similarities are probably homologous we have felt justified in adding the fossil hominoid to the original cladogram to produce Fig. 3.

Sivapithecus indicus from India and Pakistan[3,11] can also be linked with *S. meteai* and the orang-utan on the basis of a newly described skull belonging to this species[42]. This skull, which was described after this review was written, shares with the orang-utan all the characters listed in Table 3, and it also provides evidence on two additional characters of the eye region which are included in Table 3. This strongly reinforces the case for the relationship of *Sivapithecus* with the orang-utan[44].

Discussion

S. meteai has long been identified as part of the *Sivapithecus–Ramapithecus* complex[3,20]. Simons and Pilbeam[3] synonymized

Table 3 Characters shared between the orang-utan and *S. meteai*

*Nasal aperture higher than broad, oval-shaped
Subnasal plane smooth, not truncated
Subnasal plane continuous with floor of nasal cavity, not stepped
Orbits higher than broad—not known for *S. meteai* but known for *S. indicus*[42]
Inter-orbital distance very narrow
*Infra-orbital foramina few in number
*Infra-orbital foramina well removed from the zygomaticomaxillary suture
Zygomatic bone flattened, facing anteriorly
Zygomatic foramina relatively large
No glabellar thickening—not known for *S. meteai* but known for *S. indicus*[42]
Extremely small incisive foramina
Slit-like greater palatine foramina
Great size discrepancy between I^1 and I^2
Thick enamel on molars
†Zygomatic foramen multiple (single in *S. meteai*)
†Zygomatic foramen situated above the level of the lower rim of the orbit (below the orbit in *S. meteai*)

* Characters considered to be shared primitive characters; all the rest are considered to be shared derived characters.

† Characters that are present in the orang-utan but for which *S. meteai* retains the primitive condition.

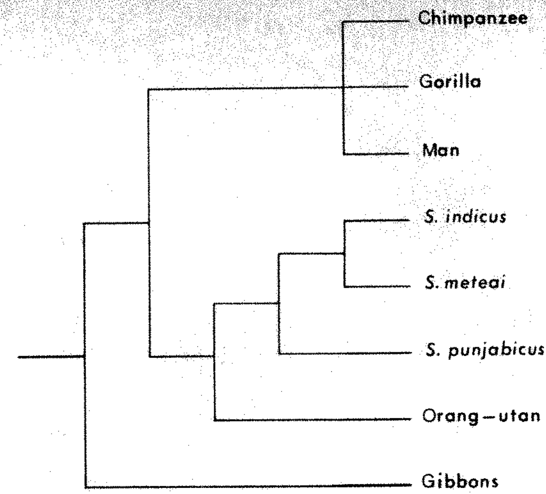

Fig. 3 Relationships of the extant and fossil Hominoidea. The relationships of the living species correspond to those in Fig. 1, and the fossils are shown as three species of *Sivapithecus* (including *Ramapithecus* as a junior synonym) which together constitute the sister group to the orang-utan.

it with *S. indicus*, but it was later reinstated as a separate species[20] on the basis of characters of the incisors, canines, premolars and posterior molars. In most of these characters it was presumed[20] that *S. meteai* possessed the derived condition with respect to the primitive hominoid morphotype and *S. indicus* the primitive condition. They both share, however, characters such as thickened enamel on the molar teeth, lower-crowned and more robust canines, and loss of molar cingula, which distinguish them from the primitive hominoid condition and indicate that the species presently assigned to *Sivapithecus* represent a clade, of which these are the distinguishing characters. As these characters are also shared by *Ramapithecus* it seems very probable that they are part of the same clade. This has been recognized implicitly by Pilbeam[11] in his combination of 'ramapithecines' and 'sivapithecines' in the family Ramapithecidae, and more explicitly by Greenfield[13] who dismissed even generic differences between them (although unfortunately he did so for the wrong reasons) and referred *Ramapithecus* to the genus *Sivapithecus*. This is certainly the simplest solution at present to a rather complicated situation, and although there is a risk that it is an over-simplification it does help to resolve many problems if the thick-enamelled Eurasian apes (excluding *Gigantopithecus*) are united in the genus *Sivapithecus*. This genus would then contain at least 3–4 species, which can be listed as follows with their geographical location and approximate ages:

S. indicus, India and Pakistan, middle to late Miocene, 11–8 Myr

S. punjabicus, India and Pakistan, middle to late Miocene, 11–8 Myr

Sivapithecus sp., China, late Miocene, 10–8 Myr

S. meteai, Turkey and Greece, late-middle Miocene, 11–10 Myr

Sivapithecus sivalensis[3] is of uncertain status, especially the type specimen of the species, and thus is omitted from the present discussion. The species of middle Miocene age assigned to *Sivapithecus* and *Ramapithecus*, *Sivapithecus darwini* from Turkey and Czechoslovakia[9] and *Sivapithecus africanus* and *Ramapithecus wickeri* from Kenya[8], are known only from extremely fragmentary dental remains and they lack the body parts that have been used in the present analysis to determine relationships. Therefore, these species also have been omitted from the present discussion.

Two consequences ensue from the recognition of the *Sivapithecus* group as a clade. First, if one member of the clade, that is, a species such as *S. meteai*, is accepted as being closely related to the orang-utan, then the other fossil species are also

linked in the same association. This would apply, for example, to species of *Ramapithecus* if they are congeneric with *Sivapithecus*. Only if characters are found to be present in more complete specimens that exclude them from this association (and also of course from the genus *Sivapithecus*) can it be accepted that they do not form part of this clade. Following this line of argument, in conjunction with the molecular and morphological evidence for the relationship of the extant apes, it is evident that '*Ramapithecus*' may not be related exclusively to man but may be related to the orang-utan.

The case for the hominid affinities of ramapithecines has most recently been reviewed by Kay[43]. He also refers '*Ramapithecus*' to *Sivapithecus*, although not as a separate species but to the species *S. sivalensis*. He shows that the species of *Sivapithecus* share the following synapomorphies with man: (1) broad mandibular body; (2) low-crowned molars with thick enamel; (3) rather reduced canine size; (4) rather reduced canine sexual dimorphism; (5) buccolingually broad upper canines; and (6) tendency to enlarged P_3 metaconids. These are said to be characteristic of the whole *Sivapithecus* clade and that this is therefore the sister clade of man. We accept Kay's interpretation of the significance of characters 1 and 5, although mandibular robusticity varies considerably for the different species of *Sivapithecus*, but there are greater difficulties with the others. Two of the characters, the enlarged P_3 metaconids and the thick enamel of the molars, are present also in the orang-utan, and therefore provide equally good evidence for a *Sivapithecus–Pongo* relationship as for a *Sivapithecus–Homo* relationship. We do not accept Kay's conclusion that canine size is reduced in *Sivapithecus* for two reasons; first, his data show that the range of canine size relative to the first molar is equivalent to the middle of the range of extant great apes: in other words *Sivapithecus* canines are relatively bigger than female great ape canines as well as being relatively smaller than male canines. Secondly, it must be considered that *Sivapithecus* may have relatively large molars for its body size[11], and if this is the case the ratio of canine/molar size may be misleading. Finally, we also disagree with the significance attached to reduced sexual dimorphism, as low sexual dimorphism has not been shown convincingly to be a valid characteristic of *Sivapithecus*.

The characters linking *Sivapithecus* with man are thus reduced to two: robust mandibles and buccolingually broad upper canines, two characters that are almost certainly functionally related. These characters certainly seem to be synapomorphies for *Homo* and *Sivapithecus*, but the likelihood of their being the result of parallel evolution must be given credence in view of the more numerous and functionally independent derived characters of the nose, the orbits, the palatal foramina and the incisors that are shown here to be shared between *Sivapithecus* and *Pongo*. We therefore consider it more likely that *Sivapithecus* species, particularly *S. meteai* and *S. indicus* but by inference also *Sivapithecus* (formerly *Ramapithecus*) *punjabicus*, are more closely related to the orang-utan than to man.

The other consequence arising from the proposed relationship of *S. meteai* and the orang-utan is that it provides an approximate minimum divergence data between the orang-utan and its extant sister group, the African apes and man. *S. meteai* itself comes from deposits about 10–11 Myr old, but the time span of *Sivapithecus* as recognized here is of the order 8–11 Myr. This age corresponds to the date of 10 ± 3 Myr suggested by the molecular evidence and strongly indicates a minimum age of at least 10–11 Myr for the divergence between the orang-utan clade and the clade containing the African apes and man. The divergence between the members of the latter must be subsequent to this period, and the molecular evidence for a prolonged common ancestry between the African apes and man suggests that their eventual divergence was considerably later than the middle Miocene and perhaps as late as the end of the Miocene 5–6 Myr ago[15].

There is one other consequence of the relationships proposed here, which will be considered briefly. The classification of the cladistic groups proposed in Fig. 3 would differ greatly from many current schemes. The most recent one by Szalay and Delson[5], for example, combines the great apes in the tribe Pongini with parallel tribes for *Dryopithecus* (Dryopithecini) and *Sivapithecus* (Sugrivapithecini). These are combined in the subfamily Ponginae, and *Ramapithecus*, *Australopithecus* and man are classified in the subfamily Homininae. These subfamilies are then grouped in the family Hominidae. Classifications based on Fig. 3 would have to recognize the chimpanzee, gorilla and man as one clade with the orang-utan and *Sivapithecus* (and '*Ramapithecus*') as another; a possible solution would be to classify these clades at subfamily level, as do Szalay and Delson[5], but with Homininae for the African apes and man, and Ponginae for orang-utan and *Sivapithecus* (and '*Ramapithecus*'). The African apes and man would then be divided at the level of tribe. An alternative classification at the family level is as follows:

- Hominoidea (Gray, 1825)
  - Hylobatidae (Blyth, 1875)
    - *Hylobates* (Illiger, 1811)
  - Pongidae (Elliot, 1913)
    - *Pongo* (Lacepede, 1799)
    - *Sivapithecus* (Pilgrim, 1910)
  - Hominidae (Gray, 1825)
    - Gorillinae (Hurzeler, 1968)
      - *Pan* (Oken, 1816)
      - *Gorilla* (I. Geoffroy, 1852)
    - Homininae (Gray, 1825)
      - *Homo* (Linnaeus, 1758)
      - *Australopithecus* (Dart, 1925)

This change from traditional classifications has long been advocated by Goodman[23], and it is one that is necessary with the recognition that the African apes are more closely related to man than they are to the orang-utan.

We thank N. Boaz, L. Brunker, E. Delson, S. Gould, T. Harrison, J. Lowenstein, L. Martin, E. Meikle and C. Stringer for helpful comments. V. Sarich provided helpful discussion on the molecular section of this paper, and much of the morphological evidence is the product of an ongoing collaboration with C.P. Groves. The Wenner-Gren Foundation, the L.S.B. Leakey Foundation and the Milton Fund of Harvard University provided grants to J.E.C. in support of part of this work.

Ancient and modern slopes in the Tharsis region of Mars

P. J. Mouginis-Mark*, S. H. Zisk† & G. S. Downs‡

The directions of lava flows in the Tharsis region of Mars are used to identify regional palaeo-slopes, vent areas and local topography. A comparison is made between these flow directions and the present day radar-measured topography; good agreement between these data sets indicates that little intra-regional tectonic deformation has occurred following the emplacement of the preserved lavas.

AS the youngest centre of constructional volcanism on Mars[1,2], the Tharsis region has been the focus of considerable attention directed towards gaining an understanding of the geophysical[3,4], geochemical[5] and volcanological[6] evolution of the area. Debate has centred on the relative importance of regional tectonic uplift versus constructional volcanism as the primary mechanism for the production of the observed relief[7,8], together with the attendant implications that such hypotheses would hold for lithospheric structure and crustal–mantle petrology. Until recently, it was believed that the centre of the broad Tharsis dome was located close to the three Tharsis Ridge volcanoes, where the surface rose to nearly 10 km above the martian datum[9,10]. New Earth-based radar measurements have shown, however, that Tharsis is much lower on average, with the mean elevation only 2–4 km above the 6.1 mbar reference surface[11]. In addition, the centre of the dome is evidently located further to the south-east than previously believed and is now centred on Syria Planum[12].

Nevertheless, considerable local topography (including numerous volcanic constructs) exist within Tharsis by virtue of the many outpourings of lava which characterize the area. As a consequence of the changing lithospheric load associated with this volcanic activity, deformation of areas such as the base of Olympus Mons would be expected if the lithospheric thickness was $\leq$150 km (ref. 13). In an attempt to search for recent tectonic deformation of this kind within Tharsis, we compare here the ancient slope directions (deduced from the orientations of lava flows) with the present-day slopes (derived from Earth-based radar measurements). Due to their propensity to flow parallel to the direction of slope, the eruptions of lava provide information on the characteristics of the local topography at the time of flow emplacement. In addition, the travel directions and areal extent of the flows can be used to describe further the nature of the volcanic activity within Tharsis because they permit the different eruptive centres and their relative volumes of lava to be recognized.

Flow measurements

Individual lava flows within Tharsis were mapped either from high resolution (20–150 m per pixel) Viking Orbiter images or from the new medium resolution (200 m) orthophotomosaics prepared by the US Geological Survey. The positions of these lava flows are shown in Fig. 1, with the exception of those flows which are located on the high flanks of the shield volcanoes. A few flow units in addition to those mapped may also exist, particularly to the west of Ulysses Patera and north of Noctis Labyrinthus, where only poor photographic coverage exists due to atmospheric opacity; some lobate flow edges are visible in these regions, but the boundaries cannot be traced for sufficient distances to infer their direction of travel.

A total of 475 lava flows longer than 20 km have been mapped (Fig. 1). These flows have typical widths of 5–10 km on the higher slopes of the volcanoes and 15–35 km on the lower flanks. Additional lava flows that spread out over wide areas and have widths greatly in excess of 40 km were deliberately excluded from this analysis because they were deemed unsuitable for the determination of their flow directions. In certain instances, particularly to the west of Arsia Mons, it has also proved difficult to map the total extent of each flow, since many flow segments are either partially buried by superposed younger units or their boundaries have become indistinct as more subdued relief is encountered close to their vents. Thus, while the flows measured here rarely exceed 200 km in length, previous estimates of 300–400 km appear to be quite plausible[14,15], while flow length maxima of ~1,000 km may also be possible for fissure eruptions originating at low elevations. For the flows included within this analysis, independent estimates of the flow thicknesses made from shadow measurements[14] indicate values between 5–20 m for the steeper slopes and 20–65 m for the generally flatter surrounding terrain.

The map of Tharsis lava flows (Fig. 1) enables both the regional slopes and the individual eruptive centres at the time of flow emplacement to be recognized. In agreement with the general observations of Schaber *et al.*[14], our analysis shows that the major palaeo-slope within Tharsis was down towards the north-west, with a high point present between Arsia and Pavonis Montes and a low located near to Olympus Mons. From the distribution of the flows, the linear extent of this north-west slope was at least 2,500 km, and there were also downhill gradients which extended away from Pavonis and Ascraeus Montes towards the north-east for 2,000 km, south-east from Syria Planum for 1,200 km and westward from Arsia Mons for ~1,000 km. While most of the flows originated from the four major shield volcanoes[14–16], additional lava flows were

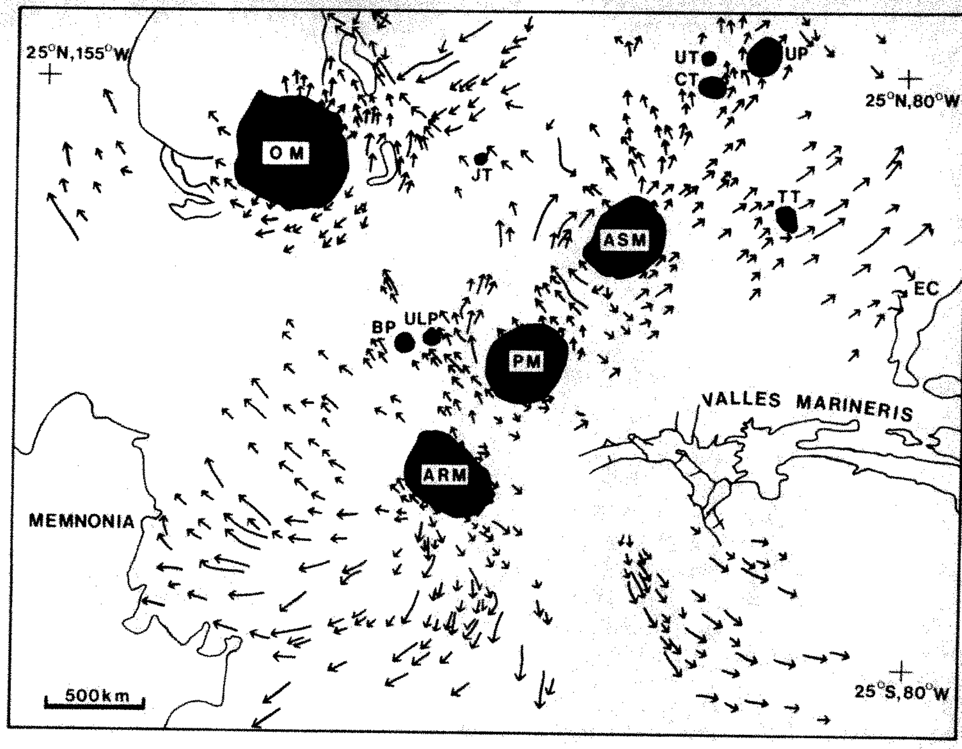

Fig. 1 Distribution of all lava flows included within this analysis. Length of arrow is equal to the length of the lava flow and shows the direction of travel. Volcanoes are shown in black where: ARM, Arsia Mons; ASM, Ascraeus Mons; BP, Biblis Patera; CT, Ceraunius Tholus; JT, Jovis Tholus; OM, Olympus Mons; TT, Tharsis Tholus; ULP, Ulysses Patera; UP, Uranius Patera; UT, Uranius Tholus. Also shown are the highland boundary in Memnonia (lower left), Valles Marineris, the Olympus Mons aureole (north-west of the volcano) and Echus Chasma (EC).

erupted in areas which lack obvious volcanic constructs (Fig. 1); Syria Planum and an area to the west of Ceraunius Fossae (25°N, 110°W) are two such examples. In these localities, several small cones of probable volcanic origin exist[17], but their significance as source regions for large volumes of magma had not previously been recorded. Lava flows >100 km in length originate from each of these two areas, indicating the existence of well developed fissure systems which were distinct from the conduits which supplied the magma to the major volcanoes.

Local deformations

In addition to illustrating the regional slopes within Tharsis, the orientations of the lava flows permit deformational features on a scale of a few hundred kilometres to be identified. Prominent amongst these is a circumferential depression, or peripheral trough, which surrounds the southern half of Olympus Mons[11]. Extending to distances of 300–350 km beyond the basal escarpment of the volcano, this depression has acted as a funnel to redirect lavas which consequently either flowed northward towards Arcadia Planitia or westward towards Amazonis Planitia. Segments of the aureole material to the east of Olympus Mons have been embayed and partially buried by lavas from both central Tharsis and Olympus Mons, while the much more extensive portions of the aureole to the north and west of the volcano, despite being down the regional slope[12], have remained unburied. From our investigation of the preserved record of volcanic activity, none of the lava flows erupted from Olympus Mons contributed to the lava pile which now constitutes central Tharsis (such as the area around Biblis and Ulysses Paterae); all the lava flows from the volcano travelled either to the north or west. This implies that the peripheral trough around Olympus Mons has been in existence for an extended period of time, rather than being a relatively recent response to crustal loading by the volcano after most of the lavas had been emplaced.

In contrast to Olympus Mons, the other three Tharsis shield volcanoes are noteworthy for the lack of preserved deformational features within the surrounding plains materials. A slight topographic rise ~330 km west of Ascraeus Mons, together with the tangential flow direction of lavas at the base of the volcano, suggest that a local depression may exist around this volcano, although subsequent infilling by lavas makes this identification uncertain. No similar evidence exists from the orientations of preserved lava flows for depressions around either Arsia or Pavonis Montes; flows from these two volcanoes travelled in almost radial directions from the summit calderas and adjacent fissure zones.

Only one example of surface deformation after lava flow emplacement can be found in the Tharsis region. To the north-east of the Olympus Mons peripheral trough, relatively old lava flows from the south-east have been partially buried and modified by more recent volcanism. In one instance, a sinuous lava channel was formed along a radial directed towards Olympus Mons and this lava channel cuts the older flows almost at right angles to the original flow direction (Fig. 2). Our interpretation of this dual flow direction is that after their emplacement, the older flows were tilted towards the south-west before the formation of the lava channel. Lithospheric loading of the area by the continuing construction of Olympus Mons could be the cause of this tectonic movement.

Present-day topography

Earth-based radar measurements of elevations on Mars have recently been referenced to the 6.1-mbar pressure surface[11].

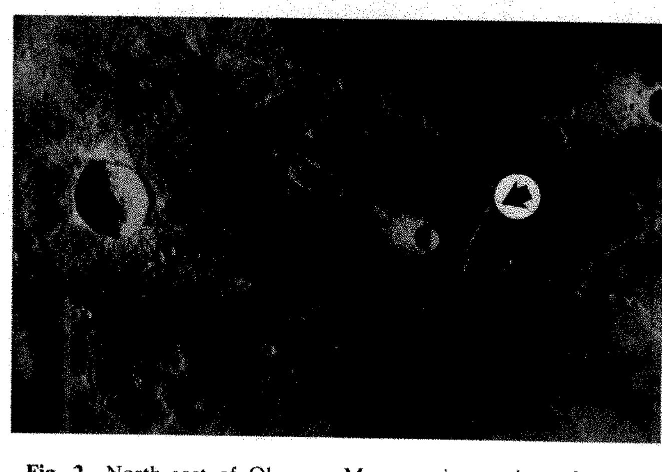

Fig. 2 North-east of Olympus Mons, a sinuous lava channel (source arrowed) cuts older lava flows which came from the south-east. The change in flow direction between these two eruptions is attributed to lithospheric loading associated with the construction of Olympus Mons. North is towards the top of image, which is centred at 29.8° N, 130.0° W. Image width is 60 km; Viking Orbiter frame 623A46.

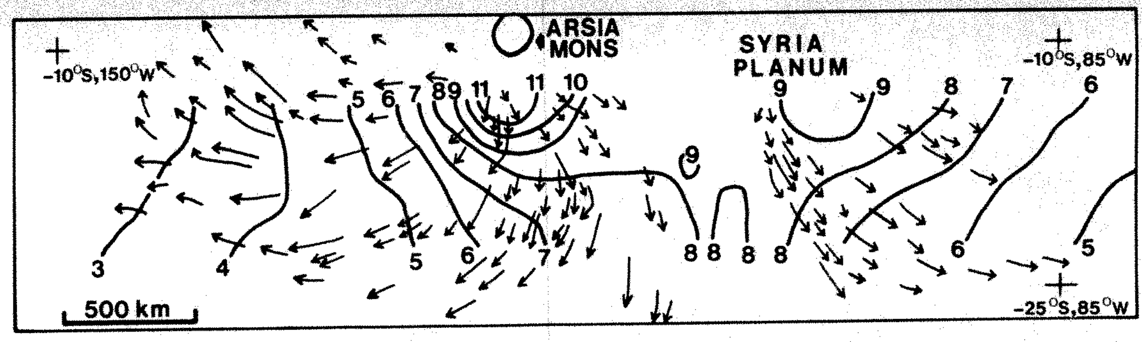

Fig. 3 Comparison of radar-derived topography and lava flow directions for the southern portion of the study area. Radar data give contours in 1-km intervals and are referenced to the 6.1-mbar pressure surface of Mars. Contours were hand drawn (by P.M.M.) from elevation measurements made in 1971 and 1973 between 14° and 21° S.

These data provide height information for the southern flanks of Arsia Mons and Syria Planum for latitudes 14–21°S. Data resolution for this area is ~10 km in longitude, 80 km in latitude and 100 m in altitude[18]. Using this radar-derived topography, it is therefore possible to compare the present day regional gradients with the observed flow directions (palaeo-slopes) to search for regional deformations which may have occurred after the cessation of the volcanic activity. Such tectonic deformation would be expected to be present if the lithosphere beneath Tharsis was thinner than ~150–180 km (refs 13, 19) due to the changing load associated with the protracted eruption of large volumes of lava[20,21].

The following comparison of these present and past slopes within southern Tharsis (Fig. 3) points to a strong agreement between the two data sets. The radar elevations corroborate that a regional slope extends downward from Arsia Mons towards Memnonia; the total change in elevation amounts today to >8 km. A slight (500–1,000 m) high is associated with the Claritas Fossae fractures, while Syria Planum represents the centre of a regional dome located at the western end of Valles Marineris[12]. Almost all the mapped lava flows cross the present day contour lines within about 10° of the local gradient (Fig. 3). Considering that the aforementioned resolution of the radar data provides only the general characteristics of the local topography, there is also good agreement between the regional slopes and the paths of the flows (such as those associated with the 'bending' of the flows south of Arsia Mons between latitudes 17°–22°, longitudes 110°–122°W). Essentially all of the observed lava flows are seen to travel generally down the present topographic gradient for their entire length. Close to the summit of Arsia Mons, however, where a parasitic shield is thought to be located[22], some flows do not follow the maximum slope. This may, on the other hand, be a consequence of the shallowness of the slopes (see below) and the relative thickness of the flows (~25 m (ref. 14)), which could have funnelled the younger flows around pre-existing units in a manner comparable to the diversion of certain terrestrial eruptions (ref. 23, p. 421).

Although the radar data set lacks sufficient areal coverage to compile a complete topographic map, scattered elevation values for parts of northern Tharsis are available[11] and permit the determination of the present-day slopes north of the equator. We have measured 14 slopes within Tharsis (all of which parallel the lava flow directions for distances of 150–1,250 km) using the radar data (Fig. 4). In each case, it is evident from the slope estimates (Table 1) that the lava flows travelled along paths that are consistent with the modern down-slope directions. All the radar-measured slopes seem to be very shallow, ranging from 0.75° for the southern flanks of Arsia Mons (profile L–L′) to 0.04° for a section of the Olympus Mons peripheral trough (profile C–C′). These slopes are, however, only best estimates from the radar data because each elevation estimate is an average of several measurements made within a 2° longitude sample bin[11]. Typically, 7–13 measurements are included in each sample, and the resulting standard errors for the averages range from 70 to 770 m (Table 1). Over the measured horizontal distances considered here, the maximum error in the slope determination would be about ±0.17°, while typical errors would be <±0.1°. Under these circumstances, only in the case of profile C–C′ could the down-slope direction of the profile change; although the absolute slopes would be different, all the remaining modern gradients are consistent with a down-slope movement of the lava flows even allowing for the resolution of the radar system.

Such a close match between the ancient and modern regional slopes indicates appreciable lithospheric stability within Tharsis. Although the absolute ages of the lava flows are not known, at least 14 distinct eruptive sequences of flows have been identified in this area[14] and these surface units have large differences in their superposed crater densities[21]. Crater counts give number densities ranging from 1.22×10^{-3} to 9.08×10^{-5} craters >1 km diameter per km^2 respectively for the Tharsis Montes unit 3 (tm_3) and Olympus Plains (op) units of Scott and Tanaka[21], suggesting a wide age range. It appears, therefore, that there was relatively little tilting of geological units during (or after) the extended period of Tharsis volcanism represented by the currently exposed lava flows. This in turn implies that the lithospheric structure beneath Tharsis was rigid enough to support the changing load associated with volcano construction, suggesting that the lithosphere may indeed have been thicker than ~150–180 km (refs 13, 19, 20).

Volcanology

In addition to the slope information, subtle differences in the style of Tharsis volcanism are also indicated by the distribution of the observed lava flows. From the large number of flows located between the three Tharsis Ridge volcanoes (Fig. 1), it

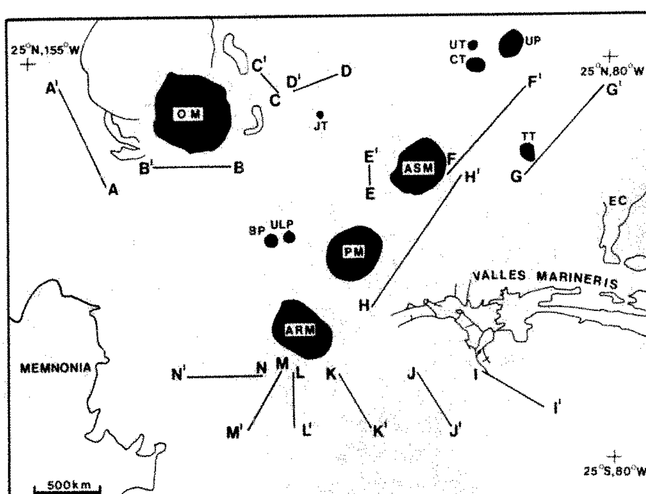

Fig. 4 Location of the surface slopes measured from Earth-based radar data (see Table 1). Each slope is coincident with the lava flow directions shown in Fig. 1, with the downslope measurement denoted by the superscript bar. Base map abbreviations are the Hsame as those in Fig. 1.

† Straight-line distances are given from the middle of the up- and down-slope points.

‡ Height difference between the mean up- and down-slope altitudes.

§ Surface slopes, estimated errors for these slope values are derived from the 1σ values in the altitude measurements.

is evident that large volumes of magma were also erupted at these localities from saddle fissures (in addition to the magma erupted from the summit calderas). Furthermore, a change in eruptive style from true shield volcanism (most of the magma erupted from near-summit vents) to flank activity (most of the magma finding egress at the saddle crests) evidently took place on both Ascraeus and Pavonis Montes late in their evolution, because no flows from their summit calderas extend across the saddle flows. Eruptions from Arsia Mons also display a similar change in vent location, with large eruptions of magma from the parasitic cone[22] postdating the near-summit activity. This sequence of vent relocations for these volcanoes is at least qualitatively consistent with the inferred history of the calderas of the Tharsis volcanoes[24].

All the small volcanic constructs of the Tharsis region (Biblis, Ulysses and Uranius Paterae and Tharsis, Uranius, Jovis and Ceraunius Tholi) show evidence of partial burial by lava flows which conform to the regional slopes identified in this analysis[25]. The absence of minor deviations from a straightline path, which most of the flows follow, indicates that there are no additional topographic rises within central Tharsis which could be other low volcanoes. Thus, it seems that the entire sequence of lava plains in this region[21] was constructed by a few major volcanic centres (not all of which were associated with the large shields); eruptions of magma were evidently confined to large, frequently reactivated fissure systems, rather than many small widely dispersed vents, during the period of activity presently exposed at the surface.

Comparing the size and number of the flows originating from Arsia Mons (42 > 100 km long) and Olympus Mons (3 > 100 km long) indicates that it was likely that these two volcanoes had appreciably different magma supply rates from their respective source regions. If it is assumed that these martian shields had eruption characteristics comparable to terrestrial volcanoes (that is, lava flow length was related to magma effusion rate[26]), the longer and more numerous flows from Arsia Mons would imply higher effusion rates than for Olympus Mons. Variations in effusion rate are also likely for different parts of Olympus Mons, because relatively long flows are only common on the eastern and southern flanks of the volcano while the aureole material to the north-west is almost devoid of embaying lavas. Thus, the traditional view that Olympus Mons is the largest volcano in the Solar System[1] may not be correct, because Arsia Mons not only has a larger caldera, but from this analysis also appears to have higher magma effusion rates and represents a topographic high that dominates the surrounding region for radial distances >1,000 km in any direction from its caldera. In comparison to both Arsia and Olympus Montes, the mass eruption rates for individual flows from Pavonis (seven flows longer than 100 km) and Ascraeus (nine flows longer than 100 km) were probably intermediate between these two extremes.

Conclusions

The use of lava flow directions as palaeo-slope indicators and Earth-based radar measurements of present topography demonstrate that little deformation of the Tharsis region has occurred over an extended period of time. Very few deformational features attributable to subsidence around the volcanoes can be recognized from the flow directions; a peripheral trough surrounds Olympus Mons and there is some evidence for a similar feature to the west of Ascraeus Mons. Only one example of surface tilting after lava emplacement has been found (to the north-east of Olympus Mons), suggesting that the increasing lithospheric load due to progressive buildup of the lava pile had little influence on local topography. It is therefore postulated that early in the evolution of Olympus Mons, the lithosphere was <150 km thick[13], thereby permitting the formation of the peripheral trough. For much of the period in which the preserved volcanic activity took place, however, lithospheric thickness has evidently been >150–180 km (refs 13, 19), as evidenced by the lack of local or regional deformation between the time of these eruptions and the present day.

Although regional slopes are very shallow today, if they truly reflect the gradients present at the time of volcanic activity, they nevertheless controlled lava flow directions over distances in excess of 1,000 km. In this respect, the rise associated with Syria Planum[12] has controlled the flow directions of many of the Tharsis lavas, while Claritas Fossae was also a local high at the time that Arsia Mons was active. It is evident that the style of volcanic activity was quite diverse within the region, with fissure eruptions from the saddles between the Tharsis Ridge volcanoes contributing large volumes of lava to the surrounding plains. In this connection, it is proposed that Arsia Mons, with its extensive lava flows and great relief, should supersede Olympus Mons for the title of the largest known volcano in the Solar System.

We thank Jim Head for his comments. This research was supported by NASA grant NER 40-002-088 of the Planetary Geology Program.

A model of the Antarctic Ice Sheet

J. Oerlemans

Institute for Meteorology and Oceanography, University of Utrecht, Princetonplein 5, Utrecht 3508 TA, The Netherlands

Numerical modelling of ice sheets and glaciers has become a useful tool in glaciological research. A model described here deals with the vertical mean ice velocity, is time dependent, computes bedrock adjustment and uses an empirical diagnostic relationship to derive the distribution of ice thickness in ice shelves. The rate of snowfall and ice/snow melt depends on the (prescribed) sea-level temperature, surface slope, elevation and distance to open water. The model is able to reproduce the major features of the Antarctic Ice Sheet. When it is run to a steady state for present climatic conditions, the main difference with the present ice sheet is that the shallow parts of the Weddell Sea become covered by grounded ice.

To understand ice-sheet histories from proxy data, and to see whether they are physically plausible, numerical ice-sheet models can have an important role. Although the theory of ice flow is formulated reasonably well (this does not apply to what happens at the ice–bedrock interface), modelling of large ice sheets requires a pragmatic approach. It is not possible to solve the full stress–strain rate relationships, together with the thermodynamic equation, for the whole Antarctic Ice Sheet, for example. This certainly applies if one wants to carry out integrations over 100,000 yr or so.

In recent years, ice-sheet models based on a flow law for the vertical mean ice velocity have become popular[1–4]; they have been used mainly for palaeoclimatic studies, and in complexity come between perfectly plastic models[5] and three-dimensional models[6]. In these models temperature is not calculated, so constant bulk flow parameters have to be used. In spite of the simplifications involved, the vertically integrated models capture most of the characteristics of large ice sheets.

Based on these observations, I have developed a vertically integrated model of the Antarctic Ice Sheet. In fact the Antarctic Ice Sheet is an excellent test case for the 'vertical mean approach', because it has a very irregular bedrock topography and subtle grounding line dynamics at some places, and its present-day physical characteristics are well documented[7].

The first version of the present model was used to investigate how sensitive the Antarctic Ice Sheet is to changes in the ice accumulation rate[2]. However, this version did not include bedrock adjustment and ice shelves, and could only be used for short integrations.

The second version, results of which are presented here, has much more internal freedom. The response of the bedrock topography to a varying ice load is computed, and a diagnostic relation for ice shelves (though simple) is included. A varying bedrock topography introduces the problem of initial conditions. It is not very well known how close the present bedrock topography is to isostatic equilibrium. A 100-m error in the equilibrium bedrock elevation will be insignificant in the central parts of the East Antarctic Ice Sheet, but is very important in such marginal regions as the Ross Sea.

Model description

The calculation of ice flow is based on a flow law relating vertical-mean horizontal ice velocity u to basal shear stress τ_b

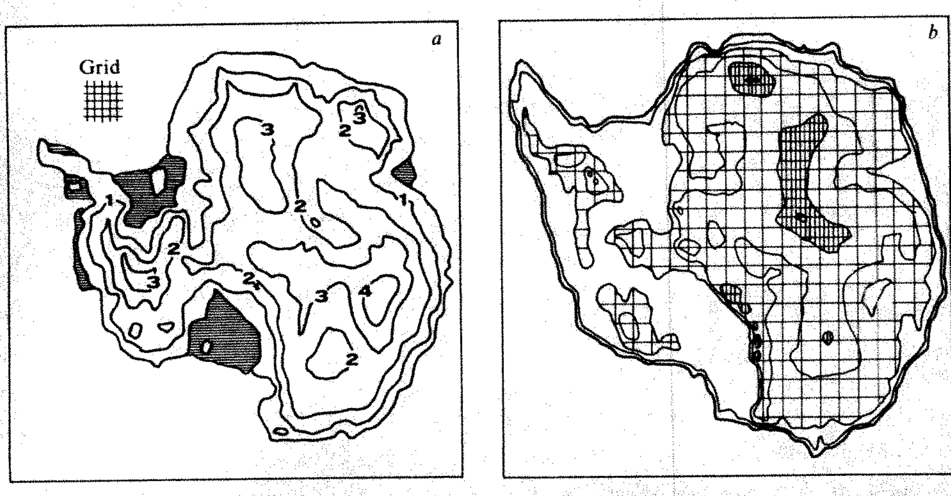

Fig. 1 *a*, Observed ice thickness as resolved on the model grid (part of which is shown in the upper left corner). Contour interval is 1 km. The major ice shelves are indicated by shading. *b*, Equilibrium bedrock topography in the case of no ice load. Contour interval is 1 km. The lowest contour level is 2 km below present sea level. Light shading indicates bedrock above sea level, heavy shading bedrock above the 2 km level. All input data are from ref. 10.

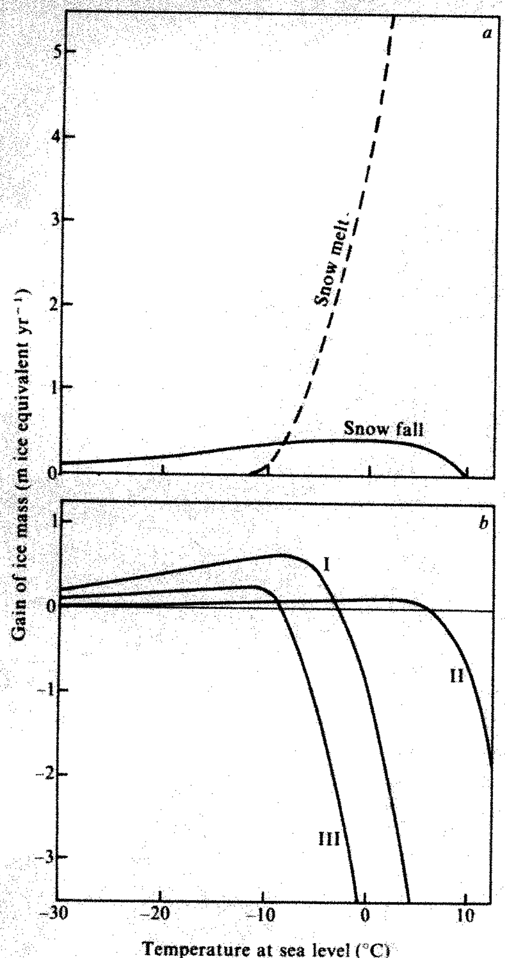

Fig. 2 Formulation of the mass balance, or ice accumulation rate, for the ice-sheet model. *a*, Dependence of snow/ice melt and snowfall on sea-level temperature for zero surface elevation and zero surface slope. *b*, The mass balance for different local conditions: I, a surface slope of 0.02 and elevation of 500 m, at the edge of the continent; II and III, the interior of the continent for elevations of 2,000 m and 0 m respectively.

(ref. 8). This law is of the Glen-type: $u = k\tau_b^m$, where k and m are flow parameters. The expression for u can be generalized to the two-dimensional case (involving assumptions that will not be discussed here), yielding the vertically integrated mass flow vector **M**:

$$\mathbf{M} = KH^{m+1}[\nabla H' \cdot \nabla H']^{(m-1)/2}\nabla H' \quad (1)$$

where H is ice thickness, ∇ is the two-dimensional (horizontal) gradient operator and $H' = H + h$ is the surface elevation (h is the bedrock elevation with respect to sea level). So ice flows down the surface slope $\nabla H'$, and the rate at which this happens increases strongly with both ice thickness and surface slope. The evolution of the ice sheet is determined by the conservation of ice mass, that is

$$\partial H/\partial t = -\nabla \cdot \mathbf{M} + G \quad (2)$$

G is the ice accumulation rate at the surface, expressed in units of ice depth per unit of time.

The response of the bedrock to the ice load is computed from:

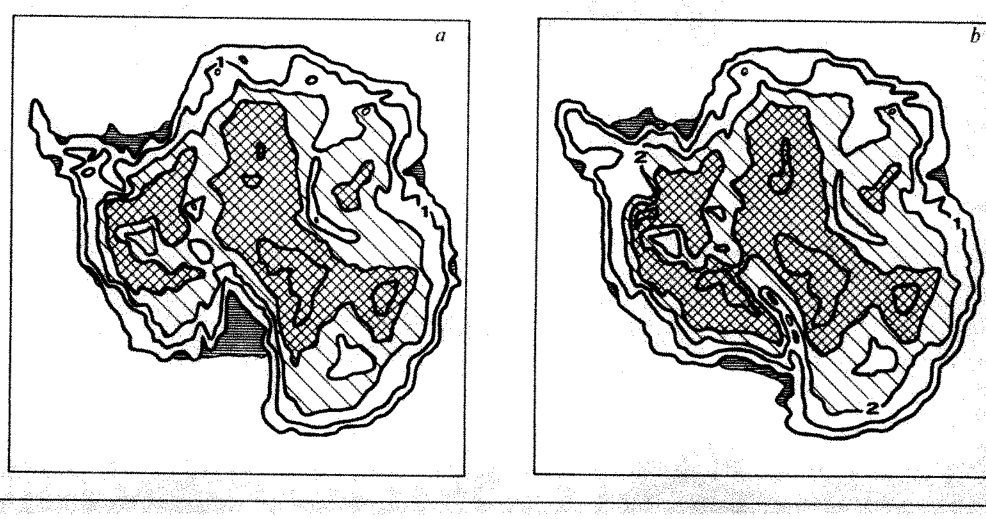
$$\partial h/\partial t = -(h - h_0 + H/3.2)/T \quad (3)$$

where h_0 is the equilibrium bedrock height without ice load. Equation (3) formulates a damped return, with time scale T, to local isostatic equilibrium. For loads with a horizontal length scale of more than a few hundred kilometres, equation (3) forms a good approximation[9]. For smaller loads, the flexural rigidity of the lithosphere becomes important. So, in general, equation (3) should work reasonably well, but for very small ice sheets or near the edge of a large ice sheet errors may occur (order of magnitude: 50 m).

Given the present bedrock topography and the distribution of ice thickness (Fig. 1*a*), and assuming that the present state of Antarctica is close to equilibrium, h_0 can be computed. Using data from the Russian Atlas of Antarctica[10], resolved on a grid with a spacing of 100 km, yields a no-ice bedrock topography h_0 as shown in Fig. 1b. This clearly shows how little of the bedrock beneath the present West Antarctic Ice Sheet is actually above sea level, even if the ice load is removed. Because we cannot be sure that the Antarctic Ice Sheet is close to a steady state, h_0 may be subject to errors. This applies in particular to the shallow Ross and Weddell seas, which were probably captured by grounded ice during the last ice age (20,000 yr ago). So it is possible that in these areas uplifting is still in progress[11]. Nevertheless, the bedrock topography displayed in Fig. 1*b* will serve as the initial condition for h, simply because a sound alternative is not available.

Ice shelves have to be taken into account to let the position of the grounding line be determined by the model. A prognostic equation for ice shelf growth/decay would not be feasible, because it would require a very small time step in the computations. Instead a diagnostic procedure is included. The thickness of floating ice at some point is calculated from the degree of enclosure (which is between 0° and 360°) by grounded ice, weighted with the distance to the grounding line and the ice thickness at the grounding line. In the present model only four directions (0°, 90°, 180° and 270°) are checked for each grid point to estimate the enclosure. An additional condition is that the ice shelf cannot be maintained if its thickness drops below 250 m. For an optimum choice of the proportionality constants appearing in this formulation, the calculated ice shelves for the

Fig. 3 Equilibrium states of the Antarctic Ice Sheet, computed with the numerical model for present sea level (*a*) and a sea-level stand of 100 m below the present one (*b*). In both integrations the initial condition was $H = 0$. Ice shelves are indicated by horizontal shading. Heavy lines are contours of ice thickness, except the outer one which gives the grounding line. The contour interval is 1 km. Light shading indicates ice thickness > 2 km, heavier shading ice thickness > 3 km.



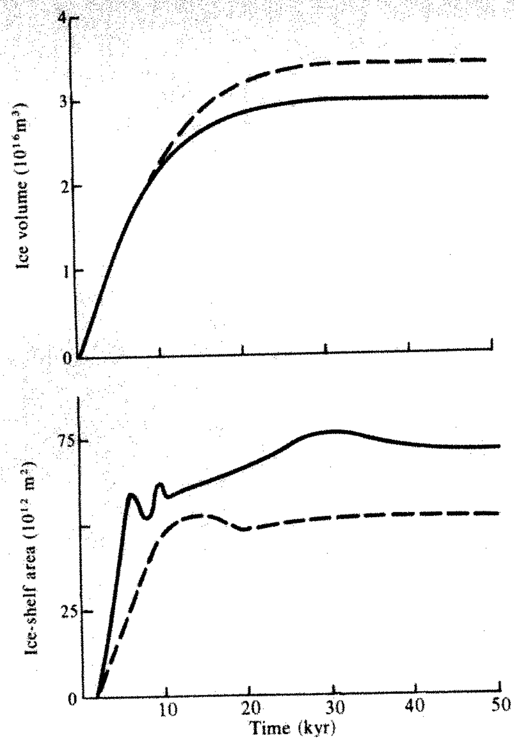


Fig. 4 Total ice volume and area covered by ice shelf, showing how the equilibrium states of Fig. 3 are reached. Solid line, experiment with present sea level; dashed line, experiment with the 100 m drop in sea level.

present distribution of grounded ice appear at the right locations with approximately the right thickness. Although ice-shelf dynamics does not explicitly occur in this procedure, it is dealt with in an implicit way, of course. It is no coincidence that ice shelves occur where the degree of enclosure is large. The compressive stresses associated with large enclosure counteract the ice thinning due to regular spreading. The present procedure mimics this mechanism well.

Because surface temperature and orographic enhancement of precipitation depend on the distribution of ice thickness, a general formulation for the ice accumulation rate G is desirable in which these effects appear in an explicit way. Based on the present distribution of surface elevation, surface slope and accumulation rate[10], the gain of ice mass due to precipitation is written as (in m ice equivalent yr^{-1}):

$$P = \max[0.05; f(\theta_0)(0.3 + 14\nabla H' - 4 * 10^{-5}H')/C] \quad (4)$$

So precipitation increases with surface slope and decreases with surface elevation. C is a 'continentality factor', which is computed by checking how many grid points in a circle of radius 500 km are covered by ice or bare ground. C ranges from 1 for an island of one grid point to 2 for the interior of a continent. The function $f(\theta_0)$, where θ_0 is sea-level temperature, models the dependence of snowfall on atmospheric water vapour content and the transition from snow to rain. Its shape is shown in Fig. 2a, in which a snowfall curve is drawn for $H' = 0$ and $\nabla H' = 0$. It is based on climatological practice and climatic change experiments with circulation models of the atmosphere[12,13].

Parameterization of ice/snow melt is based on mass-balance studies at the edge of the Greenland Ice Sheet[14]. With the assumption that the yearly cycle in surface temperature is more or less conserved in conditions of climatic change, the following approximate relation holds:

$$\begin{aligned} \text{melt} &= 0 && \text{if } \theta_s < -12\,^{\circ}\mathrm{C} \\ \text{melt} &= (12+\theta_s)^2 * 0.028 && \text{if } \theta_s \geq -12\,^{\circ}\mathrm{C} \end{aligned} \quad (5)$$

as for P, the unit is m ice equivalent yr^{-1}; θ_s is surface temperature which can be calculated from θ_0 by using a constant lapse rate γ (so $\theta_s = \theta_0 + \gamma H'$). Equation (5) only holds for temperatures below 0 °C or so, but this is sufficient because higher temperatures do not permit any ice cover to survive.

The difference between snowfall and ice/snow melt makes up the mass balance G. Given the surface slope and elevation, and the continentality factor, it only depends on sea-level temperature. The first three factors are determined by the shape of the ice sheet itself. So climatic change experiments can be performed by varying θ_0 only.

To illustrate how the mass balance depends on local conditions, Fig. 2b shows $G(\theta_0)$ for three typical conditions: (I) on the edge of an ice sheet, (II) in the interior of the continent at 2,000 m elevation, (III) in the interior at sea level.

The formulation of the mass balance described above is capable of reproducing all major characteristics of the present mass-balance field over the Antarctic Ice Sheet. It adds considerably to the internal freedom of the model. For example, zones of high precipitation rate follow the edge of the ice sheet, which is certainly realistic.

All model equations are solved with a numerical scheme on a grid with 100-km spacing between the grid points (see Fig. 1a). The time step used is 10 yr. Model parameters not yet specified are: $m = 2.5$ and $K = 0.5\ \mathrm{m}^{-3/2}\ \mathrm{yr}^{-1}$ (flow parameters), $T = 4{,}000$ yr (e-folding time scale for bedrock adjustment) and $\gamma = -8\,^{\circ}\mathrm{C\ km}^{-1}$ (lapse rate). Values of K and m were found by tuning the model to the present Antarctic Ice Sheet for prescribed and fixed bedrock elevation, ice accumulation rate and grounding line. However, the choice is not crucial: other combinations of m and K can be found to give similar results.

Results

In the first experiment the model was run to a steady state starting from no ice cover and bedrock topography h_0. The sea-level temperature was set at −14 °C. It takes ~30,000 yr before a steady state is approached, so the integration was

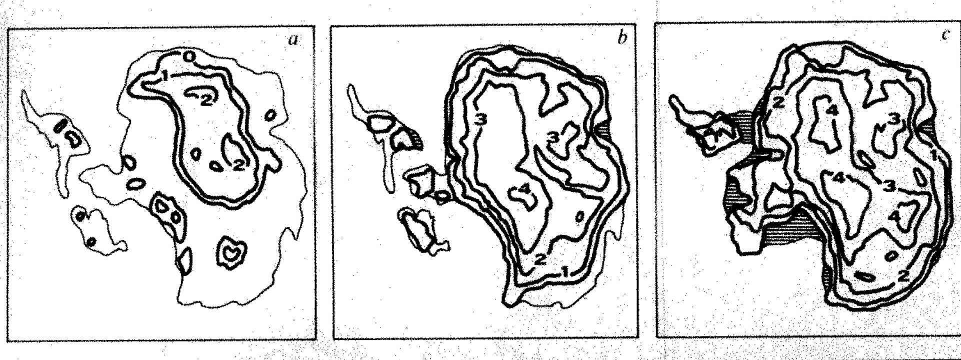

Fig. 5 Equilibrium states of the model Antarctic Ice Sheet for θ_0, the annual sea-level temperature: a, $\theta_0 = 5\,^{\circ}$C; b, $\theta_0 = 0\,^{\circ}$C; c, $\theta_0 = -5\,^{\circ}$C. Heavy lines are contours of ice thickness (km). Ice shelves are indicated by horizontal shading.

carried out over 50,000 yr This takes about 30 min central processor time on a CDC7600 computer

The calculated ice distribution is shown in Fig 3*a* Comparing this with Fig 1*a* shows that the model simulation is not too inaccurate, certainly not if one realizes that both bedrock elevations and mass balance are internally generated Also, note that the state of Fig 1*a* is not necessarily close to equilibrium, so that a sound judgement of the model performance cannot be made The major difference between the simulated equilibrium state and the present observed state of the Antarctic Ice Sheet is the extension of grounded ice in the vicinity of the Antarctic Peninsula In the model simulation a large part of the Weddell Sea is covered by grounded ice As a consequence, the ice thickness in the western and central parts of the Antarctic Ice Sheet is larger, and the total ice volume is ~25% more than the presently observed volume

The Ross Ice Shelf is well reproduced by the model, but the slope of the ice surface along the grounding line is steeper than observed This is probably because the model does not take into account enhanced ice-mass discharge by extensive basal sliding (which is supposed to operate in these regions)

Figure 3*b* also shows the equilibrium state calculated for a sea-level stand which is 100 m below the present one This was done to investigate the effect of glaciation in the Northern Hemisphere on the Antarctic ice volume The experiment was identical to the first one (the same initial conditions) except for the 100-m sea-level drop

Obviously, the West Antarctic Ice Sheet is sensitive to such a sea-level lowering the grounding line in the Ross Sea advances hundreds of kilometres At the upper (southern) tip of the Ross Sea, the ice thickness reaches 4 km Grounding line advance in the Weddell Sea is less spectacular, because in the present-day simulation a large part of the shallow sea is already covered by grounded ice Altogether, the volume of the West Antarctic Ice Sheet increases dramatically if the sea level lowers by 100 m According to Fig 4, the total ice volume increases by ~15% If sea level is reset to its present value, the ice sheet appears to remain stable Additional experiments revealed that a sea-level rise of at least 600 m is required to initiate grounding line instability in the Ross Sea (sea level temperature being equal) This suggests that in reality basal sliding must have had an important role in the deglacierization of the Ross Sea at the end of the last glacial extreme, because a 600 m sea-level rise did not occur, of course Basal melting may have been present during the grounding-line advance, thus keeping the ice thickness of the 'Ross Ice Sheet' small, or it may be triggered by the Holocene climatic warming However, such considerations are speculative

So far sea-level temperature θ_0 has been kept constant Note, however, how the model ice sheet reacts to changes in θ_0 Figure 5 shows steady-state ice sheets computed with $\theta_0 = 5, 0, -5$ °C respectively For $\theta_0 = 5$ °C, the mass balance is positive only in mountainous regions In general, the ice does not reach the coast but melts at the ice-sheet edge For $\theta_0 = 0$ °C, the ice sheet covers most of the eastern part of the Antarctic continent, but ice cover in the western part is still restricted to higher regions For $\theta_0 = -5$ °C, part of the West Antarctic Ice Sheet is formed, although the (present) Antarctic Peninsula is not yet attached to the main ice sheet A further drop of θ_0 of a few °C creates the ice sheet shown in Fig 3*a* There is not much in between a steady state in which the Weddell Sea is not covered by grounded ice did not appear

An interesting feature in these experiments is the large ice thickness occurring for $\theta_0 = -5$ °C in the central parts of East Antarctica (compare with Fig 3), this is due to the higher snowfall rates (see Fig 2) However, such findings critically depend on the parameterization of the mass balance and should be considered with caution

Discussion

The experiments described above should be considered as a first step in developing a more or less complete model of the Antarctic Ice Sheet Fine tuning of the model has not yet been attempted and several physical processes are not yet included (for example, the impact of extensive basal sliding) So what can we learn from these experiments?

First, it seems that a vertically integrated model is capable of reproducing the influence of mountain ranges on the distribution of ice thickness This is particularly clear if one considers an experiment in which the bedrock topography is fixed (see ref 2) In that case the model simulation is very good and errors are only due to the poor resolution of some bedrock irregularities In fact the value of the flow parameter *K* used in this study was found by tuning the fixed-bedrock model version to the present distribution of ice thickness Even if the mass balance and bedrock elevation are free, the simulated ice sheet closely resembles the present Antarctic Ice Sheet Moreover, because we do not know whether the ice cover in the Weddell Sea region represents an equilibrium state, we cannot state that the model result of Fig 3 is in error (there is some evidence that ice cover on the Antarctic Peninsula is expanding[15])

Experiments carried out by Budd and Smith[16] using a similar model of the Antarctic Ice Sheet produced results in agreement with those presented here, although they used a different flow law This again demonstrates that for large-scale modelling of ice sheets the precise form of the flow law is not important models can be easily tuned to give similar results

The Quaternary history of the Antarctic Ice Sheet[17] seems to fit in the picture emerging from the numerical experiments For a small sea-level drop (due to formation of ice sheets in the Northern Hemisphere) the ice sheet jumps to a state with large ice volume It returns to a state with small ice volume only if sea level and sea-level temperature are sufficiently high (during a Northern Hemisphere interglacial) However, the required increase in sea level and/or temperature is very large and additional mechanisms are apparently needed to remove the grounded ice from the Ross and Weddell seas Surging of the West Antarctic Ice Sheet could be one of them

Future development of this model will include a more refined treatment of ice shelves, computation of the temperature field within the ice and a calculation of the effect of basal sliding on ice-mass discharge In such a model ice surges may occur Experiments with a one-dimensional model version including thermodynamics have shown that such events can be modelled very well by vertically integrated models[18] The computational efficiency of the vertically integrated models (as compared with models with a grid in the vertical direction) will make it possible to study possible surging of the Antarctic Ice Sheet as a 'latitude–longitude problem' instead of looking along a steady flow line[19]

Effects of volatiles on mixing in calc-alkaline magma systems

Herbert E. Huppert*, R. Stephen J. Sparks† & J. Stewart Turner‡

The intimate mixing between different magmas of disparate densities, characteristic of some calc-alkaline magma systems, is explained by a new mechanism involving the emplacement of a layer of wet undersaturated mafic magma at the base of a magma chamber containing more differentiated magma Turbulent transfer of heat between the mafic magma and the overlying magma leads to crystallization and exsolution of volatiles in the lower layer For an initial water content of a few per cent the bulk density of the mafic magma can become equal to that of the overlying magma causing overturning and intimate mixing of the magmas The mechanism is most probable in the low pressure environment of a high level magma chamber

THE replenishment of a magma chamber by an influx of new magma from depth has been recognized as important in determining petrological and geochemical characteristics of volcanic and plutonic rocks[1] and in triggering volcanic eruptions[2–5] Previous investigations of the fluid dynamics of replenishment[3 6–9] have been directed mainly towards understanding systems involving dry basic magmas and have not been concerned with effects resulting from the release of gas In this article we investigate some of the fluid dynamical phenomena due to the presence and release of water vapour which can occur when a magma chamber is replenished by hydrous magma, and consider specifically magmas of the calc-alkaline association We note that the term 'calc-alkaline' is a common, but imprecisely defined way of describing magmas which are generally associated with orogenic belts and some island arcs Such magmas are usually, but not ubiquitously, characterized by low amounts of Fe enrichment and relatively high amounts of volatiles

There is increasing evidence that intimate mixing of magmas is a common phenomenon In basaltic magmas mixing can be explained in many circumstances because differentiated basaltic magmas can have the same density as higher temperature, more primitive basaltic magmas[3 6 9] Also the relatively low viscosity of many basaltic magmas allows rapid mixing between them However, evidence for magma mixing in volcanic rocks of the calc-alkaline association is also common The belief that mixing has an important role in the evolution of many basaltic andesites, andesites and dacites is based on observations of disequilibrium phenocryst assemblages, inhomogeneous glass compositions, wide ranges of compositions of glass inclusions in neighbouring phenocrysts, banded pumice fragments and mafic clots or micropillows incorporated in more silicic pumice or lava which show distinctive quench textures[5 10–14] Possibly the most convincing petrographical evidence for intimate mechanical mixing comes from the occurrence of bimodal phenocryst assemblages Many basaltic to andesitic lavas, for example, contain both calcium-rich and calcium-poor plagioclase phenocrysts and orthopyroxene and augite with high Fe/Mg ratio together with pyroxene with low Fe/Mg ratio[11–14] Petrological arguments often indicate that mixing between two or more compositionally distinct magma batches must have occurred only shortly before eruption, leading to the suggestion that mixing may even trigger an eruption[2 4 5 10] or alternatively that the mixing was a consequence of the eruption

If magma mixing is accepted as a widespread process in many calc-alkaline magma systems, there is a major physical problem to solve Dry magmas of the calc-alkaline association show a steady decrease in density with differentiation along with the decline in temperature[15] In a conventional model of a volcano, the plumbing system or chamber is filled with magma which gradually differentiates during repose periods If new undersaturated magma replenishes a chamber from depth (perhaps resulting in an eruption) and forms a lower layer it will, in general, be more primitive, hotter and denser But the decrease in density of the new magma due to crystallization and thermal effects alone is not sufficient to make the densities of the new and resident magmas equal Thus there does not at first sight appear to be a driving force in such a situation to cause mixing This argument, however, assumes that vapour is absent (no free volatiles) Calc-alkaline magmas are frequently rich in water, and Anderson[16] has summarized the evidence which suggests that the water content of many mafic to intermediate calc-alkaline magmas is often in the range 1–4% by weight Eichelberger[5] has shown that the presence of either dissolved or exsolved volatiles in calc-alkaline magmas has large effects on bulk density We continue along this line to demonstrate that even a small percentage of volatiles can have profound effects on the fluid dynamics of convection in replenished magma chambers

We consider in this article the influence of water exsolution on the densities of oversaturated hydrous mafic magmas and show that the induced changes in density can be substantial at low to moderate pressures This idea follows on from the study of Eichelberger[5] who, influenced by observed density differences of mafic inclusions within rhyolitic lavas, proposed that vesiculation of hydrous mafic magma at the interface between two layers can cause density changes large enough to allow mafic magma to become buoyant in more silicic magma However, only the relatively thin interfacial region would be destabilized by the process suggested by Eichelberger, and not the entire lower layer We aim to demonstrate that density changes in the whole layer of saturated hydrous basaltic or andesitic magma can be considerable and that, at low to moderate pressures, intimate mixing can take place between magmas of the calc-alkaline association

Effects of volatile release on magma density

It follows from basic principles that at equilibrium the bulk density of a hydrous saturated magma in the presence of excess water is given by

$$\sigma^{-1} = RT(N-n)/P + (1-N+n)/\rho \qquad (1)$$

where σ is the bulk density of the magma, R is the gas constant, T is the temperature in Kelvin, P is the pressure, N is the total weight fraction of water, n is the saturated weight fraction of water dissolved in the melt phase of the magma, and ρ is the

0028-0836/82/240554-04$01.00

weighted density of crystals plus melt The first term in equation (1) represents the contribution due to the gas and the second term that due to the crystals and melt Only if $N > n$ is there any gas, otherwise $\sigma = \rho$ The perfect gas law can be used in equation (1) because at the temperatures and pressures under consideration the departures from this law are less than a few per cent

The weight fraction n can be estimated from data on the saturation concentration of water in silicate melts[17] The solubility of water can be calculated from the empirical formula

$$n = s(1-x)P^{1/2} \tag{2}$$

where s is the solubility constant and x is the weight fraction of the crystalline phases in the magma

As an example, we consider the case of hydrous basaltic magma injected into the base of a magma chamber containing more fractionated, cooler and lower density magma (basaltic andesite, andesite or dacite) We make the simplifying assumptions that the crystallization of the basaltic magma involves only anhydrous phases The bulk density, ρ, of the residual melt and crystals has been calculated by assuming that the crystals have a constant density of 2 8 g cm^{-3} and by evaluating the decrease in density of the residual melt as water is concentrated by crystallization The density of the melt was calculated using the method of Bottinga and Weill[18] Variations of ρ with T alone due to thermal expansion are neglected because they are negligibly small in comparison with changes in bulk density of the magma due to volatile exsolution The solubility constant $s \approx 0\ 0014$ bar$^{-1/2}$ is taken from solubility data of water in Mount Hood andesite[17]

Finally, we require a relationship between temperature and crystal content The fractional crystallization of calc-alkaline magmas is quite complex and varies from volcano to volcano Thus a unique relationship cannot be accurately formulated However, inspection of estimates on the eruption temperatures and on fractional crystallization models of calc-alkaline magmas suggests that

$$T = 1{,}373 - 200x \tag{3}$$

is a plausible expression[14 19 20] The results of our density calculations are not in fact strongly dependent on temperature and thus an approximate relationship such as equation (3) seems acceptable

Figure 1 presents the results of bulk density calculations for a hydrous basalt crystallizing at 0 5, 1 5 and 3 0 kbar pressure with an initial temperature of 1,100 °C and zero initial crystal content The specific calculations presented are representative of the general behaviour of gas-rich magmas and are similar to the results of Eichelberger[5] From equation (2), the maximum total weight fraction of dissolved water in a silicate melt is represented by $N = SP^{1/2} \equiv N_0$ For $N < N_0$, the magma is initially undersaturated It continues to be undersaturated until the weight fraction of crystals $x = 1 - (N/N_0)$, when saturation first occurs During this stage the bulk density increases slightly as the proportion of crystals in the system increases Further crystallization involves exsolution of small water vapour bubbles and, assuming these remain suspended in the magma, leads to a continuously decreasing bulk density In general, if the total water content is decreased, keeping all other variables fixed, the density increases If the pressure is increased, keeping all other variables fixed, the density of the gas bubbles increases and thus so does the bulk density

The specific calculations demonstrate that the bulk density of hydrous basaltic magma can vary as a consequence of total water content and substantially as a result of volatile exsolution The approximate densities of dry degassed magmas of the calc-alkaline association are indicated on the right-hand side of Fig 1 It follows that at 1 5 kbar, for example, oversaturated basaltic magma can reach the same density as dry, or even volatile undersaturated, andesitic, dacitic or rhyolitic magma This comparison of hydrous basalt densities with 'dry' densities is merely presented to illustrate the very substantial variations that can occur in the bulk density of a fixed magma composition if excess volatiles are present in the lower layer

Even at pressures >1 5 kbar the changes can still be large enough to cause density inversions to occur in some magma chambers, although the total water contents required are at the high end of the range reported by Anderson[16] If water contents between 1 and 4% are typical of calc-alkaline mafic to intermediate magmas, the density changes necessary for convective mixing to take place can occur in shallow-level magma chambers

Geological applications

When mafic magma is injected into the base of a chamber containing less dense, more differentiated magma, any mixing

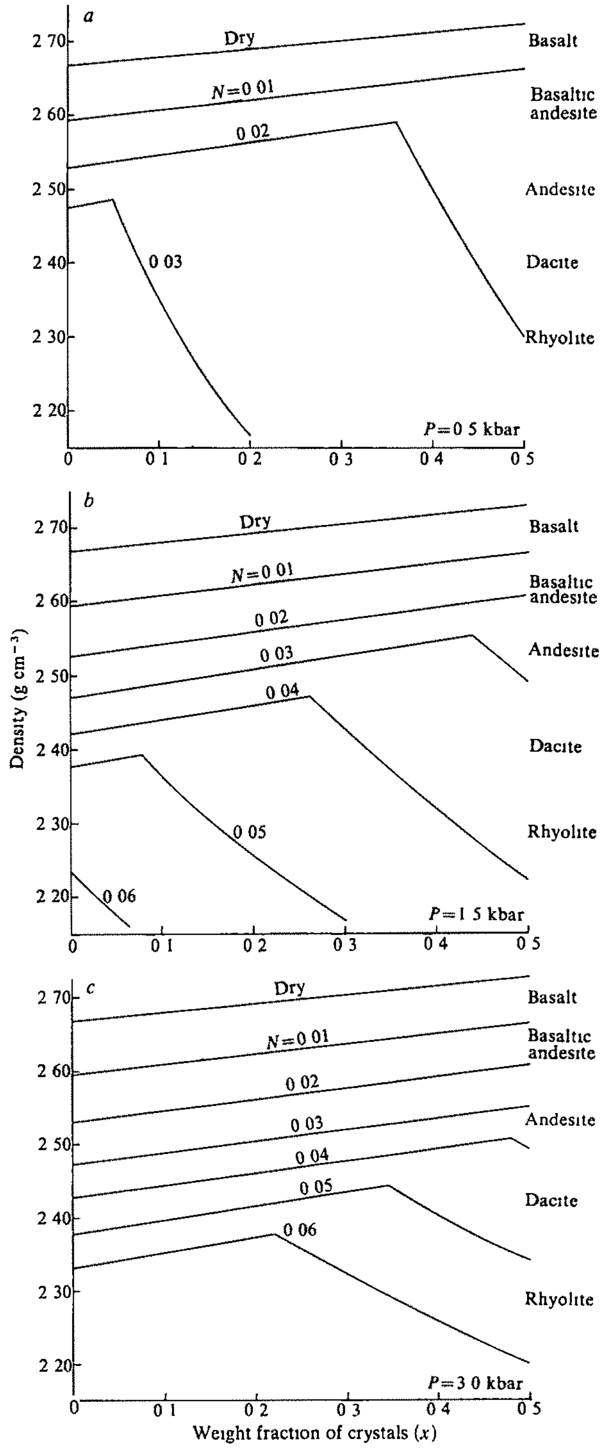

Fig. 1 The bulk density of wet basaltic magma as a function of the weight fraction of crystals for various total weight fractions of water, N, at a, 0 5 kbar, b, 1 5 kbar, and c, 3 0 kbar

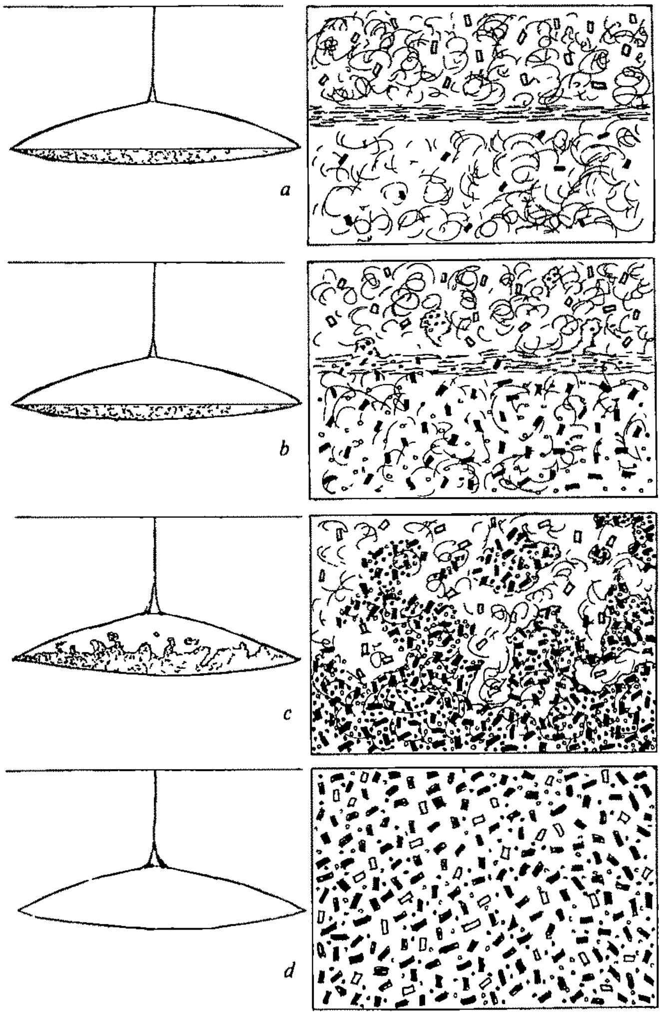

Fig. 2 Schematic model for a magma chamber replenished by an influx of hot, wet basaltic magma The four diagrams on the right represent close-up views at the height of the interface of the corresponding diagrams on the left *a*, The heavier magma of the lower layer loses heat across the interface and crystallizes *b*, The magma of the lower layer becomes saturated and further crystallization produces exsolution of water vapour bubbles *c*, The bulk density of the magma of the lower layer becomes equal to that of the overlying magma and the lower-layer magma rises into the upper layer *d*, Intimate mixing between the magmas results

will initially be strongly inhibited by the density contrast A two-layered or multi-layered system, with a horizontal interface separating the recently injected hot, denser, mafic magma from the cooler, less dense, silicic magma above, therefore seems a likely precursor to any well-mixed state Subsequent crystallization is one process for producing a decrease in density of the lower layer In the case of picritic basalt magmas, crystallization of dense components, notably olivine, leads to a decrease in the density of the residual liquid which can be sufficient to cause overturning and mixing with overlying differentiated basalt[6,7] In the case of calc-alkaline magmas, changes in the density of the liquid composition due to crystallization alone may not be sufficient to result in overturn We suggest that it is the release of water vapour once the lower layer has become saturated, which is essential

The overall process we envisage has a qualitative resemblance to one proposed[6,7] for basaltic magma chambers We suppose that hydrous mafic magma enters a chamber containing more differentiated magma, as depicted in Fig 2*a* This influx may be a consequence of tectonic activity and could possibly trigger an eruption[2,4] We assume that the volume of new magma forming the lower layer is much less than that of the upper layer and so the evolution of the lower layer proceeds with little change in the upper layer This is depicted quantitatively for the case of a dry basaltic magma chamber in Fig 7 of ref 7 As in our previous analyses of dry basaltic systems, the hydrous mafic magma transfers heat through a sharp interface and crystallizes (Fig 2*a*) As crystallization proceeds, the weight fraction of dissolved water increases in the residual liquid until the magma is saturated It can be shown[7,21,22] that the Rayleigh number of layers, even as thin as a few metres, of viscous andesitic magma at a temperature excess of 100 °C often exceeds 10^6 Thus the convective motions will be turbulent, as depicted in Fig 2

After the magma saturates, small bubbles form and, along with the crystals, are held in suspension by the vigorous turbulent convective velocities in the lower layer (Fig 2*b*) The bubbles remain in suspension because the velocity of rise of small gas bubbles relative to quiescent fluid is insignificant in comparison with the r m s turbulent vertical velocities in the lower layer Similar reasoning applies to the crystals, quantitative calculations for the velocities in this case are given in ref 7 The exsolution of water vapour causes the bulk density of the lower layer to decrease continually in accord with the results presented in Fig 1 Eventually, the bulk density may become equal to that in the overlying magma (which has changed by only an insignificant amount), whereupon overturning and hybridization of the magmas occur (Fig 2*c*, *d*) Further reactions involving the gas phase may be possible during the mixing We emphasize that we chose the simple and arbitrary chamber geometry depicted in Fig 2 for schematic purposes only The processes we have described are fundamental and would also occur in more complex and geometrically irregular plumbing systems Note that the magma in the upper layer need not be compositionally homogeneous, the same processes would occur if the upper layer were compositionally zoned, though the mixing would be confined to the lower parts of the system[9]

Eichelberger[5] proposes a different mechanism for mixing in which the interface between the mafic and silicic layers vesiculates and becomes unstable This mechanism seems possible and is incorporated in Fig 2*b* However, the interface thickness can be calculated[7] to be quite small, of the order of a few centimetres for temperature differences between layers of ~100 °C, and will thicken to only a few metres as the layers exchange heat Thus, while instability of a vesiculating interface may account for the occurrence of some mafic inclusions in silicic volcanic rocks, it cannot account for the mixing of large volumes of magma

There are several further predictions which follow from the general model when applied directly to calc-alkaline systems For a given pressure the mafic magma must have a water content within a restricted range for the mechanism to be viable For example, as illustrated in Fig 1*b*, at 1 5 kbar the total water content for the mafic magma to be initially undersaturated must be <5 4% and, assuming that a fluid model is applicable only up to a crystal content of 50%, the total water content for saturation to occur must be >2 8% Overturning into an upper rhyolitic layer of density 2 3 g cm^{-3} will not occur unless the total water content exceeds 3 8% If the upper layer of andesitic magma has degassed however, the total water content of the mafic magma needs only to exceed 3 0% Thus there will be situations in the calc-alkaline association where overturning cannot occur and a final compositional stratification will result Due to the variation of these limits on water content with chamber pressure, with the composition of the more differentiated magma and with the water content of the input mafic magma, both compositional zonation and intimate mixing could occur in the same magmatic system, but at different depths The data in Fig 1 suggest that the mechanism we propose is most easily achieved in high-level conduits and near surface chambers beneath volcanoes

There are considerable viscosity variations amongst calc-alkaline magmas, which will result in large variations in the time scale of the evolution of the layers A quantitative analysis can be made for the heat transfer in a two-layer system[7] and,

from equation (11a) of ref 7, the temperature and crystallization history of the lower layer can be predicted For basaltic systems the calculations suggest that the time taken to overturn can range from weeks to years depending on the initial thickness of the lower layer In calc-alkaline magmas, silica enrichment can result in increases in viscosity from two to more than four orders of magnitude over the viscosity of tholeiitic basalts Application of the two-layer system model[6,7] indicates that the time for overturn varies directly as the cube root of the viscosity, and hence overturn times may be increased by factors of order 10 or more for calc-alkaline magmas Incubation times are then typically years or decades For more complex layered systems, a similar overturn mechanism can occur[9], but the thermal history of the system cannot yet be quantified However, overturn times are likely to be considerably longer

In connection with volcanic activity, we note that in a rigid chamber of fixed volume, exsolution of gas in the lower layer must result in increasing chamber pressure Blake[4] has shown that an increase of chamber pressure sufficient to exceed the chamber wall fracture strength can occur by influx of new magma of volume typically of the order of 10^{-3} of the chamber volume Exsolution of a gas phase in the lower layer will result in increasing chamber pressure, and thus the generation of gas due to crystallization could trigger an eruption For example, if the lower layer constitutes 5% of the total chamber volume and a density decrease of 0 1 g cm^{-3} occurs due to vesiculation in this layer, the volume of gas will be 2×10^{-3} of the chamber volume Thus many situations can be envisaged where eruption could be triggered by vesiculation in the lower layer

We also note that the mixing during overturn may produce reactions between the magmas and volatiles which could be significant in driving or triggering volcanic eruptions Vesiculated mafic magma from the lower layer will be transported during the mixing process to environments which, on average, will be lower in temperature and pressure Further crystallization of the mafic magma during mixing will yield additional gas release The bubbles will have to expand, or alternatively increase their internal pressure, which will generate extra chamber pressure to drive magma to the surface

Most of the convincing petrographical evidence for hybrid magma in the calc-alkaline association comes from stratovolcanoes erupting small-to-medium volumes of mafic to intermediate volcanic products[10,12,14] In such systems stagnant magma occupies the high-level conduits and reservoir systems beneath the summit during quiescent periods Such magma will have undergone partial or complete degassing during previous periods of activity and periods of quiescence We envisage that this magma will become either just saturated in volatiles, or in some cases undersaturated if magma degassed at the surface sinks back into the shallow-level reservoir Many eruptions from such volcanoes are envisaged to occur during ascent of fresh magma from depth We suggest that as new magma arrives in the shallow-level system, oversaturation can occur and that mixing will ensue between the old degassed magma and the new volatile-bearing magma

There are other mechanisms which can produce magma-mixing phenomena For example, as shown in Fig 1, a saturated mafic magma containing excess volatiles can be lower in density than the more differentiated resident magma In this case the new magma is immediately buoyant and ascends as either a laminar or an entraining turbulent plume[3] Mixing can also occur by sidewall crystallization of a mafic magma forming a turbulent layer of light silicic melt[23,24] Mixing between the boundary-layer fluid and chamber fluid can form hybrid magma, although there is no evidence that this mechanism can produce large volumes of hybrid magma There are no doubt other situations which also lead to local mixing within the complex, near-surface plumbing systems of volcanoes We have tried to document a plausible mechanism which is fluid-dynamically possible, and also consistent with conventional ideas on the plumbing systems of volcanoes The mechanism is capable of explaining the common occurrence of hybrid calc-alkaline volcanic rocks In some circumstances basaltic magma can become lighter than even dry rhyolitic magma and thus mixing of mafic magmas derived from the mantle and silicic magmas derived from the crust could occur

Population dynamics of human helminth infections: control by chemotherapy

Roy M. Anderson* **& Robert M. May†**

* Department of Pure and Applied Biology, Imperial College, London University, London SW7 2BB, UK

An analysis is presented of the population dynamics of the major helminth parasites of man with the aim of understanding observed patterns in the age-specific prevalence and intensity of infection Mathematical models are used to investigate the possibility of controlling helminth diseases by mass chemotherapy, and to explore the advantages of selective treatment of the most heavily infected individuals in a community

OVER 30 years ago Stoll[1] noted that the major helminth infections of man were among the most prevalent of all human infectious diseases Today the global picture is similar, and we still live in a very 'wormy world' there are roughly 1,000 million cases each of roundworm (*Ascaris lumbricoides*), pinworm (*Enterobius vermicularis*) and whipworm (*Trichuris trichuria*), over 600 million cases of hookworm (*Necator americanus* and *Ancylostoma duodenale*), 300 million cases of filarial infections

0028-0836/82/240557—07$01 00

(principally *Wuchereria bancrofti* and *Onchocerca volvulus*) and over 200 million cases (500 million people at risk) of schistosomiasis (*Schistosoma mansoni, Schistosoma haematobium, Schistosoma japonicum* and *Schistosoma intercalatum*)[2-5]

In contrast to most viral and bacterial diseases, helminth populations exhibit a remarkable degree of temporal stability in human communities[6,7] These parasite populations tend to be robust to perturbation, resulting from either seasonal changes in climate or the introduction of control measures This is in part a consequence of the human host's inability to acquire strong immunity to re-infection, so that helminth infections are persistent in character with hosts being continually re-infected In endemic regions of the world, a newborn child can expect to harbour worms for most of its life (Fig 1)

The wide range of methods used in attempts to control helminth infections include chemotherapy, improved sanitation and hygiene, education and (in the case of indirectly transmitted infections such as schistosomiasis and filariasis) vector control[8-10] New techniques, based on the use of monoclonal antibodies, raise the exciting possibility that vaccination against human helminths may be feasible in the future[11] Today, safe, effective and cheap chemotherapeutic agents are available for many of the major helminth infections of man (excluding the filarial worms)[12,13] There remains, however, a need for a better understanding of the most cost-effective ways of delivering these drugs, not at the individual level, but in the community as a whole Among the unresolved epidemiological questions concerning the use of antihelmintic agents are the following What proportion of the population must be treated, and how often, to achieve a defined reduction in parasite prevalence and abundance? How rapidly will the parasite population return to its pre-control level once chemotherapy ceases? Is the selective treatment of the more heavily infected individuals of greater benefit to the community, both in terms of costs and of reducing the prevalence of disease symptoms, when compared with random or blanket chemotherapy? This article examines certain theoretical and observational aspects of these questions

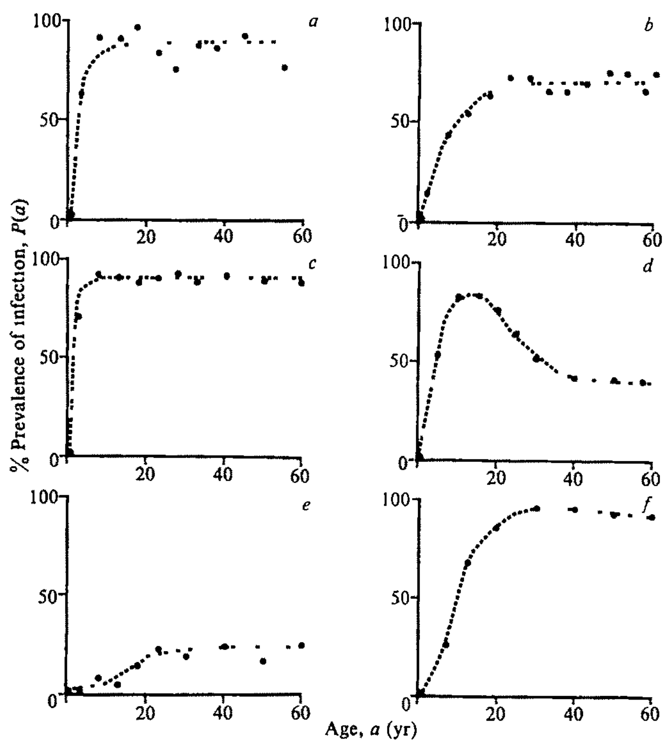

Fig. 1 Examples of horizontal age–prevalence data for some major helminth parasites of man in communities where the infections are endemic *a*, *A lumbricoides* in Iran[16], *b*, hookworm (both *Necator* and *Ancylostoma*) in Taiwan[60], *c*, *T trichuria* in the Philippines[61], *d*, *S haematobium* in Tanzania[34], *e*, *W bancrofti* in India[62] (prevalence of microfilaria carriers), *f*, *O volvulus* in Mali[49] The dashed lines are fitted by eye to illustrate the general trends, the solid dots are observed values

Population dynamics

An understanding of the factors which regulate parasite abundance, and contribute to the observed stability of helminth populations, is of obvious significance to the design of optimal control policies[14,15] Recent attempts to extend the pioneering work of Macdonald can be summarized as identifying five principal factors controlling the observed dynamics of the major helminth infections of man[7,16-18]

(1) The relative time scales on which the dynamics of the host and parasite populations operate These are largely determined by the expected life spans of the human host and the various developmental stages of the parasite The human host typically has a life span an order of magnitude or more in excess of any of the parasitic stages (Table 1*a*) For example, the adult worms in the human host have life spans of 1–16 yr depending on the species of parasite Note, however, that measurement of this parameter is difficult in practice and hence the values in Table 1*a* are only approximations Free-living infective stages plus infected vectors have much shorter life expectancies than those of the adult parasites These empirical observations enable certain simplifications to be made in the analysis of parasite population behaviour, without any serious loss of detail or accuracy[7,15-17] Given the information in Table 1*a*, we can examine the dynamics of the adult parasites under the assumptions that the host population is effectively constant in size on a time scale appropriate to changes in adult parasite population size and that the populations of the infective stages (or vectors) are essentially at equilibrium due to the rapidity with which changes in these populations occur when compared with those in the adult worm populations[14,15]

(2) The regulation of parasite population growth in the human host Although man is unable to develop an effective protective immunity to re-infection, he can mount immunological and nonspecific responses to the invasion of helminth parasites, which act in conjunction with resource limitation to reduce worm survival, establishment and fecundity in a manner that depends on the density of parasites in the host (refs 19, 20, Fig 2) These density-dependent responses are the major regulatory mechanisms controlling the growth of the total parasite population in any human community The net severity of these constraints in the host population depends critically on the statistical distribution of worm numbers per host[21-23]

(3) Worm distributions these are typically highly aggregated[21,22,24], with the majority of worms being harboured by a minority of the human population The generative mechanisms of such patterns are many and varied but include genetic, spatial and behavioural factors The negative binomial probability distribution has proved to be a good empirical model for observed patterns, this distribution is defined by two parameters, the mean worm burden per host, M, and a parameter, k, which varies inversely with the degree of parasite aggregation Observed k values are very small, and it is not unusual for >65% of the worm population to be harboured by <15% of the human community (Table 1*b*) This high degree of contagion enhances the severity of density-dependent constraints on parasite population growth[23]

(4) The reproductive biology of the parasite The major human helminths are dioecious and the production of transmission stages therefore depends on the probability that a female worm is mated This probability is a function of the statistical distribution of parasite numbers per host, there exists a critical average worm burden, termed the breakpoint, below which mating frequency is too low to maintain the parasite[7,17,25,26] The precise level of this breakpoint is in part determined by the degree of worm contagion in the human population Recent studies of *Ascaris* and hookworm infections[7,16], both of whose distributions tend to be highly aggregated in human populations, suggest that the breakpoint is typically very low—of the order of 0 3–0 5 worms per host Mating prob-

abilities thus seem to be of limited significance to the overall population stability of helminth parasites, and the breakpoint concept therefore appears to have little practical significance for disease control[7 16 26]

(5) The reproductive or transmission potential of the parasite The basic reproductive rate, R_0, is used to measure this potential and is defined as the average number of female offspring produced throughout the lifetime of a mature female parasite which themselves achieve reproductive maturity, in the absence of density-dependent constraints[7 16 25 27] If the parasite population reaches a steady state (stable endemic disease) the effective reproductive rate, R, is equal to unity, in other words, each female parasite exactly replaces herself in the next generation R_0 has recently been estimated for several helminth infections in different regions of the world[7 16 28], these estimates typically lie in the range 1–5 and are generally lower than those recorded for many viral, bacterial and protozoan infections of man[29 30 70] (Table 1c) The condition $R_0 = 1$ defines a transmission threshold below which the parasite is unable to maintain itself in the human population[7 16 25] The value of R_0 is determined by many individual components representing the birth, death and transmission rates of the various developmental stages in the parasites' life cycle Estimates of R_0, however, can be obtained directly from epidemiological data recording the prevalence and intensity of infection in different age classes of the host population The parameter R_0, in conjunction with the life expectancy of the adult parasite, A, the degree of worm aggregation, k, and the severity of density-dependent constraints on worm population growth, z, acts to determine the average intensity, M^*, and prevalence, P^*, of infection at equilibrium in a given community

Mathematical models

It follows from the relative time scales recorded in Table 1a that a description of the temporal dynamics of parasite population growth can be given in terms of one variable, $M(t)$, the mean adult worm abundance per host at time t[7 14 15] Assuming the parasites to be distributed in a negative binomial manner in the human population, with clumping parameter, k, the dynamics of infection by helminths in any defined human community may be described by a single differential equation for $M(t)$, of the general form

$$\mathrm{d}M/\mathrm{d}t = (M/A)\,[R_0 f(M,k,z) - 1] \qquad (1)$$

R_0, A and k are as defined above, z is an inverse measure of the severity of density dependence (see Fig 2) while f denotes the net force of these constraints acting on parasite population growth in an individual host For example, in ascariasis, density-dependent processes seem to act mainly on worm fecundity[16], such that, within a given host, the rate of egg production per female worm decays approximately exponentially as worm burden increases (Fig 2) This gives

$$f(M,k,z) = [1 + (1-z)M/k]^{-(k+1)} \qquad (2)$$

and the equilibrium average worm burden, M^*, and prevalence, P^*, are given by

$$M^* = [R_0^{1/(k+1)} - 1]\,[k/(1-z)] \qquad (3)$$

and

$$P^* = 1 - [1 + M^*/k]^{-k} \qquad (4)$$

If density-dependent constraints severely restrict worm fecundity the hosts with the maximum egg output may not

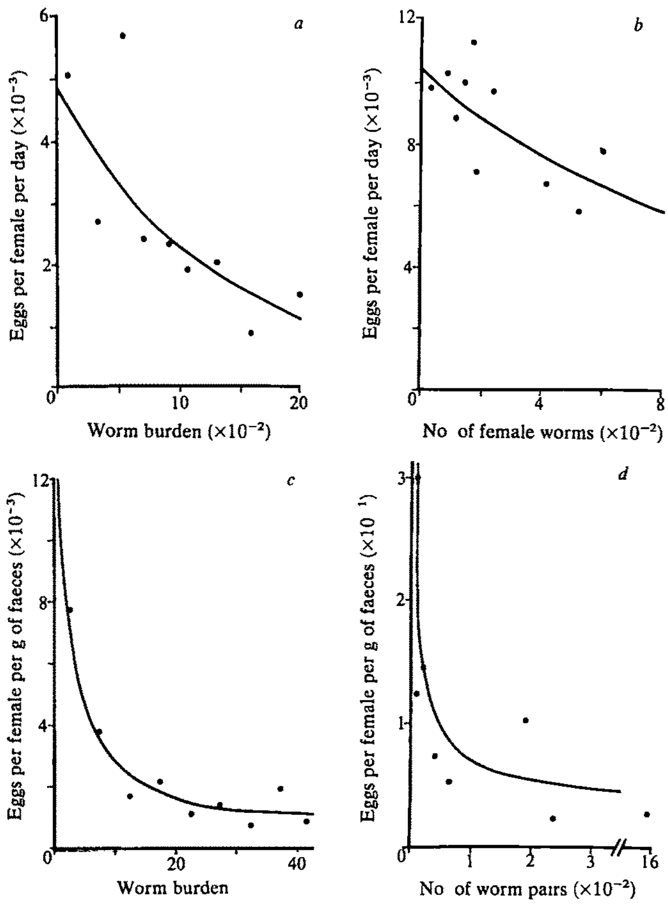

Fig 2 Examples of the decline in worm fecundity (in terms of egg output) as the burden of parasites in the human host increases (density-dependent egg production) ●, Observed values, —, best-fit power or exponential models a, *N americanus* (data from ref 63) The solid line denotes the best-fit exponential model of the form $y = \hat{a}\,e^{-\hat{b}i}$ where y is the egg output per female worm per day, i is worm burden per host, and $\hat{a}$ and $\hat{b}$ are constants with values $\hat{a} = 4\ 8\times10^3$, $\hat{b} = 0\ 73\times10^{-3}$ ($r^2 = 0\ 7$) b, Mixed infections of *N americanus* and *A duodenale* (data from ref 64) The solid line denotes the best-fit exponential model, as defined for a, with parameter values $\hat{a} = 10\ 3\times10^3$, $\hat{b} = 0\ 7\times10^{-3}$ ($r^2 = 0\ 7$) c, *A lumbricoides* (data from ref 16) The solid line denotes the best-fit power model of the form $y = \bar{a}i^{\bar{b}}$ where y and i are as defined for a, and $\bar{a}$ and $\bar{b}$ are constants with values $\bar{a} = 9\ 0\times10^{-3}$, $\bar{b} = -0\ 6$ ($r^2 = 0\ 9$) d, *S mansoni* (data from refs 59, 65) The solid lines denote the best-fit power model as defined for c with parameter values $\bar{a} = 38\ 4$, $\bar{b} = -0\ 36$ ($r^2 = 0\ 7$)

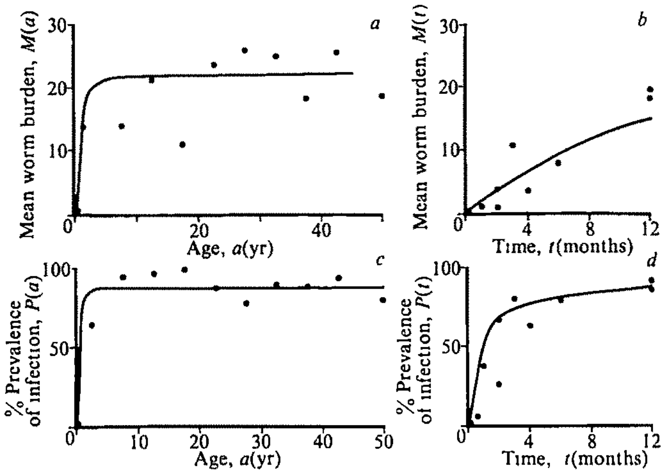

Fig. 3 The fit of the model defined by equations (8) and (9) in the text to data of the epidemiology of *A lumbricoides* in Iran (data from ref 16). ●, Observed values, —, model predictions. *a*, *c*, Rise in the average worm burden and prevalence of infection, respectively, with host age. The data were collected by means of a horizontal epidemiological survey[16]. *b*, *d* Show, respectively, the increase in parasite intensity and prevalence with time in a sample of people who were cleared of worms by antihelmintic treatment at time $t=0$. Note the rapidity with which both the average worm burden and prevalence approach their pre-control levels (indicated by the plateau levels in *a*, *c*). Estimates of the parameters of the model [equations (8), (9)] are as follows $R_0=4.3$, $M^*=22$, $A=1$ y, $z=0.96$, $k=0.57$. The density-dependent function, f, used in the model was as defined in equation (2) and the parameter values listed above were used to make the predictions in all four graphs, *a–d*.

necessarily harbour the maximum parasite burden. However, given the typical maximum worm burdens recorded in human communities, the observed patterns of density-dependent fecundity (Fig 2) suggest that such situations are unlikely to arise in practice. The qualitative dynamical behaviour of the model defined in equation (1) is independent of the precise form of function f. The quantitative properties, however, will depend on whether density-dependent processes act on worm fecundity, survival or establishment, or any combination of these. Human helminth fecundity is invariably density dependent (see Fig 2) but information on survival and establishment is extremely limited, and practically difficult to obtain.

Equation (1) may be used to approximate the dynamics not only of directly transmitted infections (such as *Ascaris*), but also of indirectly transmitted ones (such as *Schistosoma*) since the parameter R_0 represents the appropriate combination of transmission factors for the complete life cycle of any given parasite species[7,14,15,28,31]. The epidemiological data most commonly available are from horizontal and longitudinal studies of age–prevalence and age–intensity relationships[32]. The model can be extended to describe the way the mean worm burden, $M(t,a)$, changes with time, (longitudinal changes), and host age, a (horizontal changes)[28]

$$\partial M/\partial t+\partial M/\partial a=\Lambda(t)-M/A \tag{5}$$

The function $\Lambda(t)$ is defined for notational convenience as

$$\Lambda(t)=(R_0/AL)\int_0^{\infty} l(a)\,M(t,a)\,f(M,k,z)\,\mathrm{d}a \tag{6}$$

where $l(a)$ is the probability that a host survives to age a and L denotes human life expectancy ($L=\int_0^\infty l(a)\,\mathrm{d}a$). For human communities in which the prevalence and average intensity of infection have remained relatively constant with time (where $\partial M/\partial t\simeq 0$), equation (5) reduces to a simple differential equation for the change in average worm burden, $M(a)$, with host age, in this equation, Λ is a constant defined by equation (6) with $M(t,a)$ replaced by $M(a)$. For endemic infections of *Ascaris* and hookworm, the average worm burden rises rapidly as host age increases to reach a plateau such that the mean worm burden, $M(a)$, in the majority of age classes is essentially equal to the mean worm burden of the total population [the M^* of equation (3)], consequently, a good estimate of Λ is given by

$$\Lambda=(R_0M^*/A)\,f(M^*,k,z) \tag{7}$$

It is here assumed that the distribution of parasites in the entire community (consisting of all age classes) remains approximately negative binomial in form with mean M^* and clumping parameter k. The precise overall distribution will generally be formed from a mixture of negative binomial distributions (one for each age class) as a consequence of age-dependent human mortality and differences in exposure to infection[33]. The use of a common aggregation parameter for the entire community, however, remains a good approximation provided parasite life expectancy is short in relation to that of man[33]. Available empirical evidence suggests that the negative binomial distribution remains a reasonable empirical model of hookworm and roundworm numbers per host even when a sample consists of a mixture of individuals from different host age classes[7,16,34].

In this limiting case of steady infection, when $\partial M(t,0)/\partial t\simeq 0$, the appropriately simplified form of equation (5) yields an age–intensity relationship of the form

$$M(a)=\Lambda A\,[1-e^{-a/A}] \tag{8}$$

Here Λ is given by equation (7). The predicted age–prevalence curve (the proportion of each age class infected) then follows as

$$P(a)=1-[1+M(a)/k]^{-k} \tag{9}$$

Equations (8) and (9) can be used to obtain estimates of Λ, A and R [using equation (7)] from observed age–prevalence and age–intensity data[7,16,28,35].

We have assumed that the net rate of infection, Λ, is independent of host age and depends only on the average number of transmission stages present in the host's environments. This is often the case for infections such as *Ascaris*[14], but in many instances, Λ varies with age as a result of changes in the contact rate with infective stages (or infected vectors), the severity of density-dependent factors (mediated by age-related changes in host resistance to infection) or the degree of worm contagion in different age classes of the population[7,28,31]. For schistosome and filarial infections, age-related changes in acquired resistance and contact with infection are known to be important, although much controversy still surrounds their relative significance[28,36] (Fig 1).

The model defined in equations (8) and (9) can provide an accurate description of observed trends[16]. Figure 3 presents data pertaining to the epidemiology of *Ascaris* in Iran. The model can be seen to mimic changes both in the observed horizontal trends of intensity and prevalence in different age classes of the population (Fig 3*a*, *b*) and in the re-infection with time of individuals who were given a single treatment with a chemotherapeutic agent.

Control by chemotherapy

Effective and safe antihelmintic agents are available for the treatment of most major helminth infections of man[12,37,38], including mebendazole[5,39,40,66,67] (for enterobiasis, ascariasis and trichuriasis), pyrantel pamoate[8] (for ascariasis, enterobiasis, trichuriasis and hookworm), levamisole[40,41] (for ascariasis), bephenium hydroxynaphthoate[8] (for *Ancylostoma*) and the recently developed praziquantel[42–45] (for schistosomiasis). However, questions concerning the best way to use these drugs for the benefit of the community rather than the individual remain to be answered[10]. The above models can be adapted to examine these issues: we focus first on the long-term effects of the use of mass chemotherapy and, second, on the selective treatment of the most heavily infected individuals in a community.

Mass chemotherapy in the long term. When a drug is administered randomly within a population by treating a pro-

portion, g, of the community per unit of time and the drug has an efficacy h (where h represents the average proportion of the worm burden killed by a single, or short course of treatment), the resulting increase in the per capita death rate of adult parasitic worms, c, is then[7,16]

$$c = -\ln(1-gh) \qquad (10)$$

By subtracting the net death rate due to treatment, cM, from the right-hand side of equation (1), the average worm burden, $\bar{M}$, at the new equilibrium established by the control programme can be shown to be

$$\bar{M} = k([R_0/[1-A\ln(1-gh)]]^{1/(k+1)}-1)/(1-z) \qquad (11)$$

It is assumed that density-dependent constraints act in the manner defined in equation (2); other assumptions give similar results. To eradicate the infection the effective reproductive rate R (the basic reproductive rate, R_0, modified by the action of chemotherapy) must be reduced below unity. To achieve this, the proportion treated per unit of time must be greater than a critical value, $\hat{g}$ (ref. 7):

$$\hat{g} = (1-\exp[(1-R_0)/A])/h \qquad (12)$$

Even when $g > \hat{g}$ treatment must be continued for a period of time greater than the maximum life span of the adult worm. If treatment ceases before the average worm burden is below the breakpoint (which, unfortunately, we have seen is usually close to zero worms per host), the parasite population will rapidly return to its pre-control level (the speed of return depends on the values of R_0 and A). For helminths, however, eradication is not always a practical goal, and control policies are more often oriented to the elimination of disease rather than of infection because the two are not necessarily equivalent[3,5,45,46,68].

The model defined in equation (5) can be used to examine the impact of a defined programme of chemotherapy on the prevalence and intensity of infection both with time and in different age classes of the population (Fig. 4). The numerical results shown in Fig. 4 mimic the dynamics of endemic *Ascaris* and illustrate two important points—the rapidity with which certain helminth infections return to their pre-control level once chemotherapy ceases[47], and the differential impact of antihelmintic treatment on the prevalence and intensity of infection. Simply monitoring prevalence may lead to the incorect conclusion that control measures have little impact on parasite abundance. The principal advantage of these models is that (given estimates of parameters R_0, A, k and z) they can be used to predict quantitatively the outcome of a defined programme of chemotherapy and to define the level of treatment required for eradication.

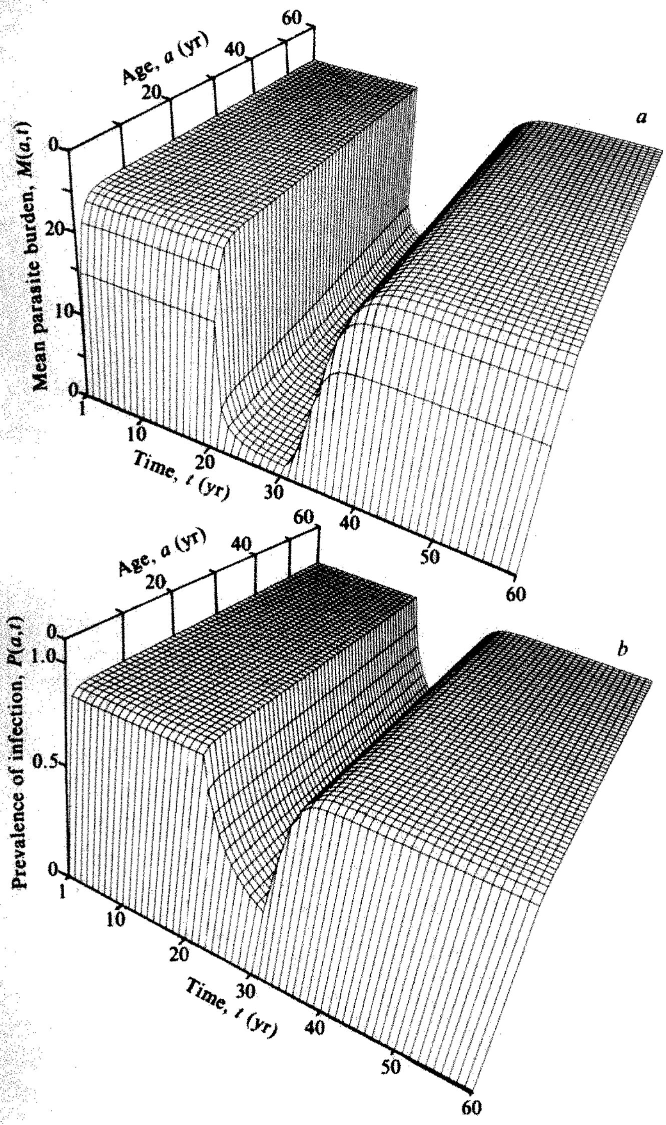

Fig. 4 Two three-dimensional graphs obtained by the numerical solution of the partial differential equation defined in equation (5). The simulations are designed to mimic the dynamics of endemic ascarasis in a human community, both with time and in different age classes of the population. *a*, Changes in the average worm burden; *b*, changes in prevalence. For the first 10 yr the helminth infection is at its endemic equilibrium (with M^* in the older age classes set at 22 worms per host). In year 10, mass chemotherapy is initiated and applied randomly in the community on a continual basis where 20% of the population is treated each month ($g = 0.25$ per month) with a drug of 95% efficacy ($h = 0.95$). After 10 yr the treatment is stopped and the graphs display the return of the parasite population to its pre-control equilibrium level. The human survivorship function, $l(a)$, was chosen to mimic typical patterns in the developing world with a life expectancy, L, of 50 yr. The density-dependent function f was as defined in equation (2) and the remaining parameters of the model were set at the following values: $R_0 = 4.3$, $k = 0.57$, $z = 0.96$, $A = 1$ yr. Note the rapidity with which the infection returns to its pre-control level once chemotherapy ceases and the differential impact of control on the average worm burden, $M(t,a)$, and the prevalence of infection, $P(t,a)$.

Single applications of mass chemotherapy. Antihelmintic drugs are often used intensively over short periods of time to reduce the prevalence of disease symptoms in a community. Frequently, such applications are given at irregular intervals with long time periods between successive treatments. The objectives are to maximize the short-term benefits and minimize the number of treatments (and hence cost). In 1924, Smillie[48] argued that the optimum way to apply mass chemotherapy was selectively to treat the most heavily infected individuals; Warren has recently re-opened this debate[5,49–51,69]. A major disadvantage of this strategy can be the extra cost involved in identifying the most heavily infected individuals; in practical terms this can be done either by faecal egg, urine egg or blood larval counts, or by noting the occurrence of clinical symptoms of disease. Conversely, there are advantages in targeted treatment if the drug has side effects, or if there are any worries about the evolution of drug resistant strains of the parasite[52].

We can use our models to calculate the proportional reduction achieved by mass chemotherapy, in quantities such as the average worm burden, the prevalence and the average egg output. We denote the levels of these parameters before control as M^*, P^* and E^* respectively and define the probability that an individual harbours i parasites as $p(i)$, and that he receives treatment as $g(i)$, where

$$g(i) = a[1-(1-\alpha)e^{-i/I}] \qquad (13)$$

a and α (both < 1) are constants defining the upper and lower bounds on $g(i)$, respectively, while I is a measure of the selectivity of the treatment. For example if $I = 40$, ~60% of individuals with 40 worms receive drug treatment. A continuous function for $g(i)$ is more realistic than a step function, as in

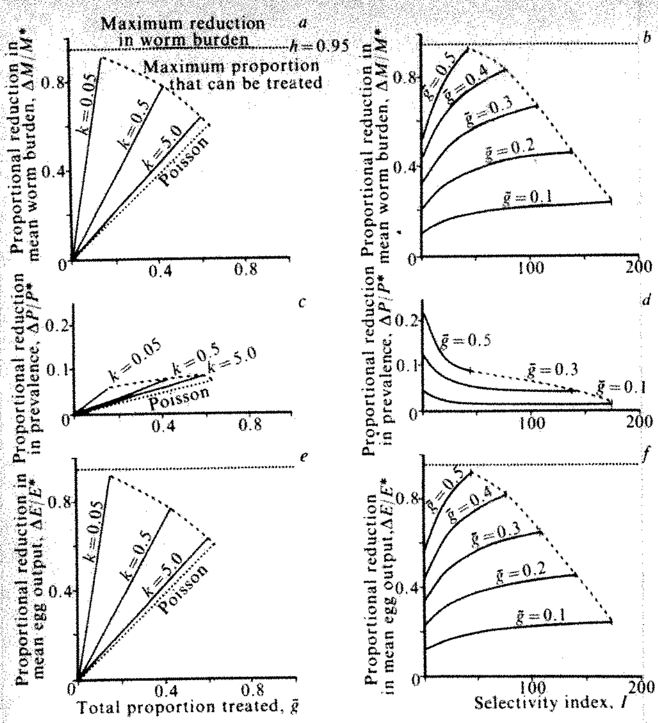

Fig. 5 The impact of selective chemotherapy on the proportional reduction in mean worm burden, $\Delta M/M^*$, the prevalence of infection, $\Delta P/P^*$, and the average egg output per host, $\Delta E/E^*$. *a*, *b*, Relationships between the proportional reduction in average worm burden immediately after a single mass treatment in a community in relation to *a*, the proportion of the population treated, $\bar{g}$, and *b*, the degree of selectivity in treatment, *I*, where the selective function is as defined by equation (13), for various assumptions about the distribution of worms in the human population (that is, various values of the negative binomial clumping parameter, *k*). The relationships in *a* and *b* were calculated using equation (14) with the following parameter values: $M^* = 40$, $I = 40$, $\alpha = 0$, $a = 1$, $h = 0.95$ and $k = 0.5$ (in *b*). *c* and *d*, *f* and *e* show, respectively, similar relationships for the proportional reductions in prevalence and average egg output. The proportional reduction in prevalence, $\Delta P/P^*$ is defined by the relationships $\Delta P/P^* = aJ(I, M^*, k)/[1-(1+(M^*/k))^{k}]$ where $J(I, M^*, k) = [1+(1-h)(M^*/k)]^{-k} - (1-\alpha)[1+(1-y)(M^*/k)]^{-k} - \alpha(1+(M^*/k))^{-k}]$ and $y = h\exp(-1/I)$. The parameter values for *d* and *c* are as defined for *a* and *b*. The proportional reduction in average egg output, $\Delta E/E^*$, is defined by the relationship $\Delta E/E^* = aK(I, M^*, k)/D(I, M^*, k)$ where $K(I, M^*, k) = [[1+(1-x)(M^*/k)]^{-(k+1)} - (1-\alpha)\ y\ [1+(1-xy)(M^*/k)]^{-(k+1)}]$, $D(I, M^*, k) = [1+(1-x)(M^*/k)]^{-(k+1)}$ and $x = \exp(-\bar{b})$ where $\bar{b}$ is as defined in Fig. 2 legend and *y* is as defined above. The parameter values for *e* and *f* are as defined for *a* and *b* excepting *h* is set at unity.

practice there is always considerable uncertainty about the worm burden harboured by any given individual. The proportional reduction in the average worm burden, $\Delta M/M^*$ [where $\Delta M = h\sum_{i=0}^{\infty} ip(i)g(i)$], achieved by treating a proportion $\bar{g}$ [where $\bar{g} = \sum_{i=0}^{\infty} g(i)p(i)$] of the total population with selectivity I is given by

$$\Delta M/M^* = \bar{g}\,h\,\frac{G(I, M^*, k)}{H(I, M^*, k)} \tag{14}$$

where h, M^* and k are as defined earlier. The functions G and H are defined as

$$G(I, M^*, k) = [1-\hat{z}(1-\alpha)[1+(1-\hat{z})(M^*/k)]^{-(k+1)}] \tag{15}$$

and

$$H(I, M^*, k) = [1-(1-\alpha)[1+(1-\hat{z})(M^*/k)]^{-k}] \tag{16}$$

where $\hat{z} = \exp(-1/I)$.

Figure 5 displays the impact of various programmes, using different selectivity levels (I), and various proportions treated ($\bar{g}$) on the average worm burden, the prevalence and the average egg output, given various assumptions concerning the degree of worm clumping in the human population. Three points emerge from this analysis.

(1) Selective treatment is highly beneficial (in terms of the number of treatments administered), provided the worms are highly clumped in their distribution in the host population (in practice this is indeed the case; see Table 2*b*). For example, in the case shown in Fig. 5*a*, where the selectivity index is set at 40 worms per host, a 50% reduction in average worm burden ($M^* = 40$) is achieved by treating 8% of the population when the worms are highly clumped ($k = 0.05$), while 52% of the population must be treated to achieve the same result when the parasites are randomly distributed ($k \to \infty$). (2) There is little benefit to be gained from being too selective (Fig. 5*b*, *d*, *f*). This is fortuitous since it would be difficult in practice to distinguish between individuals who carried say 50 or 75 worms. (3) Of all the three epidemiological variables considered in Fig. 5, selective treatment has the least effect on prevalence. The proportional reduction in prevalence declines as the selectivity index, I, increases (Fig. 5*d*).

The principle conclusion of this analysis is that, despite the extra cost involved in identifying heavily infected individuals, very substantial benefits may be gained from selective treatment, in terms of reducing both the abundance of the parasite (and hence, in general, the frequency of disease symptoms) and the number of treatments administered. This is primarily a consequence of the highly clumped nature of helminth distributions in human communities. The analysis is most applicable to the control of gut-dwelling helminths. For filarial infections, a reduction in worm burden (and hence transmission) may have no short-term impact on disease prevalence as a result of the permanent damage (such as blindness) induced by heavy infections before control. An added problem in the case of tissue-dwelling helminths is that drug-induced parasite mortality may have toxic side effects in those individuals harbouring heavy worm burdens.

Control by vaccination

Although vaccines against helminth infections are not available at present[11,53], we briefly consider the potential benefits to be gained, at the community level, from their development and use. If a safe and effective vaccine is developed, giving protection for an average period of v years, then the proportion of the population, p, that must be immunized per unit of time to reduce R below unity must exceed a critical value $\bar{p}$:

$$\bar{p} = [1-(1/R_0)]v^{-1} \tag{17}$$

For example, if the vaccine gives life protection against a helminth infection with an R_0 value of 3 (appropriate for hookworm in endemic areas, see Table 2), it would be necessary to protect 67% of the community by a single vaccination (or course of vaccination) in infancy. However, if the vaccine only gives protection for a few years, then a large proportion of the population must be repeatedly immunized to sustain the necessary level of herd immunity for community protection. The relative merits of this type of vaccine when compared with cheap antihelmintic agents will therefore depend critically on cost factors since both forms of treatment will have to be administered repeatedly.

Conclusions

A major priority for the community control of infectious diseases is clearly the development of safe, effective and cheap agents (whether drugs or vaccines) to protect the individuals most at risk. These goals have been largely achieved for many of the common infectious diseases and yet they remain endemic throughout large regions of the world[49]. In the less developed countries, the availability of resources for primary health care is a major factor restricting the effective control of these diseases. It would therefore seem desirable to devote effort to elucidating the optimum ways of using the available methods,

for the benefit of the community as a whole. A knowledge of the population dynamics of the disease agent has a central role in this field of research[28,30,33].

Human helminth infections are good examples of the discrepancy between our knowledge of how to treat an individual and how to control the infection in a community. The present analysis suggests that it is possible to determine, in quantitative terms, the level of antihelmintic treatment required in the community either to suppress parasite abundance to a defined level (to eliminate disease symptoms) or to eradicate the infection. More important, given the limitation of resources in areas where such infections are endemic, the analysis indicates that more attention should be given to the practical problems involved in selective treatment because the benefits to be gained by this approach seem very substantial. These benefits will be further enhanced, if, as has been suggested (but as yet unconfirmed[54]), the heavily infected individuals are predisposed to this state, not by the laws of chance, but as a consequence of genetic, behavioural or social factors.

This work was supported in part by US NSF grant DEB81-02783 (R.M.M.) and in part by the UNDP/World Bank WHO Special Programme for Research and Training in Tropical Diseases (R.M.A.). We thank K. Dietz for helpful discussions and comments on the manuscript.

Structure of the expanded state of tomato bushy stunt virus

I. K. Robinson & S. C. Harrison

Gibbs Laboratory, Harvard University, Cambridge, Massachusetts 02138, USA

The full three-dimensional structure determination of tomato bushy stunt virus has shown how its protein subunit can accommodate to different packing environments in the viral coat and how the size of the particle is nonetheless determined without ambiguity. Reversible, cooperative expansion of the virus at pH *values above neutrality and in the absence of divalent cation requires further bonding alternatives for the subunit. We report here the structure of the expanded tomato bushy stunt virus particle, determined at 8 Å resolution by X-ray crystallography. Subunit conformational changes are localized, and folded domains are essentially invariant. The bonding properties of the subunit can account for controlled polymorphism of the assembly.*

THE tomato bushy stunt virus (TBSV) particle comprises a single strand of RNA (molecular weight (M_r) 1.5×10^6) and 180 copies of a 40,000 M_r coat protein[1]. The subunits of the coat are arranged in a $T=3$ icosahedral lattice[2] as shown in Fig. 1*a*. High-resolution crystal structure analysis[3] has revealed the positions of all amino-acid residues in the C-terminal 75% of the protein chains; these form a shell having inner and outer radii of 110 and 170 Å. The N-terminal parts of the protein subunits and the whole of the RNA are invisible in the icosahedrally averaged, high-resolution electron density maps; they

0028–0836/82/240563—06$01.00

are thus believed to be spatially disordered. These components together fill the cavity in the interior of the virus[4,5].

The ordered part of the protein folds into two structural domains linked by a short 'hinge'. The 170-amino acid 'S'-domains pack tightly into the shell between radii of 110 and 140 Å. The three symmetrically distinct positions of this domain, shown in Fig. 1*b*, are denoted A, B and C. They have identical folding of their polypeptide backbone, but adjust to three 'quasi-equivalent' environments by differences in conformation of certain side chains on their surfaces and, more dramatically, by the ordered folding of 35 residues at the N-terminal end of the 60 C-position S-domains. These 35 residues form the so-called 'extended arm' and 'β-annulus'[3]. The A- and B-position S-domains make an extensive contact with each other, which is broken in C positions by interposition of the arm. Distal residues of the arm interdigitate with corresponding residues of two other C subunits to form the β-annuli. A coherent internal scaffold is thereby created, which precisely determines the curvature and size of the virus particle.

The second domain, called 'P', forms strong dimers that lie on the 2-fold and quasi-2-fold axes of the constellation of S-domains. These dimers project to the outer radius of 170 Å and are clearly visible in electron micrographs of the virus[6].

Expansion

TBSV and many other related viruses undergo a structural phase transition in solution that is controlled primarily by *p*H and divalent cation concentration. The phenomenon was first observed in bromegrass mosaic virus (BMV) by Incardona and Kaesberg[7] using various physicochemical techniques. These all gave results consistent with a model in which the particle mass was conserved and the hydrodynamic radius increased by ~10%. For this reason we will refer to it as 'expansion' of the virus.

BMV exhibits an anomalous titration of two protons per subunit associated with the phase transition at *p*H 6.7. This has been interpreted[8,9] as due to formation of hydrogen bonds
